2.2 Oxygen Windows

In some zeolite-type structures, the spatial linkages between these SBUs produce oxygen windows that define the useful pore diameters within the zeolite structures. These provide another way of classifying zeolite frameworks but it must be realized that these oxygen windows arise from the geometric arrangements of SBUs and are not necessarily the SBUs themselves.

Tables 2–5[11] lists all known zeolite-type frameworks on the basis of their major pore dimensions, and Table 6 illustrates the shorthand notation used. The pore diameter dimensions are based upon crystallographic measurements assuming that the oxygen radius is 1.35 Å. Note that not all pores are circular, or planar, so maximum and minimum diameters are given in these cases and even these may be

altered by the state of hydration of the framework and also are temperature dependent. The maximum flexibility of the oxygen windows is roughly 0.3 Å over their useful temperature range. Included in Tables 2–5 are the structure-type codes allocated by the IZA Structure Commission following the rules set up by an International Union of Pure and Applied Chemistry (IUPAC) Commission on Zeolite Nomenclature. These tables include:

1. natural aluminosilicate zeolites;
2. natural minerals with zeolite frameworks but with tetrahedrally coordinated atom (T) atoms *other* than Si or Al (zeotypes).
3. structures basically of zeolite framework type but not strictly three-dimensional in that a proportion of the subunits are not linked by all tetrahedral corners; in these cases, terminal OH groups are included in the incomplete 'frameworks' and this is signified by a hyphen that precedes the IUPAC code, as in '–PAR' for partheite;
4. synthetic aluminosilicate zeolites;
5. synthetic zeotypes;
6. synthetic and natural phases of silica constructed from SBUs;
7. felspathoids, for example, cancrinite; this arises because the cancrinite cage structure can be identified as a structural subunit of zeolites, that is, as a zeolitic cavity, and the *Atlas* includes several felspathoid frameworks because of their close relationship to zeolites;

These subheadings will be used later to furnish a more detailed description of zeolite structure types.

2.3 Zeolite Channels

Each channel system is defined as being one-, two-, or three-dimensional with respect to the zeolite framework and a simple notation describes whether or not the channel

systems interconnect and their spatial relationships to the crystallographic axes of the zeolite unit cell (see Table 6).

Three examples will suffice to demonstrate this information: Figure 3 shows the polyhedral units in the synthetic zeolite Linde Type A, which link to provide a three-dimensional interconnecting array of channels, Figure 4 illustrates the essentially two-dimensional system of channels in the mordenite framework, and Figure 5 shows the major channels in synthetic zeolite Linde Type L arranged as parallel one-dimensional channels and shown as a stereo pair. Table 6 lists the *Atlas* notations for these structures with explanations, including the symbols used in Tables 2–5.

2.4 Zeolite Structural Families

As has been discussed already, the primary building unit of all zeolite and zeotype frameworks is the tetrahedral unit, which can be linked to produce the SBUs seen in Figure 2. In some cases, it is convenient to describe zeolite structure-type frameworks by the recognition of larger assemblages of tetrahedra. Examples of this approach will now be discussed to emphasize how it can be used to simplify complex frameworks.

2.4.1 Structures Based upon Linkages of the Double Hexagonal Ring SBU, (D6R)

The chabazite framework is a sequence of D6R units joined, via S4Rs, into the same sequence as that in cubic close packing, that is, ABCABCABC (see Figure 6, also Figure 2 and Table 1). This means that an easy way to describe the chabazite structure is that of a NaCl-type arrangement with a D6R unit at each corner of a simple cubic assemblage.

This produces a large cavity, created by the D6R constructional elements, and access to it is governed by passage through an eight-oxygen aperture (S8R) as listed in Table 5. Eleven specific cation and water locations have been identified by single-crystal X-ray studies within the chabazite framework. In the natural mineral, some calcium ions reside in the D6Rs in the dehydrated state, but in the fully hydrated mineral, the cations have near complete coordination spheres of water and ‘float’ inside the larger cavities.

The movement from relatively loosely bound sites within the larger cavities to smaller cages with little associated water is common behaviour for cations in zeolites. Their presence in the large cavities, in what has been described as a brine is, of course, the source of facile cation-exchange properties. It

has been estimated that the hydrated cation concentration in zeolite cavities is around 5 M.

Gmelinite also has a framework, which can be described as a linkage of D6R units. In this case, they are arranged in the sequence ABABAB, that is, that of a hexagonal close-packed array. This architecture also produces a large cavity containing sites for four divalent hydrated cations.

An extension of this approach can be to consider stackings of S6R SBUs in the zeolite structure so that chabazite would be described as AABBCCAABBCC and gmelinite as AABBAABB. On this basis, erionite has the stacking arrangement of AABAAC and offretite AABAAB (Figure 7). These zeolites often occur naturally as intergrowths, and from the same syntheses, as might be anticipated from their framework similarities.

2.4.2 *Structures Based upon Linkages Between Chains of Tetrahedra*

In phillipsite, S4R are linked to form chains resembling a double crankshaft (Figure 8). Gismondine has a related

Table 6 Examples of the notation used in Baerlocher, Meier, and Olson[11] to describe the major channels in zeolitic frameworks

Zeolite framework	IUPAC code	Notation[a]	Description of notation
Linde type A	LTA	⟨100⟩ *8* 4.1***	⟨100⟩: channels parallel to all crystallographic equivalent axes in the cubic system, viz. x, y, z; *8*: channel constricted by an S8R; 4.1: the crystallographic dimension of the S8R in Å
Ferrierite	FER	[001] *10* 4.2 × 5.4* ↔ [010] *8* 3.5 × 4.8*	Channels parallel to the 001 crystallographic axis constricted by a 10SR with dimensions 4.2 × 5.4 Å intersecting (↔ or ↔) with channels parallel to the 010 axis constricted by an S8R with dimensions 3.5 × 4.8 Å
Linde type L	LTL	[001] *12* 7.1*	Channels parallel to the 001 axis constricted by 12SR of 7.1 Å diameter

[a]Number of asterisks denotes dimensionality of the channel. Other symbols used in Tables 2–5: | no direct access from one channel system to another; ⊥ channels interconnect at right angles; + two constrictions to the same channel.

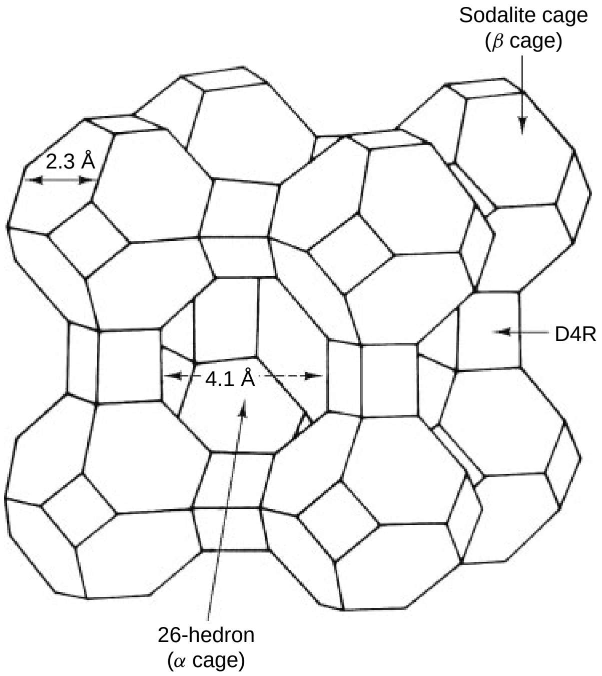

Figure 3 Framework of synthetic zeolite A (LTA) showing constituent cage structures and their dimensions

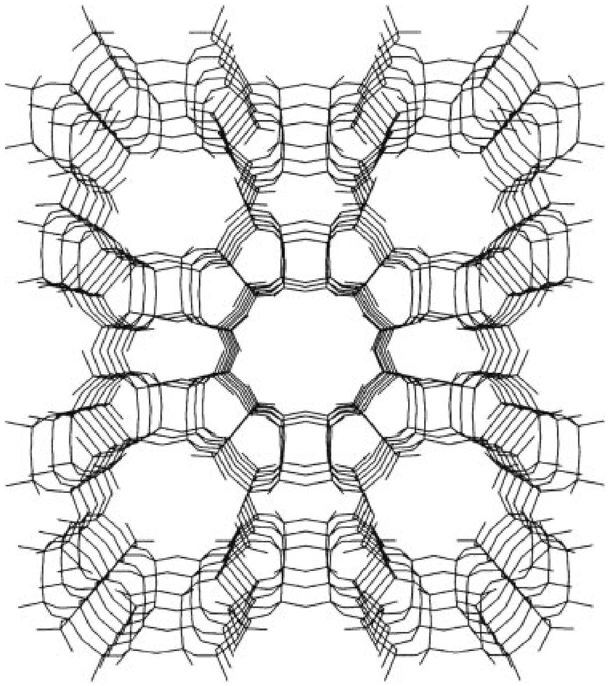

Figure 4 Framework of mordenite (MOR) showing channels

structure but with chains joined together in a different way, as shown in Figure 9. The differences can be seen to be variations in the relative spatial orientations of the linked tetrahedra described as up (U) and down (D), and adjacent tetrahedra are arranged as two pointing up and two down (UUDD). Note that, again, restricting S8R units have been created (Table 5), but of different diameters to those seen in chabazite. The cations reside close to the S8R positions.

It must be emphasized that both phillipsite and gismondine have unique frameworks. Mineralogically speaking they both are members of different families (see Tables 11 and 13).

Figure 1 illustrated the chain of tetrahedra identified in the natrolite framework. These are of UDUD alignments derived from the 4–1 SBU (Figure 2) whereby the '1' links adjacent chains. Other zeolites in this family are mesolite, gonnardite, and scolecite (see Table 12). The natrolite family of structures also has S8Rs as restricting dimensions. The cations sit in sites close to four oxygens, two each from adjacent 4–1 chains. They are relatively unhydrated at these sites and are difficult to replace by ion exchange.

2.4.3 *Structures Based upon Assemblages of Cages*

In some cases, it is easiest to describe a zeolite by relating the framework to a series of component polyhedra, each polyhedral cage being a clustering of linked tetrahedra. The

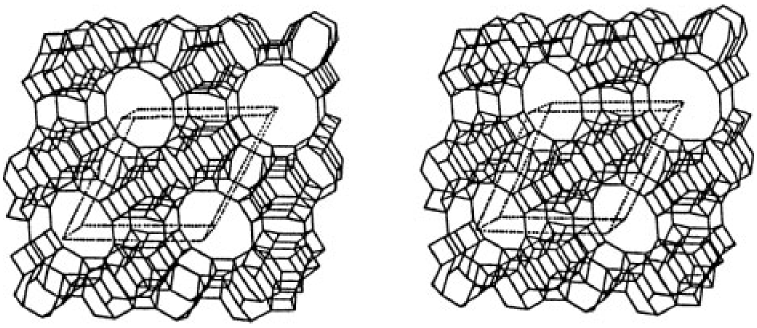

Figure 5 Stereopair of zeolite L (LTL) structure viewed along [001]

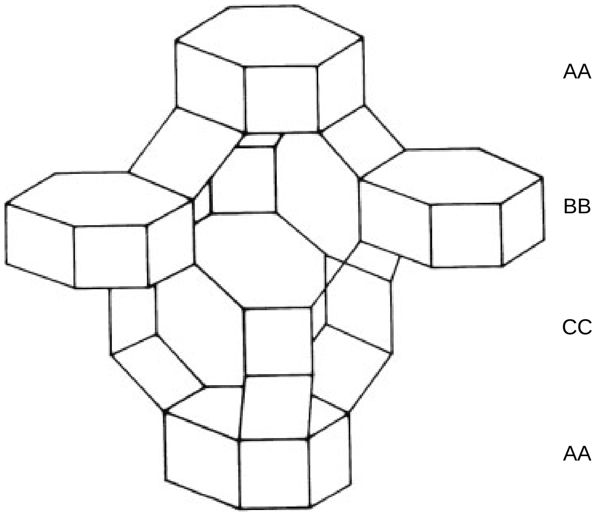

Figure 6 Structure of chabazite showing AABBCC sequence of S6Rs

best-known example of this approach is for the synthetic zeolites A, X, and Y.

The polyhedra making up the A framework can be seen in Figure 10. The smallest unit is the D4R SBU, which joins truncated octahedral units to surround a large central cavity. The truncated octahedra are the structural unit of the felspathoid sodalite (discussed later). These sodalite cages are also often described as β-cages while the large cavity, which has 48 sides, is known as an α-cage or a 'Type I' 26-hedron. Note that the LTA framework is composed entirely of these three polyhedra, which share all their faces with each other. This is therefore a space-filling structure. An alternative view of the LTA-type structure is as a series of β-cages jointed by cubes (D4R) to propagate cubic symmetry in which each β-cage occupies a position analogous to that of the atoms in an NaCl array, that is, a similar approach to that described in chabazite.

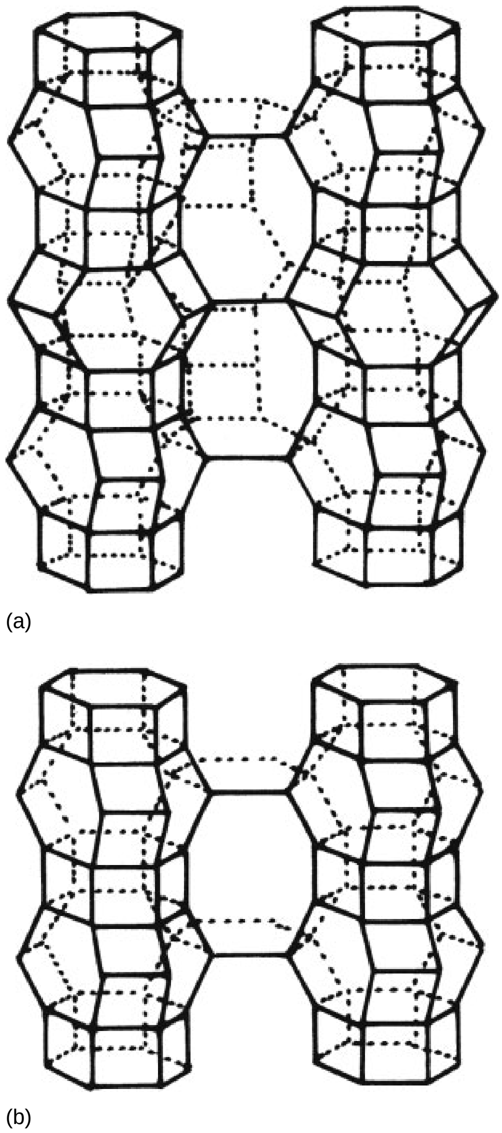

Figure 7 Structure of (a) erionite (AABAAC, S6R sequence) and (b) offretite (AABAAB, S6R sequence)

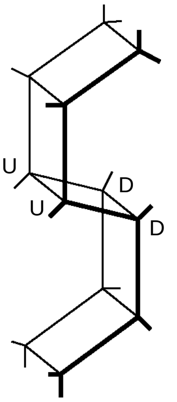

Figure 8 The 'double crankshaft' chain element of structure in gismondine (GIS) and related zeolites (U = up, D = down describes the configuration of linked pairs of Si,AlO_4 tetrahedra)

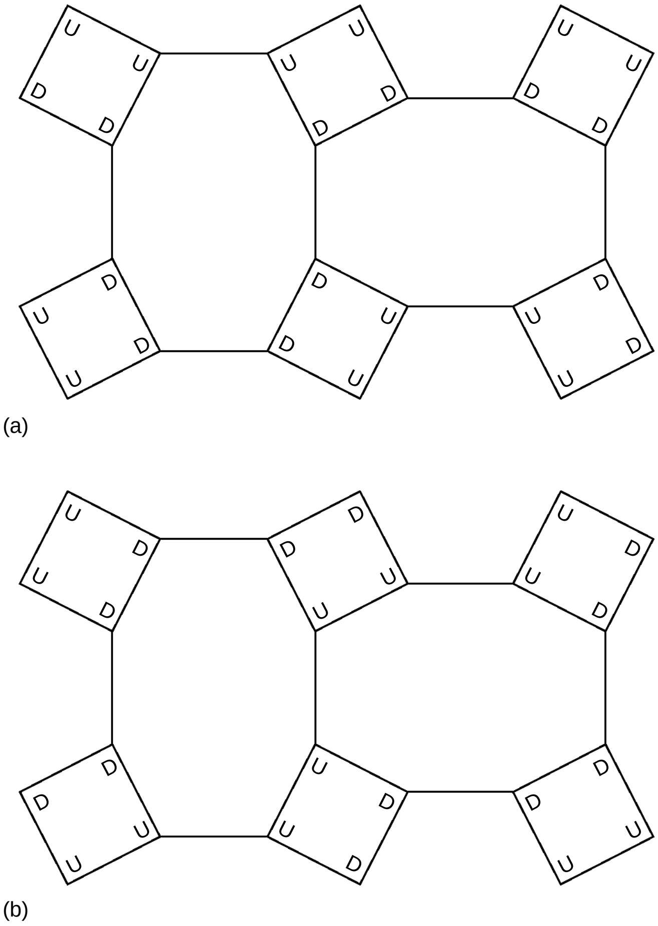

Figure 9 Linkage of chains in (a) phillipsite (PHI) and (b) gismondine (GIS)

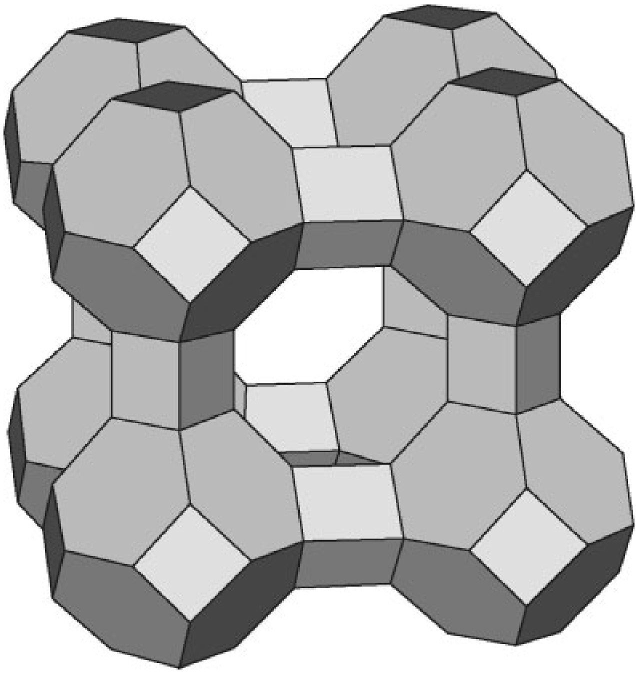

Figure 10 LTA structure emphasizing the linkage of truncated octahedra (β-cages) via D4R units (compare with Figure 3)

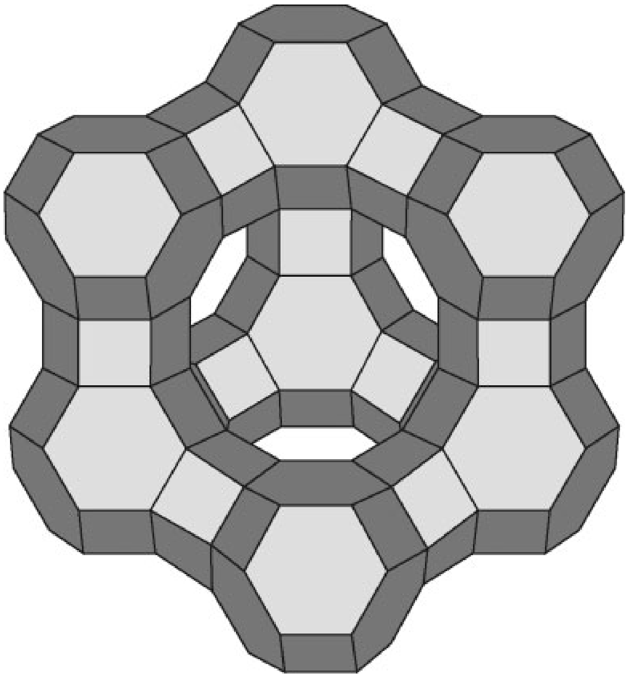

Figure 11 Faujasite (FAU) structure emphasizing the linkage of truncated octahedra (β-cages) via D6R units

This way of imagining polyhedral linkages can be extended to consider the FAU framework shared by the synthetic zeolites X and Y and the natural zeolite faujasite. Here (Figure 11) the composite polyhedra are the 6DR, which

link β-cages to create a large internal cavity, the 'Type II' 26-hedron. Again this is a space-filling arrangement that can be alternatively viewed as an assemblage of β-cages joined by one half of their available S6R faces to produce another framework of cubic symmetry in which the sodalite units have the same spatial arrangement to each other, as do the carbon atoms in a diamond lattice. Zeolite X and Y are synthetic faujasites with the FAU framework, and differ only in the relative amounts of Si and Al isomorphously substituted in tetrahedral interstices. Their cation sites will be considered later.

2.4.4 Summary

This section has attempted to give an appreciation of the ways in which zeolite structures arise. It has not been intended to be all-encompassing and other types of framework will arise in further sections. It will also be appropriate to introduce additional information on zeolite cation and water locations on various industrially significant zeolites. Not all zeolites will be described and full details of known cation and water sites were collated by Mortier to 1982.[12] No further compilation has yet been made.

3 ZEOLITE COMPOSITIONS

3.1 Natural Aluminosilicate Zeolites

Table 7 lists the currently known aluminosilicate zeolites based upon definition by their unique frameworks following Baerlocker, Baerlocher, Meier, and Olson.[11] It also contains typical unit cell compositions, the IUPAC code, and type localities, but is restrictive in the sense that it does not consider the mineralogical aspects of the study of zeolites. The authoritative body for these is the Subcommittee for Zeolite Nomenclature of the Commission on New Minerals and Mineral Names of the International Mineralogical Association. Their guidelines have been cited in a recent book on natural zeolites by Tschernich,[13] as follows.

1. A new zeolite must have a unique framework. Evidence of a framework different from existing species must be demonstrated as a condition for approval of a new species. Zeolites that have the same framework and are separated by a well-established gap in chemical composition that is controlled by the structure are acceptable as separate species.
2. A new mineral cannot be defined solely on the basis of exchangeable cations. Because cations in zeolites are largely exchangeable, the dominance of one over all the others should not be the basis for a mineral species. End members, or intermediate members, of a zeolite composition cannot be considered new species. Existing species with the same frameworks that are defined only by the exchangeable cations should be redefined.
3. A new zeolite cannot be defined solely on the basis of Si/Al ratio.
4. A new zeolite cannot be defined solely by the symmetry difference from order or disorder of the aluminum and silicon in the framework.

Following these guidelines extends the list of accepted naturally occurring zeolite species because, as seen in Section. 2.4.2, there are families of zeolites with the same framework but of different cation content. In some cases, the guidelines have become blurred with inconsistencies arising whereby end members of cation composition are accepted as distinct zeolite species in one family but not in another.

Before going on to list these families, one further point needs to be made. This arises because there are several instances where a unique zeolite framework has been first characterized from a laboratory preparation and later identified as a natural species. The first of these was mazzite, prepared first as synthetic zeolite ZSM-4 (or omega) but known in nature prior to the allocation of the IUPAC code; hence its inclusion in Table 7. The other species have been discovered in nature after an IUPAC code had been allocated to their synthetic analogs. The details for these materials are given in Table 8.

3.1.1 Natural Aluminosilicate Zeolite Families

Analcime Family. Table 9 lists all known aluminosilicate minerals with the ANA structure, with their compositions and type localities. It does not include all compositional variations, only those that have been given different mineral names.

Chabazite Family. Table 10 records details of the chabazite family.

Gismondine Family. Four minerals are accepted with the gismondine framework, again based upon variation of cation content and Si/Al disorder. These are listed in Table 11.

Natrolite Family. This family also contains four members distinguished by different Si/Al framework ordering and cation content, as shown in Table 12.

Phillipsite Family. Family details are in Table 13.

Stilbite Family. Details are in Table 14.

Other Zeolites with Isotypic Frameworks (Listed in Table 15). Heulandite and clinoptilolite share the same anionic framework and the differences between them have been the subject of much discussion, best summarized by Gottardi and Galli.[14] These authors suggest heulandite has

Table 7 Aluminosilicate zeolites with unique frameworks

IUPAC code	Name	Idealized unit cell composition	Type locality(ies)
ANA	Analcime	$Na_{16}[Al_{16}Si_{32}O_{96}]\cdot 16H_2O$	Island of Cyclopes (Sicily), Mount Etna (Sicily), Dumbarton (Scotland)
BIK	Bikitaite	$Li_2[Al_2Si_4O_{12}]\cdot 2H_2O$	Bikita (Zimbabwe)
BOG	Boggsite	$Na_4Ca_7[Al_{18}Si_{78}O_{192}]\cdot 74H_2O$	Neer Rd. Pit (Columbia County, Oregon, USA)
BRE	Brewsterite	$(Sr,Ba)_2[Al_4Si_{12}O_{32}]\cdot 10H_2O$	Strontian (Scotland)
CHA	Chabazite	$Ca_6[Al_{12}Si_{24}O_{72}]\cdot 40H_2O$	Oberstein (Germany)
DAC	Dachiardite	$Na_5[Al_5Si_{19}O_{48}]\cdot 12H_2O$	San Pieri di Campo (Elba, Italy)
EDI	Edingtonite	$Ba_2[Al_4Si_6O_{20}]\cdot 8H_2O$	Old Kilpatrick (Dumbarton, Scotland)
EPI	Epistilbite	$Ca_3[Al_6Si_{18}O_{48}]\cdot 16H_2O$	Iceland, Faroes
ERI	Erionite	$(Na_2,Ca_{3.5})K_2[Al_9Si_{27}O_{72}]\cdot 27H_2O$	Durkee Opal Mine (Swayze Creek, Baker County, Oregon, USA)
FAU	Faujasite	$(Na_2,Ca,Mg)_{29}[Al_{58}Si_{134}O_{384}]\cdot 240H_2O$	Sasbach (Kaiserstuhl, Baden, Germany)
FER	Ferrierite	$Na_2Mg_2[Al_6Si_{30}O_{72}]\cdot 18H_2O$	Kamloops Lake (British Columbia, Canada)
FRA	Franzinite	$(Na,K)^{+}{}_{30}Ca^{2+}{}_{10}(SO_4)^{2-}{}_{10}(H_2O)_2$ $[Al_{30}Si_{30}O_{120}]$	Italy
GIS	Gismondine	$Ca_4[Al_8Si_8O_{32}]\cdot 16H_2O$	Capo di Bova (Rome, Italy)
GME	Gmelinite	$(Na_2,Ca)_3[Al_8Si_{16}O_{48}]\cdot 24H_2O$	Glenarm (Co. Antrim, N. Ireland), Montecchio Maggiore (Vicenza, Italy)
GOO	Goosecreekite	$Ca_2[Al_4Si_{12}O_{32}]\cdot 10H_2O$	Goose Creek Quarry (Leesburg, Loudoun County, Virginia, USA)
HEU	Heulandite	$Ca_4[Al_8Si_{24}O_{72}]\cdot 24H_2O$	None
LAU	Laumontite	$Ca_4[Al_8Si_{16}O_{48}]\cdot 16H_2O$	Bleigrube Lead Mine (Huelgoat, Brittany, France)
LEV	Levyne	$Ca_9[Al_{18}Si_{36}O_{108}]\cdot 50H_2O$	Dalsnipa (Sandoy, Faroes)
MAZ	Mazzite	$(Na_2,K_2,Ca,Mg)_5[Al_{10}Si_{26}O_{72}]\cdot 28H_2O$	Mont Semiol (Montbrison, Loire, France)
MER	Merlinoite	$K_5Ca_2[Al_9Si_{23}O_{64}]\cdot 24H_2O$	Cupaello Quarry (Santa Rufina, Rieti, Latium, Italy)
MON	Montesommaite	$(K,Na)_9[Al_9Si_{23}O_{64}]\cdot 24H_2O$	Pollena (Monte Somma, Vesuvius, Italy)
MOR	Mordenite	$Na_8[Al_8Si_{40}O_{96}]\cdot 24H_2O$	Morden (King's County, Nova Scotia, Canada)
NAT	Natrolite	$Na_{16}[Al_{16}Si_{24}O_{80}]\cdot 16H_2O$	Hohentwiel (Hegau, Baden-Württemberg, Germany)
OFF	Offretite	$(Ca,Mg)_{1.5}K[Al_4Si_{14}O_{36}]\cdot 14H_2O$	Mont Semiol (Montbrison, Loire, France)
PAU	Paulingite	$(K_2,Ca,Na_2)_{76}[Al_{152}Si_{520}O1344]\cdot{\approx}700H_2O$	Rock Island Dam (Douglas County, Washington, USA)
PHI	Phillipsite	$K_2(Ca,Na_2)_2[Al_6Si_{10}O_{32}]\cdot 12H_2O$	Aci Castello (Sicily)
STI	Stilbite	$Na_4Ca_8[Al_{20}Si_{52}O_{144}]\cdot 56H_2O$	Helgusta Iceland Spar Mine (Reydarfjordur, Iceland)
TER	Terranoviate	$Na^{+}{}_{4.2}K^{+}{}_{0.2}\ Mg^{2+}{}_{0.2}Ca^{2+}{}_{3.7}(H_2O)_{29}$ $[Al_{12.3}Si_{67.7}O_{160}]$	Terranova Bay, Antarctica
THO	Thomsonite	$Na_4Ca_8[Al_{20}Si_{20}O_{80}]\cdot 24H_2O$	Old Kilpatrick (Dumbarton, Scotland)
TSC	Tschörtnerite	$Ca^{2+}{}_{64}(K^{+}{}_2,Ca^{2+},Sr^{2+},Ba^{2+})_{48}$ $Cu^{2+}{}_{48}(OH)^{-}{}_{128}(H_2O)_x\ [Al_{192}Si_{192}O_{768}]$	USA
YUG	Yugawaralite	$Ca_2[Al_4Si_{12}O_{32}]\cdot 8H_2O$	Yugawara Hot Springs (Kanagawa Prefecture, Honshu, Japan)

the cation composition $(Ca + Sr + Ba) > (Na + K)$ with clinoptilolite being rich in monovalent cations.

An unusual variation is that seen in leonhardite, which is merely a water-deficient laumontite and should now be discontinued as a named mineral. This also applies to the name 'svetlozarite', which has been used for a Ca-rich dachiardite containing stacking faults.

Cowlesite. Cowlesite is the name given by Wise and Tschernich (see page 121 in Tschernich[13]) to a mineral found at the Neer Road, Goble, Oregon location. It has the composition $Ca[Al_2Si_3O_{10}]\cdot 6H_2O$ and has now been found at many locations worldwide. It is listed by the IMA as a zeolite but its framework has not yet been characterized.

3.2 Naturally Occurring Zeotypes

Table 16 lists minerals that have zeolite frameworks but have atoms other than just Si and Al in their

Table 8 Natural zeolites identified after characterization of their laboratory-made analogs

IUPAC code	Synthetic analog	Natural species	Idealized unit cell composition of natural species	Type locality
*BEA[a]	Beta	Tschernichite	$Ca[Al_2Si_6O_{16}]\cdot 8H_2O$	Neer Rd. Pit (Goble, Columbia County, Oregon, USA)
EAB	TMA-E(AB)	Bellbergite	$(K,Ba,Sr)_2Sr_2Ca_2(Ca,Na)_4Al_{18}Si_{18}O_{72}.30H_2O$	Bellerberg (also Bellberg) volcano, 2 km north of Mayen, Eifel, Germany
MFI	ZSM-5	Mutinaite	$Na_3Ca_4Si_{85}Al_{11}O_{192}.\ 60H_2O$	Mount Adamson Antartica
LOS	Losod	Bystrite	$Ca(Na,K)_7Si_6Al_6O_{24}S_{4.5}\cdot H_2O$	Malo-Bystrinskoe deposit, Russia
LTL	Linde type L	Perlialite	$K_9Na(Ca,Sr)[Al_{12}Si_{24}O_{72}]\cdot 15H_2O$	Mounts Evelochorr and Yukspor (Khibina Massif, Kola Peninsula, Russia)
NES	NU-87	Gottardiite	$Na_3Mg_3Ca_5Si_{117}Al_{19}O_{272}\cdot 93H_2O$	Mount Adamson Antartica

[a]The asterisk denotes a well-defined framework subunit for which the pure end members have not been synthesized.[11]

Table 9 The analcime family

Mineral name	Idealized unit cell composition	Type locality	Comment
Analcime varieties	$Na_{16}[Al_{16}Si_{32}O_{96}]\cdot 16H_2O$	Isle of Cyclops (Catania, Sicily)	Ca,Mg-rich;[a] identified but not confirmed as distinct species (see also wairakite below)
Leucite[b]	$K_{16}[Al_{16}Si_{32}O_{96}]\cdot H_2O$		
Pollucite	$(Cs,Na)_{16}[Al_{16}Si_{32}O_{98}]\cdot nH_2O$	San Piero in Campo (Sicily)	Cs must be present in excess of 50% to be defined as pollucite
Wairakite	$(Ca,Na_2)_8[Al_{16}Si_{32}O_{98}]\cdot 16H_2O$	Wairakei (New Zealand)	Ca should be in excess of 50% to be defined as wairakite

[a]Mg-rich analcime has been described as doranite. [b]Also ammonioleucite, $(NH_4,K_{16})[Al_{16}Si_{32}O_{96}]$.

Table 10 The chabazite family

Mineral name	Idealized unit cell composition	Type locality
Chabazite	$Ca_6[Al_{12}Si_{24}O_{72}]\cdot 40H_2O$	Oberstein (Germany)
Willhendersonite	$Ca_2K_2[Al_6Si_6O_{24}]\cdot 10H_2O$	San Venanzo Quarry (Terni, Italy)
Herschelite	$Na_6K_2Ca_2[Al_{12}Si_{24}O_{72}]\cdot 36H_2O$	Aci Castello (Sicily)

Table 11 The gismondine family

Mineral name	Idealized unit cell composition	Type locality
Amicite	$K_4Na_4[Al_8Si_8O_{32}]\cdot 10H_2O$	Höwenegg (Hegau, Germany)
Garronite	$NaCa_{2.5}[Al_6Si_{10}O_{32}]\cdot 14H_2O$	Garron Plateau (Co. Antrim, N. Ireland)
Gismondine	$Ca_4[Al_8Si_8O_{32}]\cdot 16H_2O$	Capo di Bova (Rome, Italy)
Gobbinsite	$Na_5[Al_5Si_{10}O_{32}]\cdot 11H_2O$	Gobbins Escarpment (Co. Antrim, N. Ireland)

tetrahedral interstices. Kehoeite has the apparent composition $(Zn,Ca)Al_2(PO_4)_2(OH)_2\cdot 5H_2O$ and has formerly been included in this category, but is now known to be a mixture of different minerals.

Lovdardite has a particular significance as it contains three-membered rings of linked tetrahedra, which also have been identified in synthetic zeolite-like substances.

3.3 Natural Zeolite-like Minerals with Incomplete Frameworks

Baerlocher, Meier, and Olson[11] have included materials in their listing in which the Si/Al tetrahedra do not share all four corners to complete a framework. These minerals have an appreciable content of hydroxyl groups located at

Table 12 The natrolite family

Mineral name	Idealized unit cell composition	Type locality
Gonnardite	$(Na_{10}Ca_4)[Al_{18}Si_{22}O_{80}]\cdot{\approx}20H_2O$	Chaux de Bergonne (Gignat, Puy de Dome, France)
Natrolite	$Na_{16}[Al_{16}Si_{24}O_{80}]\cdot 16H_2O$	Hohentwiel (Hegau, Baden-Württemberg, Germany)
Mesolite	$Na_6Ca_5[Al_{16}Si_{24}O_{80}]\cdot 22H_2O$	Nova Scotia (Canada)
Scolecite	$Ca_8[Al_{16}Si_{24}O_{80}]\cdot 24H_2O$	None
Paranatrolite	$(Na,Ca)_{16}[Al_{16}Si_{24}O_{80}]\cdot 24H_2O$	Mont Saint-Hilaire (Montreal, Canada)
Tetranatrolite	$(Na,Ca)_{16}[Al_{16}Si_{24}O_{80}]\cdot 16H_2O$	None

Table 13 The phillipsite family

Mineral name	Idealized unit cell composition	Type locality
Harmotome	$Ba_2(Ca_{0.5}Na)\ [Al_5Si_{11}O_{32}]\cdot 12H_2O$	Andreasburg (Germany)
Phillipsite	$K_2(Ca,Na_2)_2\ [Al_6Si_{10}O_{32}]\cdot 12H_2O$	Aci Castello (Sicily)
Wellsite	$Ca_{1.6}Ba_{0.4}(Na,K)\ [Al_5Si_{11}O_{32}]\cdot 13H_2O$	None

Table 14 The stilbite family

Mineral name	Idealized unit cell composition	Type locality
Barrerite	$Na_{16}[Al_{16}Si_{56}O_{144}]\cdot 52H_2O$	Capo Pula (Sardinia)
Stellerite	$Ca_8[Al_{16}Si_{56}O_{144}]\cdot 56H_2O$	Komandar Islands (Bering Sea)
Stilbite	$Na_4Ca_8[Al_{20}Si_{52}O_{144}]\cdot 56H_2O$	Helgusta Iceland Spar Mine (Reydarfjordur, Iceland)

tetrahedral corners. The justification for their inclusion as zeolite-like minerals arises from the recognition of the openness of their incomplete frameworks in which are recognizable zeolitic cavities and channels. Three minerals of these are aluminosilicates (partheite, roggianite, and wenkite) and the other is a beryllosilicate, chiavennite. Further details of these minerals are in Table 17.

Table 15 Other isotypic zeolites

Mineral name	Idealized unit cell composition
Heulandite	$Ca_4[Al_8Si_{28}O_{72}]\cdot 24H_2O$
Clinoptilolite	$(Na,\ K)_6[Al_6Si_{30}O_{72}]\cdot 20H_2O$
Laumontite	$Ca_4[Al_8Si_{16}O_{48}]\cdot 16H_2O$
Leonhardite	$Ca_4[Al_8Si_{16}O_{48}]\cdot 14H_2O$
Dachiardite	$Na_5[Al_5Si_{19}O_{48}]\cdot 12H_2O$
Svetlozarite	$Na_5[Al_5Si_{19}O_{48}]\cdot 12H_2O$

3.4 Further Information on Natural Zeolites and Related Species

It can be seen from earlier sections that some anomalies have arisen between the recognition of zeolite species by mineralogists and the characterization of their frameworks by crystallographers. Many mineralogists (amateur and professional) collect natural zeolite specimens because of their beauty and novel crystal habits. Both Tschernich[13] and Gottardi and Galli[14] have provided excellent texts covering the mineralogical properties of zeolites. These authors provide line drawings of zeolite crystal habit and details of their geological occurrences and genesis. Tschernich lists classical mineralogical physical and optical properties, as do Gottardi and Galli, who also provide details of cation sites and framework configuration. These authors also discuss, in detail, the interrelationships between the zeolite families as well as their chemistries and syntheses.

Table 16 Naturally occurring zeotypes

IUPAC framework code	Mineral name	Idealized unit cell composition	Type locality
ANA	Hsianghualite	$Li_{16}Ca_{24}[Be_{24}Si_{24}O_{96}]$	Hunan (China)
	Viseite	$Na_2Ca_{10}[Al_{20}Si_6P_{10}O_{60}\ (OH)_{36}]\cdot 16H_2O$	Visé (Belgium)
LOV	Lovdarite	$K_4Na_{12}[Be_8Si_{28}O_{72}]\cdot 18H_2O$	Lovozero (Russia)
RHO	Pahasapaite	$(Ca,Li,K,Na)_{11}Li_8[Be_{24}(PO_4)_{24}]\cdot 38H_2O$	None
WEI	Weinebenite	${Ca^{2+}}_4(H_2O)_{16}\ [Be_{12}P_8O_{32}(OH)_8]$	Weinebene, Austria

Table 17 Zeolite-type minerals with incomplete frameworks

IUPAC framework code	Mineral name	Idealized unit cell composition	Type locality
–CHI	Chiavennite	$Ca_4Mn_4[Be_8Si_{20}O_{52}(OH)_8]\cdot 8H_2O$	None
–CLO	Cloverite	$(C_7H_{14}N+)_{24}$ $[F_{24}$ $Ga_{96}P_{96}O_{372}(OH)_{24}]$	None
–PAR	Partheite	$Ca_8[Al_{16}Si_{16}O_{60}(OH)_8]\cdot 16H_2O$	Taurus Mts (Turkey)
–ROG	Roggianite	$Ca_{16}[Al_{16}Si_{32}O_{88}(OH)_{16}](OH)_{16}\cdot 26H_2O$	Alpe Rosso (Val Vigezzo, Novara, Italy)
–WEN	Wenkite	$Ba_4(Ca,Na_2)_3[Al_8Si_{12}O_{39}(OH)_2(SO_4)]\cdot 3H_2O$	None

Tschernich provides a comprehensive list of outmoded zeolite mineral names. Table 18 gives examples of some of the more well known.

3.5 Synthetic Species

3.5.1 Synthetic Aluminosilicate Zeolites

As mentioned earlier, pioneering work by Barrer showed that some natural zeolite species could be synthesized in the laboratory. This has led to many synthetic routes and to a proliferation of other species with novel structures not known in nature.

Table 19 lists all synthetic zeolites (included those analogous to naturally occurring ones) whose structures are confirmed in Baerlocher, Meier, and Olson.[11] Note that many are still described by acronyms related to their original source. In some cases, this is to the discoverer, for example, those synthesized for the first time by George Kerr from the Mobil Corporation have been given the code ZK. In other cases, the code relates to the company in whose laboratory the discovery was first made. Examples of this are ZSM, which comes from Zeolite Socony Mobil, and LZ, which relates to the Linde Company. Full explanations of these codes are available.[15] Table 19 also reflects the earlier confusion in the zeolite literature whereby claims to have discovered new materials were later discredited. It should also be remarked that often the isotypic structures reflect synthetic success in preparing analogs with differing Si/Al ratios, that is, with various amounts of Al isomorphously substituting Si tetrahedral positions. The best-known examples of this can be seen in the synthetic faujasites Linde X and Linde Y and the high-silica zeolites exemplified by the BETA, EMC-2, EU-1, MAZ, MEI, MEL, MFI, MFS, MTT, MTW, NES, and TON frameworks. Their production reflects the high catalytic activity noted for silica-based structures containing very small proportions of isomorphously substituted Al. By the same token, synthetic analogs of natural species can be high-silica materials (e.g. as seen in CHA, ERI, FAU, FER, MAZ, and OFF variants).

Table 18 Some well known zeolites and their outmoded names

Zeolite	Outmoded name
Analcime	Analcite
Chabazite	Acadialite, haydenite, phacolite, seebachite, herschelite
Epistilbite	Orizite, parastilbite, reissite
Gismondine	Gismondite, zeogonite (with phillipsite)
Gmelinite	Sarcolite
Laumontite	Laumonite, scheiderite, sloanite, leonhardite
Levyne	Levynite, mesoline
Mesolite	Mesotype
Mordenite	Arduinite, flokite, pseudonatrolite, ptilolite, steelite
Natrolite	Galaktite, mesotype, fargite, laubanite
Phillipsite	Christianite, wellsite
Stilbite	Desmine, epidesmine, foresite
Thomsonite	Comptonite, faroelite, mesole, mesotype

3.5.2 Synthetic Zeotypes

In 1983, workers at the Union Carbide (formerly Linde, now Union Oil Products (UOP)) laboratories in Tonawanda near New York reported a new class of microporous inorganic solids. Some materials were layered but, of the 20 new phases reported,[16] no less than 14 were framework compounds based upon three-dimensional arrays of linked $[AlO_4]^{5-}$ and $[PO_4]^{3-}$ coordination polyhedra. These novel zeotypes were designated by the acronym $AlPO_4$. As would be expected, the linkage of the Al/P tetrahedra created an uncharged framework and so no charge-balancing cations are present and the materials have water in the voids of the framework. Clearly these do not have the property of ion exchange expected from a zeolitic type material. Subsequent work demonstrated that many other closely related microporous materials could be synthesized with a wide variety of cations in the tetrahedral interstices, including those requiring a charge-balancing cation. Furthermore, a high proportion of these novel zeotypes have structures isotypic with some 15 natural and synthetic aluminosilicate zeolites. Table 20 lists synthetic zeotypes with unique frameworks and Table 21 classifies further examples according to isotypic aluminosilicate frameworks.

The acronyms used in these tables require further explanation. The known Aluminophosphate ($AlPO_4$) structures also have a number (e.g. $AlPO_4$-5), or a further letter code (e.g. $AlPO_4$-D), appended. They are the labels given by the first literature report and have no scientific significance. Note that the ATT framework, coded as $AlPO_4$-12 TAMU, marks that the material was first synthesized at Texas A&M University. Similarly, those encoded as MCM are Mobil products. Apart from those that are self explanatory, such as gallosilicate ABW or beryllosilicate gismondine, the remaining acronyms

Table 19 Synthetic aluminosilicate zeolites[a]

IUPAC code	Name or acronym	Idealized composition	Other isotypic synthetic aluminosilicates
ABW	Li-A(BW)	$Li_4[Al_4Si_4O_{16}]\cdot 4H_2O$	$CsAlSiO_4$, $RbAlSiO_4$, $TlAlSiO_4$
ANA	Analcime	$Na_{16}[Al_{16}Si_{32}O_{96}]\cdot 16H_2O$	Ca-D, Na-B, pollucite
*BEA[b]	BETA	$Na_n[Al_nSi_{64-n}O_{128}]$, $n < 7$	–
BIK	Cs-aluminosilicate bikitaite	$Cs_{0.35}[Al_{0.35}Si_{2.65}O_6]$	–
BRE	CIT-4	$Ba^{2+}{}_2\ (H_2O)_{10}\ [Al_4Si_{12}O_{32}]$	Synthetic Brewsterite
CAS	Cesium aluminosilicate (Araki)	$Cs_4[Al_4Si_{20}O_{48}]$	–
CHA	Chabazite	$Ca_6[Al_{12}Si_{24}O_{72}]\cdot 40H_2O$	LZ-218, Linde D, Linde R, ZK-14, ZYT-6, SSZ-13
EAB	TMA-E(AB)	$(Me_4N)_2Na_7[Al_9Si_{27}O_{72}]\cdot 26H_2O$	Bellbergite
EDI	Edingtonite	$Ba_2[Al_4Si_6O_{20}]\cdot 8H_2O$	KF, Linde F
EMT[c]	EMC-2 (hexagonal faujasite)	$Na_{21}(18\text{-crown-}6)_n[Al_{21}Si_{75}O_{192}]$	ECR-30, SZM-20 ZSM-3, CSZ-1
EPI	Synthetic Epistilbite	$Ca^{2+}{}_3\ (H_2O)_{16}\ [Al_6Si_{18}O_{48}]$	
ERI[d]	Erionite	$(Na_2,Ca)_{3.5}K_2[Al_9Si_{27}O_{72}]\cdot 27H_2O$	LZ-220, Linde T
ESV	ERS-7	$H^+{}_{5.06}Na^+{}_{0.07}\ [Al_{5.13}Si_{42.87}O_{96}]$	
EUO	EU-1	$Na_n[Al_nSi_{112-n}O_{224}]\cdot \approx 26H_2O$, $n < 19$, typically $n = 3.6$	TPZ-3, ZSM-50
FAU[c]	Synthetic faujasites	$(Na_2,Ca,Mg)_{29}[Al_{58}Si_{134}O_{384}]\cdot 240H_2O$	Linde X, Linde Y, LZ-210

MEI	ZSM-18	$Na_n[Al_nSi_{34-n}O_{68}]\cdot 28H_2O$, $n = 2.1-5.7$	–
MEL	ZSM-11	$Na_n[Al_nSi_{96-n}O_{192}]\cdot \approx 16H_2O$, $n < 16$	–
MER	Merlinoite	$K_5Ca_2[Al_9Si_{23}O_{64}]\cdot 24H_2O$	K-M, Linde W, barium silicate merlinoite
MFI	ZSM-5	$Na_n[Al_nSi_{96-n}O_{192}]\cdot \approx 16H_2O$, $n < 27$	AZ-1, FZ-1, LZ-105, NU-4, NU-5, TSZ, TSZ-111, TZ-01, US1-108, ZKQ-1B, ZMQ-TB, ZBM-30
MFS	ZSM-57	$H_{1.5}[Al_{1.5}Si_{34.5}O_{72}]$	–
MOR	Mordenite	$Na_8[Al_8Si_{40}O_{96}]\cdot 24H_2O$	Na-D, Ca-Q, Zeolon, LZ-211
MSO	MCM-61	$K^+{}_{2.1}\ C_{12}H_{24}O_6\ [Si_{27.9}Al_{2.1}O_{60}]$	MESOPOROUS
MTT	ZSM-28	$Na_n[Al_nSi_{24-n}O_{48}]\cdot \approx 4H_2O$, $n < 2$	EU-13, KZ-1, ISI-4
MTW	ZSM-12	$Na_n[Al_nSi_{28-n}O_{56}]\cdot \approx 4H_2O$, $n < 2.5$	NU-13, Theta-3, CZH-5, TPZ-12
NES	NU-87	$H_4[Al_4Si_{64}O_{136}]\cdot nH_2O$	Gottardiite
OFF[d]	Offretite	$(Ca,Mg)_{1.5}K[Al_4Si_{14}O_{36}]\cdot 14H_2O$	Linde T, LZ-217, TMA-O
PHI	Phillipsite	$K_2(Ca,Na_2)_2[Al_6Si_{10}O_{32}]\cdot 12H_2O$	ZK-19
RHO	Rho	$(Na,Cs)_{12}[Al_{12}Si_{36}O_{96}]\cdot 44H_2O$	LZ-214
TON	Theta-1	$Na_n[Al_nSi_{24-n}O_{48}]\cdot \approx 4H_2O$	NU-10, ISI-1, KZ-2, ZSM-22

[a]When synthetic analogs of naturally occurring aluminosilicate zeolites have been synthesized they are listed by the natural mineral names and their idealized compositions. [b]For *BEA the asterisk denotes a well-defined structural subunit for which the pure end members have not been obtained. [c]The structures EMT and FAU also crystallize as a series of structural intermediates. [d]ERI and OFF also form as a series of structural intermediates.

in both Tables 20 and 21 denote zeotypes prepared by Union Carbide workers who have developed the following shorthand notation for framework materials in which tetrahedral positions accommodate atoms other than Si and Al.

1. Silicoaluminophosphates are described as SAPO, for example, the AFR structure assigned to SAPO-40 (see Table 20).
2. Metal aluminophosphates have the generic acronym MeAPO and metal aluminosilicophosphates are MeAPSO. More specific descriptions come by inserting the appropriate chemical symbol(s) into the code. There are many examples of this in Table 21, for example, AsPO-34, AsVBeAPO-34, CoAPO-34, MnAPSO-34, FeAPSO-44, and so on The letters C, M, and Z are sometimes used

Table 20 Synthetic zeotypes with unique frameworks

IUPAC code	Name or acronym	Idealized composition	Other isotypic synthetic zeotypes[a]
ACO	ACP-1	$(C_2H_{10}N_2^{2+})4\ (H_2O)_2\ [Al_{0.88}Co_{7.12}P_8O_{32}]$	
AEI	$AlPO_4$-18	$[Al_{24}P_{24}O_{96}]$	MCM-7
AEL	$AlPO_4$-11	$[Al_{20}P_{20}O_{80}]$	
AET	$AlPO_4$-8	$[Al_{36}P_{36}O_{144}]$	MCM-37
AFI	$AlPO_4$-5	$[Al_{12}P_{12}O_{48}]\cdot R\cdot qH_2O$, R = Pr_4NOH	MCM-6[b]
AFO	$AlPO_4$-41	$[Al_{20}P_{20}O_{80}]$	–
AFR	SAPO-40	$[(Si,Al,P)_{32}O_{64}]\cdot 2TPA\cdot OH$	–
AFS	MAPSO-46	$(PrNH_2)_8[Mg_6Al_{22}P_{26}Si_2O_{112}]$	–
AFT	$AlPO_4$-52	$(Et_4N\cdot H_2PO_4)_{3.6}[Al_{36}P_{36}O_{144}]\cdot 76H_2O$	–
AFY	CoAPO-50	$(Pr_2\ NH_2)_3[Co_3Al_5P_8O_{32}]\cdot 7H_2O$	–
AHT	AlPO-H2	$(H_2O)_8\ [Al_6P_6O_{24}]$	
APC	$AlPO_4$-C	$[Al_6P_{16}O_{64}]$	$AlPO_4$-H3 (anhyd), MCM-1
APD	$AlPO_4$-D	$[Al_{16}P_{16}O_{64}]$	$AlAsO_4$-1
AST	$AlPO_4$-16	$[Al_{20}P_{20}O_{80}]\cdot 4R\cdot 16H_2O$, R = quinuclidinium	–
ASU	ASU-7	$(C_2H_7N)_2$ (H2O)$_2$ $[Ge_{20}O_{40}]$	
ATN	MAPO-39	$H_n[Mg_nAl_{8-n}P_8O_{32}]$	–

VSV	VPI-7	$Na^+{}_{26}H^+{}_6(H_2O)_{44}\ [Zn_{16}Si_{56}O_{144}]$	Gaulite
ZON	ZAPO-11	$(C_4H_{12}N+)_8\ [Zn_8Al_{24}P_{32}O_{128}]$	

[a]See also Tables 21 and 22 and note[d] below.[11] [b]The synthetic aluminosilicate zeolite SSZ-24 has the AFI framework. [c]The synthetic aluminosilicate zeolite Linde Q has the BPH framework (Linde Q is not the same as Q, which has the KFI structure). [d]$AlPO_4$-52, of composition $0.2(TEA)(H_2PO_4)[Al_{0.5}P_{0.5}]\cdot O_2$ has an idealized CHA-like D6R sequence AABBCCAACCBB.[16] $AlPO_4$-EN3, of composition $[Al_6(PO_4)_6]\cdot 4H_2O\cdot en$, where en = ethylenediamine, has a partially derived structure.[16] Note: (TPA), Tetrapropylammonium.

Table 21 Synthetic zeotypes with frameworks common to known aluminosilicate zeolites[a]

IUPAC code	Zeotype name or acronym
ABW	Gallosilicate ABW, berylloarsenate ABW, beryllophosphate ABW, zincophosphate ABW
ANA	$AlPO_4$-24, $AlPO_4$- pollucite, aluminosilicophosphate analcime, Cs beryllosilicate pollucite, Cs, Fe silicate pollucite, gallosilicate analcime, $Cs_2CuSi_5O_{12}$
*BEA	Boron-beta
CHA	AsAPO-34, AsAPO-44, AsVBe APO-34, BeAPSO-34, BeAPSO-44, CAPSO-34, CAPSO-44, Co APO-34, CoAPO-44, CoAPO-47, CoSAPO-34, FCAPO-34, FCAPO-44, FCAPO-47, FeAPSO-34, FeAPSO-44, FeMnAPO-44, FeTiCoAPO-34, GaAPO-44, GeAPO-34, GeBAPO-44, MAPO-34, MAPO-44, MAPO-47, MgAPSO-34, MgAPSO-44, Mg APSO-47, MnAPO-34, MnAPO-44, Mn APO-47, MnAPSO-34, MnAPSO-44, MnAPSO-47, SAPO-34, SAPO-44, SAPO-47, XAPO-34, XAPO-44, XAPO-47, ZAPO-34, ZAPO-44, ZAPO-47, Zn APSO-34, Zn APSO-44, Zn APSO-47, MCM-2
ERI	$AlPO_4$-17, As APO-17, BeAPO-17, BeAPSO-17, CAPO-17, CAPSO-17, CrGaAPO-17, FCAPO-17, FeCoMgAPO-17, MAPO-17, SAPO-17, XAPO-17
FAU	FCAPO-37, SAPO-37, XAPO-37, beryllophosphate X, zincophosphate X
GIS	Beryllosilicate gismondine, MAPSO-43
LEV	CoAPO-35, FCAPO-35, FeAPSO-35, MAPO-35, Mg PSO-35, MnAPO-35, MnAPSO-35, SAPO-35, XAPO-35, ZAPO-35, ZnAPO-35
LTA	Gallogermanate A, gallophosphate A, ZK-21, FCAPO-42, SAPO-42, XAPO-42
LTL	Gallosilicate L
MAZ	Gallosilicate mazzite
MEL	Boralite D, TS-2 (titanosilicate)
MFI	AMS-IB, BOR-C, Encilite, ZBM-30(B), ZBH (all borosilicates), TS-I (titanosilicate)[b]
NAT	Gallosilicate natrolite, Rb gallogermanate natrolite
RHO	Berylloarsenate rho, synthetic pahasapaite
–ROG[c]	–

[a]Names as listed in Table 19.[11,16] See text for explanation of acronyms. [b]Recent evidence is that the Ti may well be hexacoordinate in this and related materials. [c]A recent report suggests that roggianite has some Be in framework sites.[11] Note: Frameworkconstituent luminophosphate, (FCAPO).

as shorthand for the elements chromium, magnesium, and zinc, respectively.

3. When wide compositional ranges can be prepared as isomorphous substitutions into aluminophosphates, two generalized acronyms are used: (a) FCAPO, where FC means framework constituents, and encompasses structures containing proportions of As, Be, B, Cr, Ga, Li, and V; (b) Aluminophosphate containing Fe, Ti, as T atoms (XAPO), where Fe or Ti are in combination with Co, Mg, Mn, or Zn. Further examples of compositional variations in the unique zeotype frameworks listed in Table 20 are given in Table 22. It should be noted that not all these compounds have been fully structurally characterized at the time of writing.

The material designated $AlAsO_4$-1 comprises linked $[AlO_4]^{5-}$ and $[AsO_4]^{3-}$ tetrahedra.

Finally, it must be mentioned that catalytic interest has promoted the preparation of many high-silica zeolitic-like phases modified to include other T atoms such as B, Ti, Fe, or Ga. This modification can be at synthesis, or by postsynthesis treatment to replace Si and/or Al from existing high-silica frameworks. Not all these are recorded here because these modified materials again may not be fully characterized; however, Table 21 lists well-characterized examples, for example, analogs of the MFI (ZSM-5) framework.

3.5.3 Phases of Silica with Open Zeolite-like Frameworks

Synthetic studies on high-silica zeolites showed that silicon end members of structural groups could be prepared. Clearly these are pure silica phases and to date several have been prepared including a synthetic analog of the natural silica phase melanophlogite. These are listed in Table 23. They have sometimes been described as clathrasils, in deference to their strong structural links to clathrates as can be seen from their soap-bubble like frameworks (illustrated in Figure 12).

3.5.4 Felspathoid Frameworks

Earlier discussion introduced the concept of using the characteristic truncated octahedral elements of the sodalite framework to explain the molecular architecture of the synthetic zeolites X and Y (see Section. 2.4.3). There are other structural correlations that can be drawn between felspathoids and zeolites, for example, that the cancrinite cage (11-hedron) is a face-sharing element seen in the LTL, ERI, OFF, and LOS frameworks. Furthermore, in nature, salt ion pairs are contained in felspathoid minerals and when these are removed the residual framework exhibits the zeolitic properties of ion exchange and reversible water loss. Other similarities arise in that zeolites can imbibe salt ion pairs, and isotypic structures

Table 22 Compositional variations in unique zeotype frameworks[a]

IUPAC code	Zeotype name or acronym
AEL	AsAPO-11, BAPO-11, BeAPSO-11, BeGeAPO-11, CAPO-11, CAPSO-11, CoAPO-11, FCAPO-11, FeMnAPO-11, LiAPO-11, MAPO-11, MgAPSO-11, MnAPSO-11, SAPO-11, VAPO-11, XAPO-11, ZAPO-11, ZnAPSO-11, MCM-7
AEN	AlPO-EN3, AiPO-53(A), AlPO-53(B), CFSAPO-1A, JDF-2, MSC-1, UiO-12-500, UiO-12-as

Table 23 Phases of silica with open zeolite-like frameworks

IUPAC code	Name or acronym	Idealized composition	Isotypic framework
AST	Octadecasil	$[Si_{20}O_{40}]\cdot 2(RF)$, R = quinuclidinium or TMA	$AlPO_4$-16?
CFI	CIT-5	$[Si_{32}O_{64}]$	
DDR	Deca-dodecasil 3R	$[Si_{120}O_{240}]\cdot qR$, R = 1-aminoadamantane	Sigma-1 ($SiO_2/Al_2O_3 \approx 60$)
DOH	Dodecasil 1H	$[Si_{34}O_{68}]\cdot qR$, R = N_2 or piperidine	
DON	UTD-1F	$((Cp^*)_2Co)^+{}_2F^-{}_{1.5}(OH)\text{-}_{0.5}$ $[Si_{64}O_{128}]$ Cp* = pentamethylcyclopentadiene	UTD-1
GON	GUS-1	$[Si_{32}O_{64}]$	
IFR	SSZ-42	$[Si_{16}O_{32}]$	ITQ-4, MCM-42
ISV	ITQ-7	$[Si_{64}O_{128}]$	
ITE	ITQ-3	$[Si_{64}O_{128}]$	
MEL	Silicalite-2		ZSM-11[a], SSZ-46
MEP	Melanophlogite (natural)	$[Si_{46}O_{92}]\cdot qR$, R = N_2, CO_2, CH_4	Synthetic melanophlogite
MFI	Silicalite (silicalite-1)	$TMA_2OSi_{48}O_{96}\cdot H_2O$	USC-4[a]
MTF	MCM-35	$[Si_{44}O_{88}]$	MESOPOROUS
MTN	ZSM-39 (dodecasil-3C)	$[Si_{136}O_{272}]\cdot qR$, R = tetraethylammonium hydroxide	Holdstite, CF-3 (ZSM-39 contains 0.2% Al)
NON	Nonasil (nonasil-[$4^1 5^8$])	$[Si_{88}O_{176}]\cdot 4R$, R = 2-aminopentane	ZSM-51 (SiO_2/Al_2O_3 13 $\rightarrow \infty$)
RTE	RUB-3	$(C_8H_{15}N)_2$ $[Si_{24}O_{48}]$	
SFE	SSZ-48	$[Si_{14}O_{28}]$	
SFF	SSZ-44	$[Si_{16}O_{32}]$	
SGT	Sigma-2	$[Si_{64}O_{128}]\cdot 4R$, R = $C_{10}H_{15}$ NH_2	ZSM-58 (SiO_2/Al_2O_3 50 $\rightarrow$ 1000), B-SGT (B-analog)
STF	SSZ-35	$[Si_{16}O_{32}]$	ITQ-9
STT	SSZ-23	$(C_{13}H_{24}N^+)_{4.1}$ $F^-{}_{3.3}(OH)^-{}_{0.8}$ $[Si_{64}O_{128}]$	
VET	VPI-8	$[Si_{17}O_{34}]$	

[a]See also Tables 19 and 21.

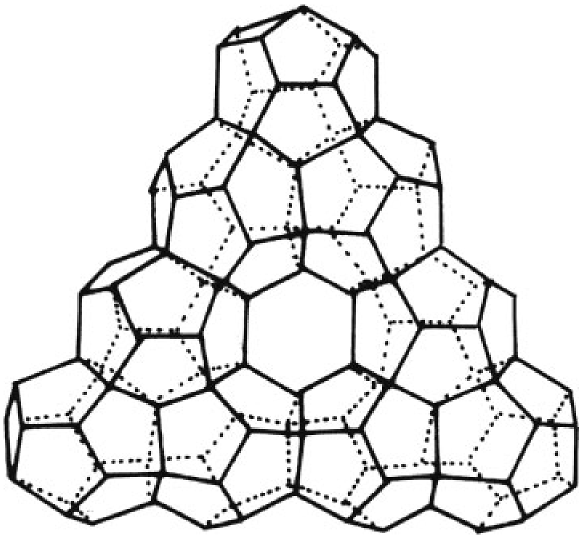

Figure 12 The clathrate-type structure of dodecasil-3C (MTN) (see Table 23)

with T atoms other than Si and Al are known in both natural and synthetic felspathoid analogs.

Table 24 lists felspathoid frameworks included in Baerlocher, Meier, and Olson.[11]

4 ZEOLITE GENESIS

4.1 Natural Species

4.1.1 Introduction

Most mineralogical displays in museums contain zeolite specimens because of their large attractive crystals and regular crystalline habit. These are of volcanic origin, which, until comparatively recent times, was regarded as their predominant mode of genesis. This view changed dramatically in the early 1960s when several of the major oil companies sent out survey teams into the western United States. These teams were hopeful of finding zeolites of sedimentary origin that might be of sufficient purity to be of commercial value. In fact, reports as early as 1891, from the first ever oceanographic survey (1873–1876) made by *HMS Challenger*, had described zeolites in 'red mud' recovered from the bed of the Pacific Ocean, and in 1914 Johannsen had reported fine-grained zeolites in beds of volcanic tuffs in Colorado, Wyoming, and Utah in the USA.

The survey teams subsequently identified many large-scale sedimentary zeolite deposits and today these are known to occur worldwide in vast quantities. The occurrences vary from those of high zeolite purity (>90%), such as those located in California, to tuffaceous materials of around 50–60% zeolite content (as in Italy). Commercial mining operations are known in USA, Japan, Cuba, Italy, Hungary, Bulgaria, Czechoslovakia, Indonesia, Korea, Russia, and South Africa. Workable deposits also exist in Mexico, Greece, and other Balkan states.

It has been reported by F.A. Mumpton[17] (1978) that more than 1000 occurrences of zeolite minerals in over 40 countries have been discovered since 1950. In addition to the hydrated aluminosilicate species, new minerals related to zeolites have been discovered, including the porous clathrasils such as Melonophlogite (a silica only framework). Species in which the aluminum or silicon has been replaced by other elements (such as phosphorus, iron, and beryllium) have also been discovered as exemplified by viscite, a silicoaluminophosphate related to analcime. At the present there are 38 different natural framework topologies, as shown in Table 25.

It is now recognized that natural zeolites arise from a wide variety of geological events and these will now be briefly discussed. Gottardi[18] and Tschernich[13] have reviewed these in more detail.

Table 24 Felspathoid frameworks listed in Baerlocher, Meier, and Olson[11]

IUPAC code	Name	Idealized unit cell formula	Isotypic materials (examples)
AFG	Afghanite	$(Na_2,Ca,K_2)_{12}$ $[Al_{24}Si_{24}O_{96}]$ ~ $(Na_2,Ca,K_2)_6(Cl_2,SO_4,CO_3)_6 \cdot 2H_2O$	–
CAN	Cancrinite	$Na_6[Al_6Si_6O_{24}] \cdot CaCO_3 \cdot 2H_2O$	Tiptopite[a], basic cancrinite, cancrinite hydrate, gallosilicate cancrinite, alumino-germanate, cancrinite
LIO	Liottite	$(Ca,Na_2,K_2)_9$ $[Al_{18}Si_{18}O_{72}]$ ~ $(Ca,Na_2,K_2)_9(SO_4,CO_3)_6Cl_3(OH)_3 \cdot 2H_2O$	
SOD	Sodalite	$Na_6[Al_6Si_6O_{24}] \cdot 2NaCl$	G, $AlPO_4$-20, Tugtupite[b], Danalite[b], Genthelvite[b], Helvite[c], Hydroxysodalite (HS), beryllophosphate sodalite, zincophosphate sodalite

[a]Natural beryllophosphate. [b]Natural alumino beryllosilicate. [c]Natural beryllosilicate.

Table 25 The 38 naturally occuring zeolite topologies

IZA Code	Mineral Name	Typical Composition
AFG	Afghanite	$(Na_2,Ca,K_2)_{12}[Al_{24}Si_{24}O_{96}]n(Na_2,Ca,K_2)_6(Cl_2,SO_4,CO_3)_6\ 2H_2O$
ANA	Analcime	$Na_{16}[Al_{16}Si_{32}O_{96}]\ 16H_2O$
BIK	Bikitaite	$Li_2[Al_2Si_4O_{12}]\ 2H_2O$

4.1.2 Formation of Zeolites in Nature

Zeolites arise naturally by broadly two routes, one predominantly at low temperatures (below 40 °C) and associated with sedimentary processes, with the second being at higher temperatures and linked to volcanic and associated thermal processes.

Low-Temperature Diagenic Routes to Zeolite Formation.

1. Land processes. Strictly, the majority of diagenic routes are also associated with vulcanism because they are a consequence of alteration processes to wind-blown glassy volcanic ashes or layers of pyroclastic tuffs.

   Alteration can be in a hydrologically open system when percolation of meteoric water through tuff layers creates a series of zeolitized zones. The deeper zones contain, successively, zeolites such as clinoptilolite, mordenite, chabazite, phillipsite, and analcime. (The name clinoptilolite will be used throughout the rest of this article to signify silica-rich, alkali metal forms of heulandite as this is the preferred designation in most literature references to this material.) Typical examples of this are in the John Day Formation (Oregon, USA) and at Oahu (Hawaii). At some locations (e.g. in Japan), similar zeolite zoning is linked to burial diagenesis where pressure and temperature effects have contributed to the formation of zeolites in underlying zones, with the lowest zones containing the most dense zeolite (e.g. analcime).

   Hydrologically closed systems also create zeolites when glassy volcanic ash falls into a saline lake under arid, or semiarid, conditions. Conditions of high pH and salt concentration arise from evaporation, producing ideal conditions for zeolites to form. Lake Tecopa, California, and Lake Magadi in Kenya contain zeolites formed in this way. The silica source in this route is not confined to glassy ash and can be clays, plagioclases, or even biogenic silica.

   Finally, some soils contain relatively high proportions of zeolites (≈15%). These result again from arid or semiarid environments where evaporation produces a high concentration of sodium carbonate, which can alter clay minerals to produce zeolites. Examples of this are the heulandite found in the Harwell soil series in Southern England and the analcime in the San Joaquin Valley (California).

2. Marine processes. Sea water reacts with ocean-bed sediments containing volcanic ash, or biogenic silica from Radiolarians, to form zeolites. This process is common in deep-sea sediments and phillipsite makes up 80% of the sediment in the Indian and Pacific Oceans. Clinoptilolite is abundant in Atlantic sediments and both phillipsite and clinoptilolite are found in manganese nodules on the ocean beds.

   Zeolites created in shallow sea sediments are also widespread. Other marine zeolites include analcime, merlinoite, chabazite, stilbite, and more rarely, erionite, mordenite, and laumontite. Figure 13 shows a schematic of the zoning patterns of autogenic zeolites and feldspars in tuffs of saline alkaline lakes, saline alkaline soils, deep-sea sediments, open hydrologic systems and burial diagenesis

Hydrothermal Routes at Higher Temperatures. Zeolites are commonly found in veins or cavities in volcanic rock as a result of the alteration of cooling lava flows coming into contact with surface water. Hot thermal salt solutions are created that circulate through the flow, dissolving out glass to form zeolites. Examples of this mode of occurrence occur in basalts and are common at many locations throughout the world. Zeolites arise in pegmatites from late-stage

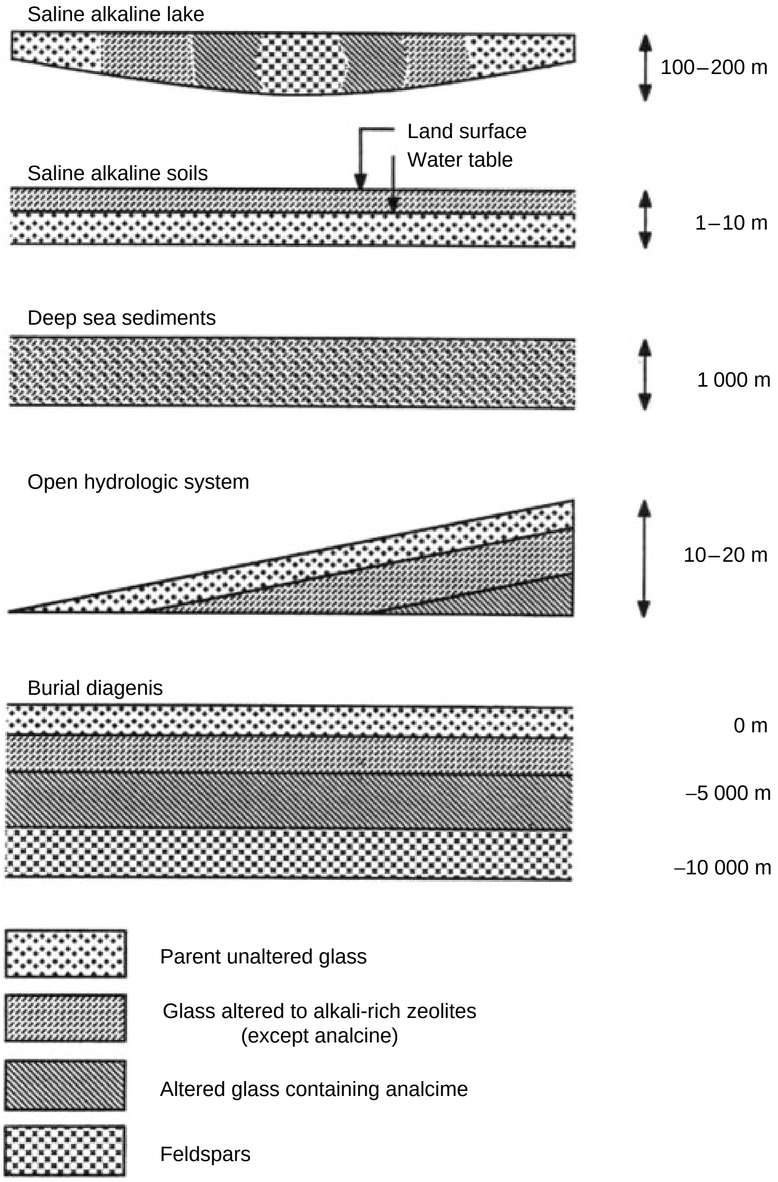

Figure 13 Schematic representation of zoning patterns of autogenic zeolites and feldspars. (Reprinted from Ref. 17. © 1978, with permission from Elsevier)

crystallization involving alteration of pegmatic minerals, and also ultimately when silica-rich hot water is expelled, which then alters surrounding rocks to zeolite phases. Examples of this can be seen in the Elba granodiorites (Italy) and in the borolanite found near Altnahara (Scotland).

Hydrothermal ore deposits can contain local zeolites (e.g. the Andreasburg sulfide deposit in Germany) arising from circulating hot fluids. Similarly, zeolites arise in hydrothermal veins and cavities in felspathic rocks like the Adamello granite in Italy.

Geothermal fluids are a common agency for zeolite formation and this has been well documented in Iceland, at Wairakei (New Zealand), and in Yellowstone Park (USA). Often, well-defined zones (illustrated for Iceland in Figure 14) can be identified with, say, clinoptilolite and mordenite at shallow (cooler) depths with deeper (hotter) environs containing heulandite, laumontite, and then wairakite and analcime. These assemblages feature a continuous transition to burial diagenesis.

Other Routes. When heat from a magma chamber, or an intrusive dyke, bakes surrounding rocks, zeolites can be part of the suite of minerals produced in zones via this process of contact metamorphism. This sequence has been identified in the Rhodope Mountains of Bulgaria. Bulgaria also has been cited as the location of proposed geoautoclaves, where enclosed conditions of high temperature and vapor pressure

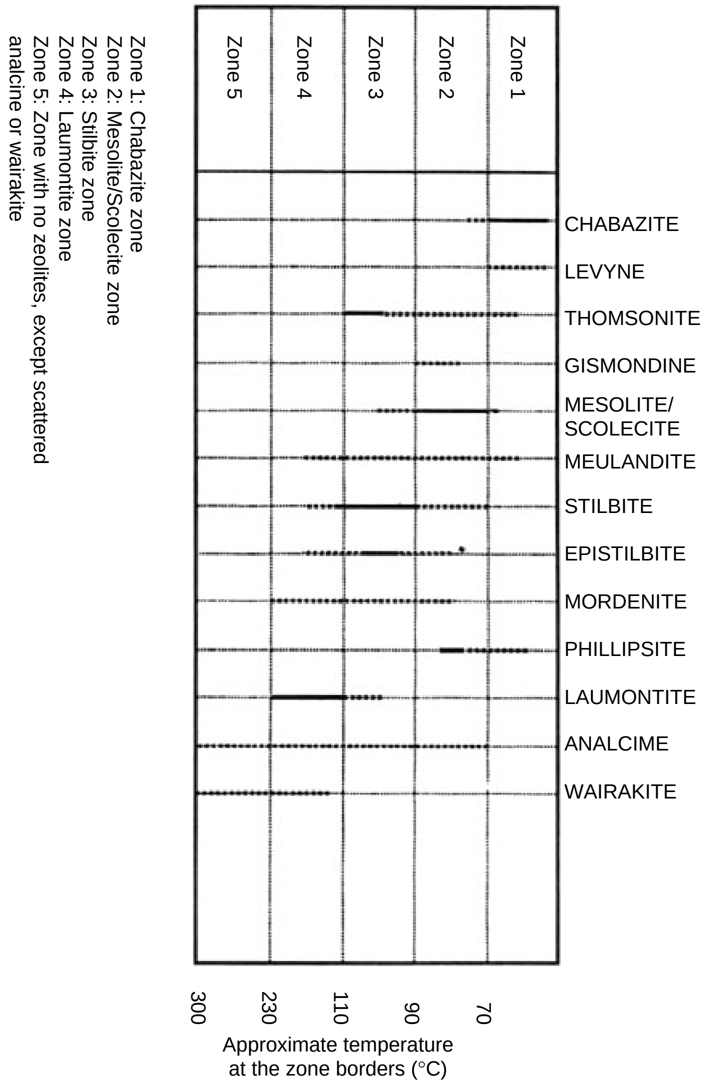

Figure 14 Temperature zoning of zeolites occurring in geothermal areas of Iceland. (Reprinted from Ref. 17. © 1978, with permission from Elsevier)

exist in an ignimbrite immediately after the deposition and zeolites are formed as a consequence.

In all the modes of formation discussed, zeolites are clearly secondary minerals, that is, created by alteration of existing rocks. Only analcime and natrolite have been suggested as primary minerals, that is, ones created by direct magmatic crystallization. This issue is still in doubt but may be true for analcimes from the Crowsnest Formation, Alberta, Canada, and the Colima lavas of Mexico.

4.2 Synthetic Species

4.2.1 Introduction

The progress of laboratory synthesis of zeolites first followed the high temperature and pressure experiments conceived by Barrer to mimic the then perceived geological genesis. With the wider realization of the sedimentary route to the formation of zeolites came studies at lower temperature, hydrothermal, conditions (e.g. by R. M. Barrer in the UK and R.M. Milton and D.W. Breck of the then Union Carbide laboratories in New York State). In 1948, Barrer[19] reported the first confirmed synthesis of a zeolite, in which he had produced a synthetic zeolite with no known natural counterpart, Zeolite P. In this first paper, Barrer documented the fundamental methodology that is still used today in exploratory zeolite synthesis:

- The effect of the reaction gel composition on crystallization product
- The effect of pH on crystallization
- The effect of temperature and time
- The nature of the starting materials

Early work concentrated on the use of inorganic cation-based formulations but both Barrer and Kerr (Mobil) pioneered the use of organic cations as ingredients for zeolite synthesis. This approach later produced the industrially significant high-silica zeolites, such as ZSM-5, and the explosion of zeotypes listed in the previous section. Some of these materials can even be best made at subambient temperatures. Another significant change of recent origin is that of the substitution of the F^- ion for OH^- as the so-called mineralizer in zeolite synthesis.

The facile way by which zeolitic frameworks can be formed is further confirmed by their production under acid and nonaqueous conditions, from the gas phase, and with organic additives as diverse as simple alcohols[20] and amines, polymers, crown ethers, and dye molecules.

4.2.2 Outline of Zeolite Synthesis

Figure 15 presents a general view of the elements of zeolite synthesis. There are a number of factors, which affect zeolite crystallization:

- Silica/alumina sources
- Hydroxide and/or fluoride concentration
- Cations (both organic and/or inorganic)

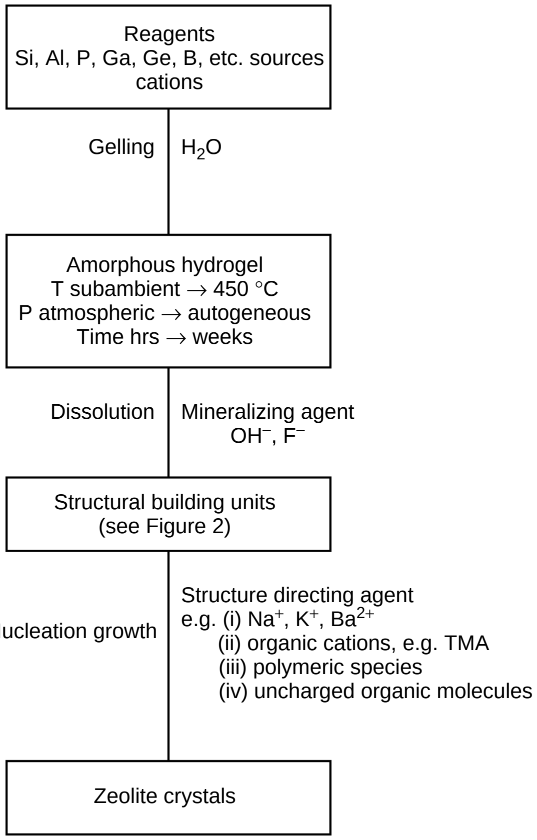

Figure 15 Schematic of the steps typical in zeolite (zeotype) syntheses

- Anions (other than OH^- or F^-)
- Water content of gel
- Time
- Reaction temperature (ambient ∼40 °C, low ∼110 °C, moderate 150 °C and high >200 °C)
- Reaction gel ageing
- Stirring
- Nature of mixture (gel, sol, or solution)
- Order of reagent mixing

Several zeolites crystallize with a fairly narrow range of Si/Al ratios, for example, Zeolites A, X and Y. However other materials like the pentasil (ZSM-5 or ZSM-11) can be produced over a wide range from ratios of 7.5 to infinity and sodalite from ratios of 1 to infinity. Attempts to change the Si/Al ratio of the final product by changing the ratio in the reaction gel often leads to cocrystallization of different zeolite types. The source of the silica and/or alumina can also affect the final product. A very wide range of silica sources have been used including natural materials such as kaolinite, volcanic glasses, rice husks, and nepheline, but most laboratory and industrial preparations use an 'active silica'. This is either a silicate, hydrated silicate, or a dispersion of high surface area silica (i.e. a silica sol.).

Aluminium sources have also been very varied and include aluminium wire, metal aluminates, aluminium alkoxide, and aluminium oxides and hydroxides. For zeotype synthesis, boehmite, a reactive aluminium oxide/hydroxide, is the preferred source with phosphoric acid providing the phosphorus content. In zeolite synthesis, if the hydroxide content is increased there is generally an increase in crystallization rate, which can be beneficial. However it must be remembered that if a number of different zeolites can crystallize from one reaction mixture with only time being the separating variable then the use of increased hydroxide can lead to cocrystallization and impure final products. The cation source can be one or more alkali metal cations, less frequently an alkaline earth cation, or an organic cation (e.g. Tetramethylammonium (TMA)). The main role of inorganic cations is to balance the negative charge created on the zeolite framework with the incorporation of Al^{3+}. As space is limited, if a monovalent cation replaces a divalent cation then we tend to see a reduction in the aluminium content of the zeolite framework. In addition to charge balancing, inorganic cations can also influence the framework structure formed, as seen in Table. 26.

It has been found that organic agents present in the gel can have a profound influence on syntheses, especially for zeotypes and high-silica species. Organic cations can interact with the reaction gel in a number of ways. They can

- act as templating of structure-directing agents
- act as gel modifiers, allowing higher silica/alumina ratios to be achieved for particular zeolite structures than could otherwise be obtained.
- interact with the gel affecting alkalinity

Table 26 Some zeolite syntheses in relation to inorganic cation content

Zeolite	Cations in Reaction Mixture	Preferred
Faujasite types	Na, Na + NMe_4, Na + Li, Na + Ba	Na
Zeolite A types	Na, Na + NMe_4, Na + K, Na + Ba, Na + Ba + NMe_4, Li + Cs + NMe_4	Na
Mordenites	Na, Ca, Sr	Na, alkaline earth ions
Zeolite L	K + Na, K, Ba, Ba + K, Na + Ba	K, Ba
XK-5 types	Ba, Na + Ba, K + Ba, Li + Cs + NMe_4	Ba
ZSM-2 type	Li + Cs + NMe_4	Li

- interact physically affecting the gelling process
- act as void filler, similar to water and indeed replacing water as the main void filler in nonaqueous systems.

Examples of their structure-directing influence can be seen in Table 27. This is a restricted list and Szostak has provided a comprehensive survey.[15]

The primary reagents are combined in an OH^- medium and the gel, so-formed, held at defined temperatures and pressures for the crystallization period (Figure 16). Gel ageing prior to this crystallization time can be needed. More recent syntheses have shown that high-silica zeolites prepared with a F^- mineralizer are almost fault-free, unlike those prepared in OH^- media.[22]

Comprehensive texts exist covering all aspects of zeolite synthesis methodology, and those by Barrer,[23] Jacobs and Martens,[24] and Szostak[25] are especially useful and for a recent historical survey the reader is directed to the review by Cundy and Cox.[26]

4.2.3 *Mechanism of Zeolite Synthesis*

Researchers have attempted to elucidate the mechanism for zeolite formation for over 50 years. Two directions of experimental work have been examined:

Identification of species during the crystallization process;

Monitoring of the crystallization kinetics.

There are a number of different factors that can operate in a crystallizing gel and these have been summarized by Sand:[27]

- Precipitation of the gel
- Gel dissolution
- Zeolite nucleation
- Crystal growth of the zeolite nuclei
- Dissolution/recrystallization of metastable phases (Oswald's Law of successive transformations)
- Formation of more stable phases
- Successive nucleation, crystal growth, and further nucleation
- Formation of the equilibrium phase.

A number of analytical techniques have been used to identify the species present in the reaction gels. These

include chemical analysis of the various phases, powder X-ray diffraction analysis to identify the crystal structure, IR spectroscopy to help identify substructural species early in the nucleation phase. Thermal analysis to yield information on the degree of hydration and thermal stability, and electron microscopy to give information on crystal shape and size. Other techniques are now also being used such as NMR, which with the advent of Magic angle spinning nuclear magnetic resonance (MAS-NMR) can now analyze both the reaction gel/solution and the final solid zeolite product. The combination of X-ray methods providing data on the long-range order and NMR providing short range order of the crystal-structure data ensures that these two methods are very powerful complementary techniques.

It is anticipated that the continued application of sophisticated NMR spectroscopy to solution and solid phases with the development of diffraction techniques to study the early stages of zeolite crystallization may ultimately clarify the problems of the mechanisms whereby zeolites are formed.

There have been two main schools of thought regarding synthetic zeolite formation: on the one hand it was considered that the crystallization process only occurred in the solution phase, with the gel just acting as a nutrient source. On the other it was proposed that there was direct hydrogel transformation. Different experimental work has supported both ideas.[28,29] Recently work on ZSM-5 has thoroughly investigated its formation,[30] and two processes have been proposed type ‘A’ and type ‘B’. Type ‘A’ occurs in highly alkaline media with a polymeric silica source depolymerizing to yield negatively charged monomers that condense aluminate species around organic cations; this is a solution process. In type ‘B’, we start with monomeric silica in the reaction gel and the fast nucleation rate leads to direct hydrogel transformation, with any dissolved silica species being incorporated into the solid product last. Subotic[31] has proposed a kinetic model to discriminate between the two mechanisms. Formation of zeolite material has been shown to occur from pH values of 2.6 (for fluoride based media) to 14 (for hydroxide based media), over a wide range of Si/Al ratios. In many instances the same zeolite product can be produced from clear solutions, gels, and solid phases, while some zeolites can only be formed with difficulty over narrow compositions, temperatures, and times. This leads one to believe that no single mechanism exists to explain zeolite formation.

The stages shown above in Figure 15 are meant to imply that zeolite crystallization proceeds via a cooperative equilibrium interaction between the gel and species in solution rather than that whereby the gel reorganizes itself without influence from the liquid phase. This emphasizes two important concepts: firstly, that water plays a critical role in the zeolite framework genesis and, secondly, the function fulfilled by OH^- (or F^-) in providing control of pH, and gel chemistry, to facilitate the production of precursors germane to the building of frameworks via SBUs (Figure 2).

The role of the cations and organic agents can now be imagined as that of organizing water structures around which the subunits of structure assemble themselves. Earlier concepts described this as a templating effect, which envisaged close correlation between the sizes of hydrated cations, or organic entities, and the production of specific sizes or shapes in the microporous frameworks obtained. Experience has shown that specific templating is rare, such as that of TPA-OH in directing ZSM-5 synthesis and the use of 1,4-diazabicyclo[2,2,2]octane (DABCO) polymers in preparing gmelinite and mordenite structures. In the latter case the size of the polymeric unit controls the zeolite produced. The modern view tends to that of a guest agency (organic or inorganic) encouraging the formation of a water clathrate as a former for zeolite or zeotype structures. This simplistic approach needs to be extended to include the role of the cation species in pH control and the ability of all agencies to stabilize the various zeolite-like frameworks in the gel crystallization stage.

4.3 Industrial-scale Synthesis of Zeolites

Industrial production of synthetic zeolites gives fine powders ($<10\,\mu m$) in their sodium exchanged form. These materials can be used ‘as synthesized’, such as for use as detergents, and Figure 16 is a schematic diagram of the production of zeolite LTA (Na form) for this purpose. The manufacture of the synthetic faujasite (FAU) zeolite Y for catalytic uses follows a similar route.

Today there are three processes used industrially: hydrogel, clay conversion, and ‘other’ such as volcanic glass conversion. The first commercial process for preparing zeolites on a large scale was based on the hydrogel procedures developed in the laboratory. Here reagents included sodium silicate, sodium aluminate, and sodium hydroxide solutions. The hydrogel process is further classified into processes that use homogeneous gels, processes based on heterogeneous gels (here one reagent is a solid while the rest are usually liquids) and finally the gel-preform process, in which the aluminosilicate is formed into a pellet prior to crystallization to a zeolite. This produces ‘binderless’ zeolite aggregate. If possible, reaction temperatures are kept just below 100 °C and the crystallization is monitored by in situ XRD and/or spectroscopic methods. The mother liquor left over after crystallization is recycled but the number of cycles is limited owing to the increased chances of cocrystallization of unwanted side products. To use zeolites as desiccants and specialized sorbents, the fine powders need to be modified, prior to use, by agglomeration (and often ion exchange). The crystallites are invariably bound together with clay minerals, such as sepiolite, attapulgite, or kaolinite (as beads or extrudates), that make up 10–20% of the final composite. The major clay-type material used in the manufacture of zeolites is kaolin. For Zeolites A and X, in the clay conversion process manufacture the kaolin is generally dehydroxylated to form metakaolin by calcining in air at 550 °C. For Zeolite Y,

the kaolin is heated to 925 °C to form a defect spinel. These intermediate products are subsequently treated with sodium hydroxide, which creates the required zeolite, so linking the existing crystallites into an aggregate suitable for industrial use. If the zeolite is to be used as an Fluidized bed cracking catalyst (FCC) catalyst, then it is spray dried to yield particles of around 60 µm. For other applications, a larger particle size maybe required and here oil-drop or extrusion techniques are used.[32]

4.4 Mesoporous Silicas

In 1992, Mobil workers[33] reported that they had prepared two mesoporous silicas, MCM-41 and MCM-48. These phases are related to the mineral silica species imogolite and marine diatoms. MCM-41 is a hexagonal structure while MCM-48 is a cubic one, and these two names actually represent families of materials. The pore sizes of these materials can be affected by which surfactant is used as the structure-directing agent during synthesis. To indicate pore sizes, the materials are usual labelled as MCM-41 (38), with the 38 representing the pore size of 38 Å. The MCM-41 family is composed of large diameter tubes, organised into an hexagonal array. It is interesting to note that the actual tube walls are amorphous silica (and/or alumino/silica) and can vary in thickness making them very different to zeolitic materials. These materials are normally prepared by cohydrolysis of tetraethylorthosilicate and a surfactant molecule like cetyltrimethylammonium hydroxide, an organo-aluminium or other organo-metal salt can also be introduced at this stage. Varying the amount and size of surfactant in the gel will change the nature of the pore structure in the crystallized product.

5 ZEOLITE PROPERTIES

5.1 Stability

Thermal and hydrothermal stability varies widely with both zeolite species and cation content, larger cations tending to make the zeolite structure less stable. It should be noted that, geologically speaking, zeolites are metastable species and interconversions in both natural and synthetic species are common, for example, synthetic gismondine (NaP) crystallizes as a cubic form but on standing at room temperature changes to the tetragonal form. Despite this variation, it should be commented that the zeolites used for catalytic purposes are very stable under the conditions of the industrial processes used. Similarly, zeolites used as sorbents and desiccants have very long useful lives. In a static application, the lifetime, to all intents and purposes, are indefinite and in a dynamic circumstance; where a regeneration process is carried out, the lifetime period should still be about five years.

Zeolites are generally very chemically stable and well able to withstand poisoning by nitrogen and sulfur compounds. Their acid stability, however, is dependent on their Si/Al ratio, with those zeolites having Si/Al ~ 1 being unable to withstand pH < 4 and those with Si/Al > 5 being usefully acid resistant in mineral acids. The loss of intracrystalline water may result in structure collapse to an amorphous phase, for example, BaA loses water between 100–180 °C then collapses above 180 °C. Alkaline stability is good up to around pH 11 and zeolite frameworks are stable to β-, α-, and γ-radiation, with only minor damage arising from prolonged exposure to neutron beams.

5.2 Zeolite Surfaces

It is important to realize that useful zeolites have large internal surfaces, that is, a reminder of the ‘sponge’ analogy, and it is *these* surfaces that control their observable surface properties. Normally, surface areas of inorganic materials are quantified by standard gas sorption techniques, for example, N_2 uptake analyzed by Brunauer, Emmett, and Teller (BET) isotherm plots, and zeolites have nitrogen surface areas in the approximate region 100–1000 $m^2\,g^{-1}$. These estimates should be considered with caution because:

1. the precalcination step, required before N_2 uptake, can cause structural change,
2. the probe molecule may not have access to all the channels and cavities in the zeolite structure and, most importantly,
3. the value for the surface area obtained depends upon the assumption of monolayer coverage as required by BET theory.

A better view of the extent of the void volume available within a zeolite comes from simple measurements of water content as listed in Table 28. Zeolites with high voidage (e.g. LTA, CHA, FAU) can be assumed to have only 1% of their useful surface on the exterior of the crystal.

One final generalization about zeolite surfaces is to mark the presence of OH groups on internal and external surfaces despite the presumption of the three-dimensional nature of zeolite architecture arising from full corner sharing of Si/Al tetrahedra. The concentration of these OH groups in synthetic species is usually low (about 2 $nmol\,g^{-1}$), but note the inclusion of incomplete framework structures in Baerlocher,

Table 28 Void fractions of some zeolites assessed from their water content[34]

Natural species	Void fraction	Synthetic species	Void fraction
Analcime	0.18	ZSM-5	0.10
Mordenite	0.28	L	0.32
Clinoptilolite	0.34	A	0.47
Gmelinite	0.44	Y	0.48
Chabazite	0.47	X	0.50

Meier, and Olson's compilation[11] (see Tables 16, 17, and 20). The OH groups are in highest concentration in synthetic high-silica zeolites and, in ZSM-5 for instance, have been identified as terminal and bridging entities. The presence of these OH groups has great significance in zeolite catalysis and modification, as will be briefly reviewed later.

5.3 Ion Exchange

5.3.1 Background

The identification of charge-balancing cations in crystallographically well-defined structures that change very little during cation-exchange processes has attracted the use of zeolites as models for the testing of the theory of ion exchange. This is true for both the equilibrium and kinetic aspects of the phenomenon.

Zeolites can have very high selectivities for specific cations but a full understanding of all the factors involved in delineating these selectivities has not yet been reached. Detailed consideration of this topic, and ion-exchange kinetics, are not appropriate here and has been reviewed elsewhere.[35]

Nevertheless, it is useful to point out that zeolites with higher framework Si content generally prefer larger, less hydrated cations (e.g. Cs with its smaller hydrodynamic radii), while those with Si/Al ~ 1 take up hydrated polyvalent cations selectively. The role of water is apparent here and also with the growing realization that water in immediate contact with an aluminous zeolite surface is hydrolyzed with two foreseeable consequences:

1. the production of OH^-, which can lead to precipitation of metal oxides/hydroxides on the surface (e.g. Zn on LTA[36])
2. immediate cation exchange, with H_3O^+ entering the zeolite phase.

The latter process seems to be very selective against alkali metal cations in the initial stages of exchange and is critically dependent on alkali metal solution phase concentration.[37] Sometimes ion-exchange processes can be described as ion sieving when a particular cation (hydrated or unhydrated) is too large to enter all, or part of, the zeolite internal structure.

5.3.2 Ion-exchange Applications

Detergency. The largest-scale industrial production of zeolites is that devoted to the production of the sodium form of zeolite A (LTA) for use in the detergent industry. This uses currently in excess of 0.5 million metric tonnes per annum worldwide. Zeolite A (NaA) is added to washing powders and other household detergents or cleansing powders as a water softener (described by the detergent industry as a builder). It has a high selectivity for Ca^{2+} (less so for Mg^{2+}) following the simple theory outlined in Section. 5.3.1.

The advantage of zeolite builders comes in their use as a replacement (sometimes only partial) for sodium tripolyphosphate, hence reducing the release of phosphates to the environment. An earlier Section. (4.3) showed the schematics of a production process for detergent grade A. It is interesting to record that the technology includes the 'design' of NaA crystals without sharp edges or corners to encourage their early removal from fabrics in the washing cycle. The release of NaA to the environment has been shown to be acceptable (Dyer[38] discusses the hazard assessment of this and other zeolites). The natural zeolites clinoptilolite and chabazite also are used as detergent builders.

Radioisotope Scavenging. Clinoptilolite has a relatively high Si/Al ratio and has the ability to scavenge cesium radioisotopes from aqueous nuclear wastes. An example of its industrial-scale use is in the development of the site ion-exchange effluent plant (SIXEP) by British Nuclear Fuels at their Sellafield site.[39] This uses a clinoptilolite, from Mud Hills, California, and meets the stringent performance requirements. The Cs selectivity of clinoptilolite has led to its possible use to reduce Cs radioisotope body burdens in sheep, and mordenite has been studied for the same use in reindeer. Mordenite also has been used to treat aqueous nuclear waste, as has an acid washed chabazite (AW500).

Clinoptilolite amendments to soil have greatly reduced cesium uptake by plants (e.g. on Bikini Atoll) and clinoptilolite from the Belli Plest deposit in Bulgaria was dropped by air to help control the Chernobyl accident. Finally, both zeolite A and a chabazite played key roles in the Three Mile Island clean-up program, again to scavenge Cs radioisotopes.

Waste-Water Treatment. There is a requirement in waste-water treatment to remove the ammonium ion and clinoptilolite has an appropriate selectivity for this ion. This zeolite is used in municipal sewage treatment in the USA and Hungary, and in Japan for cleaning up water from fish farms. The Italians have used chabazite-rich tuffs for a variety of water treatments.

These and other uses of natural zeolites have been reviewed.[40]

Agriculture and Horticulture.[40] There is a considerable literature relating how natural zeolites, and occasionally synthetic species, can be fed to various animal species (sheep, pigs, beef cattle, horses, and so on) with advantage. The benefits probably arise from a pH control effect in the animal gut (i.e. an ion-exchange phenomenon), and produce improved weight gains and disease reduction.

Other publications describe how the quality of soil can be improved by a 5–10% zeolite addition, followed by an increase in crop yield. This can be related to the zeolite acting as a controlled release fertilizer based upon an ammonium selectivity.

The zeolite most studied in both these areas is, again, clinoptilolite.

5.4 Sorption and Separations on Zeolites

5.4.1 Background

When the inherent water has been removed from a zeolite, the remaining voidage often has a useful capacity to take in guest molecules. Removal of water is described as activation and can be achieved by heating to about 350 °C. Industrially this is usually in combination with an applied vacuum or an inert gas purge. The guest molecules enter the internal regions of the zeolite host crystal through restricted dimensions prescribed by the oxygen atoms of the zeolite framework. Zeolite A (LTA; Figure 3) provides an example of this in that entry to the large cavity is via an S8R (crystallographic diameter 4.1 Å) and to the smaller sodalite unit through a S6R (crystallographic diameter 2.3 Å).

5.4.2 Uses of Zeolites as Molecular Sieves

Dimensions are comparable to molecular sizes and so zeolites can behave as molecular sieves. Indeed, this term is widely used to describe commercially available zeolites as typified by the well known Linde Molecular Sieves whose manufacture was pioneered by the Linde Corporation (latterly Union Carbide and now UOP) in New York State. These are sold as 3A, 4A, and 5A and are, respectively, the potassium, sodium, and calcium exchanged form of zeolite A, where the numbers represent their effective pore sizes in angstroms. Table 29 shows examples of the oxygen rings (windows) governing access into zeolites, with an indication of their sizes and the types of molecules able to pass through them. Note that the crystallographically measured ring sizes are not the same as their effective pore sizes. This arises principally from the thermal flexing of the aluminosilicate framework (±0.3 Å) and the inherent polarizability of organic molecules (i.e. their ability to be 'squeezed' through the window). Again zeolites have been popular models for sorbent theory, as described comprehensively in books by Barrer[41] and Ruthven.[42]

The separation of molecules on the basis of size has high potential at research and commercial levels. Many separations have been described[34,40] and the most well known are described in the following sections. It should also be pointed out that the technology exists whereby pore dimensions of zeolites can be modified by silanation or boranation. This can be done to achieve highly specific separations and/or gas encapsulation. Details are in the monograph written by Vansant.[43]

Desiccants. The ion-exchanged forms of zeolite A are well known as general laboratory and industrial drying agents in the form of extrudates or beads. The success of these materials as desiccants arises from several possible reasons, viz.:

1. their ability to exclude other molecules on the basis of size;
2. the strong affinity of water for the internal zeolite surfaces;
3. accommodation of water molecules in voids containing cations;
4. ease of regeneration;
5. long useful life (natural gas drying towers have a five-year lifetime).

Table 29 Zeolite molecular sieving, correlation between oxygen ring diameter and molecules admitted[a]

Crystallographic dimension (Å)	No. of oxygens	Zeolite	Examples of molecules admitted
2.3	6	A, X	H_2O, NH_3
3.8[b]	8	Chabazite	He, Ne, Ar, CO_2
4.1	8	A	C_2H_2, $MeNH_2$
4.2 and 5.4	10	Ferrierite	As through S8R
7.4	12	X, Y	Cyclohexane, benzene, CCl_4, B_5H_9

[a]Two zeotypes have larger rings, VPI (18SR, 12.1 Å) and cloverite (20 SR, 13 × 4.0 Å); see Table 2 for other details. [b]Distorted.

Gas Purification. There are many and varied examples using both natural and synthetic zeolites. The natural zeolites are likely to be chabazite, clinoptilolite, or mordenite. The latter two are useful for dealing with acid gas streams.

A common purification is the use of 4A to remove CO_2 from natural gas as well as sweetening the gas, that is, removing H_2S and nitrogen products. Zeolite 13X (synthetic faujasite containing only Na cations) also is used to remove undesirable larger molecules that contain S and N atoms from natural gas. In 2002, Engelhard introduced 'Molecular Gate' for the separation of both CO_2 and N_2 from natural gas using pressure swing applications (PSA). This material is one of the recently discovered titanium silicates (ETS-4). Already two plants in the USA are using this technology to removed unwanted gases from natural gas. Clearly, natural gas treatment plants link purification with drying and regeneration processes.

Gas Separation. The best-known process is the use of 5A to separate *n*- from *i*-alkanes. This is the basis of several commercial processes (e.g. Union Carbide Isosiv, and Exxon Ensorb). Their purpose is to provide feedstocks for the detergent and chemical industry. Currently there is considerable interest in using zeolites in PSA, especially in the enrichment of gases from the air. Oxygen production to hospitals is an example of this, both in the provision of oxygen lines and in portable units for individual use or in field hospitals as in the Gulf War. Again, zeolite A is widely used but clinoptilolite, mordenite, and chabazite are important PSA substrates, for example, the separation of methane and

nitrogen mixtures using clinoptilolite.[44] Earlier separations of this sort on zeolites were cryogenic in nature.

Finally, synthetic zeolites have long been used in gas–solid chromatography for permanent gas and hydrocarbon analyses. Some modern GC capillaries are coated with zeolites.

Liquid Phase Separation. UOP have pioneered several small-scale processes to fractionate mixtures of liquids. The Parex process was introduced in 1971 and by 2001 71 units were running commercially. The MX-Sorbex process was introduced in 1998 and so far 5 units have been commercialized. Very recently,[45] in 2001, UOP introduced a new Sorbex process, MaxEne, to increase the ethlene yield from Naphtha Crackers. Examples of these are listed in Table 30.

Only the Molex process depends upon molecular size, whereas the others function on the basis of a liquid chromatographic fractionation. Quite recent work[46] shows that high-silica zeolites (synthetic) make good high performance liquid chromatographic (HPLC) media. The mechanisms whereby these chromatographic separations are achieved await elucidation but it seems that both internal and external surface attractions are important, as are zeolite structures and the nature of the cation present. Silica analogs of zeolite structures are hydrophobic and so offer the possibility to separate organic molecules from aqueous environments.

Carriers. The encapsulation of molecules into zeolite voids has been used to handle unpleasant chemicals, such as vulcanizing agents, and to carry CO_2 in carbonated drinks. Other prospective uses are to store and transport methane and hydrogen.

5.5 Zeolites as Catalysts

5.5.1 Background

Some 40 years ago it was discovered that synthetic faujasites could act as effective isomerization and cracking catalysts. The latter advance, based on the pioneering work of Plank and Rosinski, produced the current situation whereby essentially all the world's motor vehicle and aviation fuels are derived from crude oil by use of a zeolite catalyst. Zeolites have replaced the earlier silica/alumina and silica/clay catalysts in this area with a resulting annual savings estimated in billions of dollars.

The success has prompted an explosion of patents, journal publications, and conference proceedings, devoted to the study of the theory, mechanism, and utility of zeolites in promoting virtually any organic (and some inorganic) reaction. Rabo[47] has compiled a comprehensive treatise on the earlier work on zeolite catalysts, and Jacobs[48] has discussed their carboniogenic activity. Amongst the copious literature the reviews by Dwyer[49] on the evaluation of zeolites and the tailoring of the acid–base properties of zeolites, and by John *et al*.[50] describing the range of reactions catalyzed and their industrial relevance are recommended. This section provides an overview of current commercial use of zeolite catalysts with some indications of their mode of action and ease of modification (see also Section. 6).

5.5.2 Commercial Processes Using Zeolite Catalysts

Table 31 provides some details of zeolite catalyst usage. The best known is that of zeolite Y as a fluidized bed catalyst (FCC) to crack crude oil for gasoline production. The zeolite is used as a promoter and comprises up to 50% of a small composite with a clay or silica binder. As such it can remain stable throughout many cycles in the catalyst riser (at 480–520 °C), where it meets the downstream of crude oil followed by a steam blast to release the cracking products, and then a stream of air in a regenerator (590–730 °C). This regeneration process cleans the catalyst of coke and the residual oil products.

Clearly the success of the catalyst depends upon its ability to withstand these extreme conditions and this is one of the advantages of the ultrastable synthetic faujasite (USY) and ZSM-5 materials and is always a consideration in the other applications listed in Table 31. It is, however, only one of the known advantages acquired when zeolites are considered as industrial catalysts. Other benefits come from the zeolite

Table 30 UOP sorbex processes for liquid phase separations[38,42]

Process	Separation	Zeolite	Desorbent
Parex	*p*-Xylene from its isomers	KBaY,	Toluene
		SrBaX	*p*-Diethylbenzene
		KbaX	*p*-Diethylbenzene
Ebex	Ethylbenzene from its isomers	NaY, SrKX	Toluene
Molex	n-Alkanes/i-alkanes, naphthalenes, aromatics	5A	Light paraffins
Olex	Linear long-chain alkanes from other alkanes	CaX SrX	
Sorbutene	1-Butene from C_4 alkanes and alkenes	–	–
MaxEne	Separates C_5-C_{11} from full range Naphtha	–	–
MX-Sorbex	High purity meta-xylene from its isomers	–	–
Sarex	Fructose from sucrose and other sugars (corn syrup feed)	CaY	Aqueous systems

properties of high internal surface area and variable pore sizes, which lead to both reactant and product selectivity via molecular sieving. This is described as shape-selectivity and is controlled by configurational diffusion, the phrase used to describe a diffusion-controlled regime in which useful catalytic reactions are encouraged by a matching of size, shape, and orientation of the product and reactant molecules to the molecular architecture of the zeolite.[51] An additional bonus comes from the ease with which zeolites can be modified; examples of this have been mentioned earlier, for example, ion exchange and the introduction of heteroatoms (other than Si and Al) into the zeolite framework. This latter change can be achieved by a postsynthetic modification and an interesting prospect is that of inducing ion exchange and catalytic properties into the uncharged frameworks of aluminophosphates ($AlPO_4$) by inserting Si atoms into existing $AlPO_4$ structures. A further modification is that of salt occlusion, that is, the introduction of a salt ion pair into a zeolite cavity to attain improved thermal stability and to reduce the deleterious effects of trace elements such as Ni, Fe, and V, which occur in some crude oils.

5.5.3 Source of Zeolite Catalytic Activity

Broadly, zeolites have high catalytic activity because their structures can produce a higher proportion of the so-called active sites per unit surface area than competing catalysts. These sites are the traditional Brønsted sites that arise from the creation of hydroxyl groups and this can be via one of the three routes illustrated below.

1. Ammonium ion exchange (e.g. as in production of USY)

$$NaZ(s) + NH_4{}^+(aq) \longrightarrow NH_4Z(s) + Na^+(aq) \quad (1)$$

$$NH_4Z(s) \xrightarrow{\text{calcine}} HZ(s) + NH_3(g) \quad (2)$$

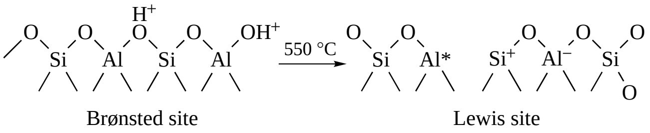
2. Polyvalent ion exchange (e.g. as in rare earth exchanged Y, ReY)

$$NaZ(s) + M(H_2O)^{n+}(aq) \longrightarrow M(H_2O)^{n+}Z(s) + nNa^+(aq) \quad (3)$$

$$M(H_2O)^{n+}Z(s) \xrightarrow{\text{calcine}} MOH^{(n-1)}(s) + HZ(s) \quad (4)$$

3. Direct ion exchange with mineral acid (e.g. with ZSM-5).

In all three cases the protonated zeolite, HZ, is created containing Brønsted sites, which, when heated above 550 °C, lose water to produce Lewis sites, viz.



(5)

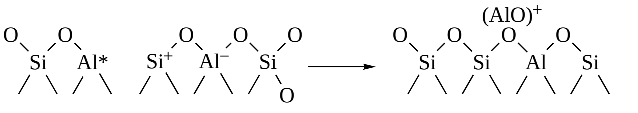
The Lewis sites are unstable, especially in the presence of water vapor, and an annealing process stabilizes the structure. This is thought to create true Lewis sites by ejecting Al

Table 31 Commercial processes using zeolitic materials

Process	Catalyst	Advantages in using zeolite-based catalysts
Catalytic cracking	Ultrastable Y[a] (USY), ZSM-5, rare earth exchanged Y (REY)	Selectivity and high rates
Hydrocracking	Y, erionite, mordenite	High conversion rates
Selectoreforming	Ni erionite, Ni erionite/clinoptilolite	Increase in octane number via LPG[b] production
Hydroisomerism	Pt mordenite	Converts low octane, pentane, and hexane to higher yields
Dewaxing	ZSM-5, ZSM-23, mordenite	Improved pour points for heavy oils and fuels (e.g. diesel)
Benzene alkylation	ZSM-5, REY	Ethylbenzene and styrene production with low by-product yield
Xylene isomerization	ZSM-5	Increase in *p*-xylene yield with low by-product yield
Methanol to gasoline conversion	ZSM-5	High gasoline yield with high-octane rating
NO_x reduction	H mordenite	Effluent clean-up in nitric acid and nuclear reprocessing plants
Aromatic hydroxylation/alkene epoxidation	Titanium silicate	Styrene to phenylacetaldehyde, ethylene to ethylene oxide and other reactions
LPG to aromatics	Ga ZSM-5	Benzene, toluene, xylene production
Methanol amination by ammonia → dimethylamine	Mordenite	–

[a](USY), Ultrastable synthetic zeolite Y treated to reduce aluminum content and improve thermal and hydrothermal stability (see Section. 6.1).
[b]LPG = liquid propane gas.

oxide/hydroxide species from the framework, viz.



(6)

This extra framework Al can be identified by MAS-NMR but is in at least two forms. It is these Al species that are thought to be the 'super acid' sites inducing the high zeolite surface reactivity.

Another aspect to zeolite catalytic activity, briefly mentioned earlier, is the use of ion-exchange modification to introduce elements of known catalytic propensity into the zeolite promoter. Examples of this are in Table 31. There has been a considerable amount of work devoted to the investigation of the dispersion of metal particles (e.g. Ni and Fe) on zeolite substrates to enhance specific organic reactions.

5.5.4 The Future

The SAPO materials seem likely to provide novel catalysts, especially as the emphasis of zeolite usage turns to chemical intermediates and fine chemical production,[50,52] and processes using the B analog of ZSM-5 (boralite) and SAPO-34 have been commercialized.

Another advance seems likely through the use of zeolites as enzyme mimics.[53] This centers on the reactions of organometallics with zeolite internal surfaces. The best-known example is the production of a $[Co^{II}(bipyridyl)(terpyridyl)]^{2+}$ complex inside the main cavity of zeolite Y that can selectively and reversibly absorb oxygen from the air. The catalytic potential of a Co phthalocyanine moiety prepared in the Y cavity has also been demonstrated.

6 COMMERCIALLY USEFUL ZEOLITES AND THEIR WELL KNOWN USES

6.1 Synthetic Zeolite A (LTA)

6.1.1 Cation Positions

The element of structure of this zeolite, illustrated in Figure 3, represents a convenient segment of the full unit cell of the LTA structure and should be described as its pseudounit cell (puc). Each puc has 12 sodium cations and, in the hydrated zeolite, eight occupy sites close to each of the S6R openings to the component β-cages (Site I), three are in sites near the centers of some of the S8R openings to the larger α-cage (Site II), and the final sodium is in the center of the puc (Site III). Each pseudo unit cell contains 27 water molecules, and 20 of these form a pentagonal dodecahedron that lines the α-cage (Figure 17). This water structure is found in some water clathrates and in LTA surrounds the central Na ion with its attendant three water molecules. It is cation–water assemblages like this that are likely to be the precursors for the formation of zeolite frameworks in synthesis gels (see Section. 4.2.3).

The remaining four water molecules are in the β-cages. If the zeolite is dehydrated, the cations adopt other convenient crystallographic sites of minimum potential energy. This, of course, is common to all zeolites and ultimate sitings depend upon the Si/Al ratios and geometries of their frameworks, as well as the nature of the cation (size, charge, bonding properties); more details are available.[12]

In the commercial sorbents Linde Molecular Sieves 3A, 4A, and 5A, the resiting of cations on calcination tailors their effective pore sizes. In dehydrated 3A and 4A, the K and Na ions, respectively, occupy positions obstructing entry to the α-cage (i.e. across the 8SR), and the cation size difference (K > Na) changes the pore size from 3 to 4 Å. When the divalent Ca^{2+} is introduced into the large cage, there are, of course, fewer cations present ($2Na^{+} \rightleftharpoons Ca^{2+}$) and, upon dehydration, these occupy Site I positions, away from the S8R windows, so opening up the effective pore size to 5 Å (note that 3A and 5A are both partially exchanged forms of NaA).

One final comment is that an increase in the Si/Al ratio in the LTA synthesis encourages the production of the crystallites with chamfered edges and corners, appropriate to their detergent use.

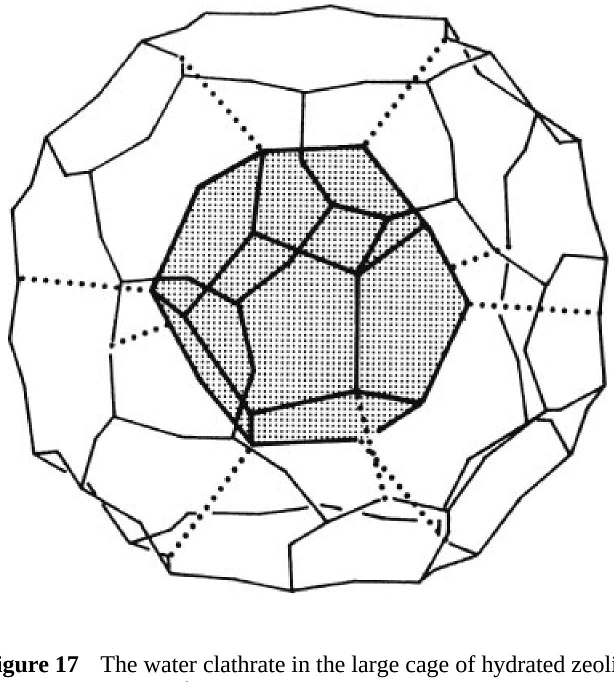


Figure 17 The water clathrate in the large cage of hydrated zeolite A. It is composed of 20 H_2O molecules arranged in a pentagonal dodecahedron

6.1.2 Commercial Uses of Zeolite A

Detergency. NaA is now a common builder, added to solid and liquid detergents and to other household and laundry products.

Desiccant. The forms 3A, 4A, and 5A are in general laboratory use as drying agents for air and nitrogen lines and organic liquids. Both 3A and 4A are used worldwide to dynamically dry liquid halocarbons and hydrocarbons, especially Liquid petroleum gas LPG and natural gas. 3A is preferred for drying refinery streams containing alkenes (cracked gas), ethene, proplene, and methanol, and 4A is used to dry other alcohols, benzene, and natural gas. Other industrial gas streams commonly dried by zeolite beads are oxygen, nitrogen, air, and CO_2 in nuclear power installations. Examples of static drying using 3A and 4A in sealed systems are widespread, for example, in sealed double-glazing units, refrigeration circuits (domestic and industrial), vehicle braking, air conditioning systems, and in heavy duty transformers filled with hydrocarbon liquids.

Gas Separation. 5A efficiently separates n- from i-alkanes. This is used to provide feedstocks to the detergent and chemical industries and is the basis of several commercial processes, that is, those developed by Union Carbide (Isosiv), British Petroleum BP, Shell, Texaco (TSF), Exxon (Ensorb), and VEB Leuna Werke, Bitterfeld, Germany (VEB) Germany. The latter process is called the Parex process. This should not be confused with the process of the same name developed by UOP to separate *liquid* C_8 hydrocarbons (see Table 30 and elsewhere), and note that UOP use 5A to separate n-alkanes from i-alkanes, naphthalenes, and aromatics in the liquid phase via their Molex process. Ambient pressure swing processes, using 5A, have been developed to produce both O_2 and N_2 from air. The nitrogen generators are used in steel-making while oxygen generators principally are used for medical purposes (for hospital oxygen lines, individual patients units, and in field hospitals), in welding, in water-oxygenating kits, and as emergency oxygen supplies in aircraft.

Gas Purification. The best-known purification process using 4A is that of natural gas; this involves two benefits, namely, peak-shaving whereby the calorific value of the gas is adjusted by CO_2 (and water) removal, and sweetening by H_2S removal. The latter purification also is used in LPG treatment. Another example is the trapping of hydrocarbons in gas and vacuum circuits.

Other Uses. The form 5A is a traditional gas–solid chromatographic substrate for permanent gas analysis, the butane isomers, and cryogenic analyses of hydrogen isotopes. It is an additive to powders to improve flow properties and to dry them (including food products) and an encapsulant for CO_2 in carbonated drinks.

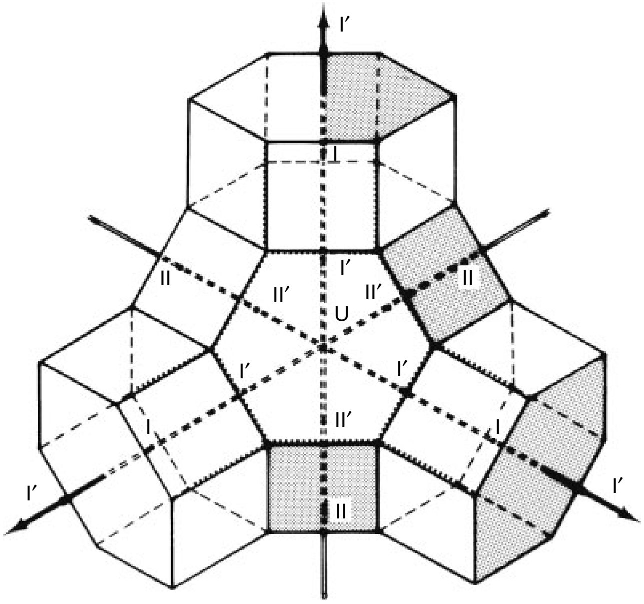

Figure 18 The cation sites of the faujasite (FAU) framework (see text for explanation of symbols). (Reprinted with permission from J.V. Smith, 'Molecular Sieve Zeolites-1', eds. E.M. Flanigen and L.B. Sand, *ACS Symp. Ser.*, 1971, **101**, 173. © 1971 American Chemical Society)

6.2 Synthetic Faujasites: Zeolites X and Y (FAU)

6.2.1 Cation Positions

Zeolites X and Y are isostructural with the natural mineral faujasite. They differ in the amount of Al occupying tetrahedral sites such that the Si/Al ratio of X is in the range 1–1.4 (but commonly 1) whilst that of Y can vary, according to synthesis conditions, up to Si/Al = 3. The cation sites available are shown in Figure 18, which represents an element of the full structure illustrated in Figure 11. The as-synthesized cation form is sodium. The cation sites can be listed as Site I in a D6R (hexagonal prism), Site I′ close to the D6R in the sodalite (β) cages, Site II′ in the sodalite cage near the S6R entrances to the large α-cage, II is in the large cages near the S6R entrances. U is at the centre of the sodalite cages and other sites (e.g. IV and V) are in less well-defined sites in the large cage.

The sites adopted by cations in these structures are complex and will not be considered here but, broadly, an increase in Si/Al (decrease in framework charge) depopulates Sites I and I′ in the hydrated zeolites in favor of positions in the large cage. Removal of water causes an increase in population of the Sites I and I′ regardless of framework charge. Details of individual cation sitings in ion-exchanged forms of X and Y are available,[12] with water molecule positions, where known.

Early references describe the Na and Ca exchanged forms of X as 13X and 10X, respectively. The figures were meant to imply their respective pore sizes, over assessments of the restriction offered by the 12SR window entry to the main cavity, which has the crystallographic dimension of 7.4 Å.

The Y framework is more stable than the X, to both thermal and hydrothermal treatments, so methods were developed to dealuminate the FAU framework to attain the improved stabilities needed for catalytic use, especially under the extreme fluidized bed conditions applied in cracking crude oil (see Section. 5.5.2). The end product is known as ultrastable Y (USY) and can be made by one of four ways: (a) acid treatment, (b) high-temperature steam treatment of the ammonium exchanged form of Y (NH_4Y), perhaps followed by acid treatment, (c) reaction of NH_4Y with an aqueous solution of $(NH_4)_2SiF_6$, and (d) reaction of NaY with gaseous $SiCl_4$.

The last treatment is the best method of retaining the excellent crystallinity and high hydrophobicity (Si/Al $>$ 25) synonymous with a good fluidized cracking catalyst (FCC).

6.2.2 *Commercial Uses of Zeolites X and Y*

Detergency. Zeolite X has been included in some builder compositions because it has a better selectivity for Mg^{2+} than does zeolite A.

Gas Separation and Purification. Zeolite X has been used for many hydrocarbon separations and to trap molecules containing S and N from industrial gases. It is used to dry and purify SF_6 in high-voltage switching apparatus and in oxygen-generating emergency supplies in fighter aircraft. It finds use in double-glazing units to scavenge residual solvents from the sealants used and to pick up iodine species from gaseous effluents from nuclear installations (as AgX).

Liquid Separation. Zeolites X and Y, in various ion-exchanged forms, are the substrates used in the processes developed by UOP for separating liquid mixtures (see Table 30). The hydrophobic nature of Y and its modified forms are used to scavenge organic molecules from aqueous environments (e.g. halohydrocarbons).

Catalysis. Various forms of zeolite Y find uses in industrial catalytic processes. These have already been listed in Table 31 and account for the second highest annual tonnage use of synthetic zeolites (approx 60 000 metric tonnes). This continues to increase as zeolite catalysts aid the shift to unleaded gasoline and to the use of cheaper feedstocks.

6.3 Synthetic Zeolite ZSM-5 (MFI)

6.3.1 *Structure and Cation Positions*

The structure of this high-silica species can be regarded as an arrangement of layers created by linking the 5–1 SBU (see Figure 2), as shown in Figure 19. The full three-dimensional framework can be regarded as a series of channels circumscribed by the 10SR seen in Figure 19. The spatial arrangement of these channels is shown in Figure 20 together with those in ZSM-11 (MEL). The cation positions have not yet been defined except that they behave as if they are occupying two distinct crystallographic sites.

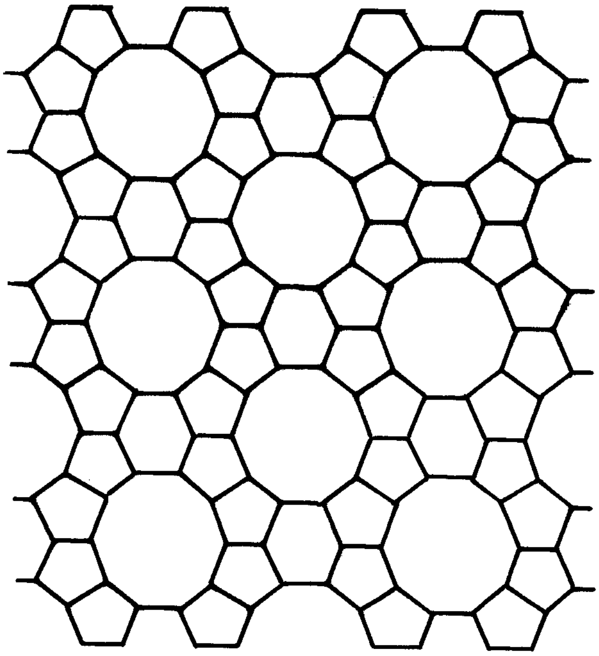

Figure 19 Sheet projection for ZSM-5 (MFI) structure showing 12SR and 8SR openings

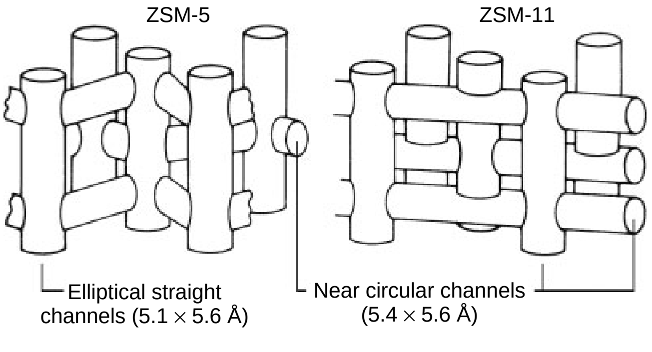

Figure 20 Channel arrangements in ZSM-5 (MFI) and ZSM-11 (MEL). (Ref. 40. Reproduced by permission of Society of the Chemical Industry)

6.3.2 Commercial Uses of ZSM-5

The hydrophobic character of the high-silica MFI framework lends itself to the separation of polar and nonpolar molecules. There are many patents claiming this use but no details of commercial processes have appeared in the literature. ZSM-5 is used as a cocatalyst in FCC compositions. This makes use of its shape-selective properties to improve the octane quality of gasoline. It has been used with both Rare-earth exchanged synthetic zeolite Y (REY) and USY. It is also an effective catalyst for the conversion of methanol to higher carbon-number molecules. This is the basis of the methanol to alkenes (MTO) and methanol to gasoline (MTG) processes developed by Mobil. This discovery offers the prospect of conversion of the methane component of natural gas to synthesis gas (carbon monoxide and hydrogen) and then to methanol and gasoline. Dimethyl ether, an important industrial intermediate, can also be obtained from these reactions.

Gallium loaded ZSM-5 is the catalyst used in the Cyclar process (UOP/BP) whereby LPG (largely propane and butane) is converted to high-octane fuels and benzene/toluene/xylene (BTX) as petrochemicals.

ZSM-5 catalyzes alkene oligomerization, using its shape-selective ability, and both Mobil and Shell (methanol to gasoline and distillates (MOGD) and polygasoline and kerosene (SPGK)) use a ZSM-5 catalyst for this purpose. The production of ethylbenzene from benzene and ethylene is catalyzed by ZSM-5 in the Mobil/Badger process. Mobil also have improved the production of benzene and xylene from toluene disproportionation using ZSM-5.

Finally, ZSM-5 is used to dewax gas oils and lubricating base oils, and to produce low-temperature diesel fuel. In all these cases, the processes catalytically remove long-chain waxy n-alkanes, which otherwise crystallize out at low temperatures and cause increased viscosity.

6.4 Mordenite (MOR)

6.4.1 Structure and Cation Positions

The structure of mordenite contains two channels (Figure 4), one restricted by a 12SR and one by an 8SR. Eight cations and water sites have been located, with the most occupied being at the centers of the 8SRs, adjacent to the 5SR units, which link the 12SR channels, and near to S4Rs, which link adjacent five-membered rings around the smaller channel.

Divalent ions (Ca^{2+}, Ba^{2+}) occupy sites in the larger channels so that, on dehydration, molecular sieving is controlled by the dimensions of the smaller channel (2.6×5.7 Å); when monovalent ions are introduced they lie in the small channels so that molecular sieving is controlled by the 12SR (dimension 6.5×7.0 Å).

Early sorption experiments were carried out on natural mordenites, which behaved as small-port sorbents (i.e. had effective pore sizes of <4 Å). Synthetic mordenite behaves as a large-port material, displaying an effective pore size closer to that expected from a 12SR opening. Later work was able to synthesize both large (LP) and small (SP) ported mordenites, and discussion has taken place over a number of years concerning the reasons for the differences between these materials. The apparent channel restrictions in SP mordenite can be ascribed to the presence of extraneous material or to the presence of stacking faults. The fact that the channels in mordenite can be enlarged by acid leaching favours the channel blockage concept. Synthetic LP mordenites have been marketed by the Norton company as Zeolon 100, 200, and 900, and the product that is available as AW300 (AW = acid washed) is also likely to be a mordenite.

6.4.2 Commercial Uses of Mordenite

The relatively high Si/Al content of mordenite confers on it a certain acid stability that enables it to be used to remove water from acid gas streams such as reformer recycle hydrogen, reformer catalyst regeneration gas, HCl, Cl_2, and chlorinated hydrocarbons. It can also be used to treat off-gas for removal of oxides of sulfur and nitrogen (SO_x and NO_x). Mordenite's ion-exchange selectivity for Cs has been used to remove Cs radioisotopes from nuclear waste (Zeolon 900) and it is used in Japan on a plant scale to separate gases from the air.

LP mordenite doped with platinum is the catalyst used in the Shell Hysomer process for alkane hydroisomerization; this can be linked to the Isosiv separation process whereby i-/n-alkanes are separated on LTA zeolite. This link is the basis of the joint Shell/UOP Total Isomerization Process (TIP). Similar catalysts have been employed to hydrocrack (i.e. dewax) diesel fuels. There have also been reports of commercial use of mordenite to catalyze methanol amination with ammonia, to produce dimethylamine.

6.5 Chabazite (CHA)

6.5.1 Cation Positions

11 cation/water sites have been identified in the chabazite framework. In the hydrated mineral, the bulk of the cations are present as fully hydrated species in the large cavity with less than one Ca^{2+} puc being in the D6R sites. On dehydration, the cation population of the D6R site increases (≈ 2) and the other ions adopt two other sites, one just outside the six-ring entrance to the D6R and the other near four rings that connect adjacent D6Rs (see framework in Figure 6). The natural mineral (with erionite) has been marketed by Norton as Zeolon 500 and by other suppliers as AW500. Synthetic chabazite can be obtained from custom synthesis.

6.5.2 Commercial Uses of Chabazite

Chabazite has found a wide variety of occasional uses as a cheap desiccant and molecular sieve and as a selective ion exchanger in the nuclear industry. Current interest is in its use as a selective sorbent (in Li form for instance) in PSA and related applications.

6.6 Clinoptilolite (HEU)

6.6.1 Structure and Cation Positions

The clinoptilolite (heulandite) structure is that of an assemblage of 4-4-1 SBUs to create a layer-like array. The layers are joined to create two channels, both composed of 10SRs parallel to the crystallographic *c*-axis, and one 8SR limited channel parallel to the *a*-axis.

In clinoptilolites rich in alkali metal ions (Na/K), and in the hydrated state, two cations have specific sites in the main channels, one is in the smaller channels, and the final one lies near the center at an S8R.

6.6.2 Commercial Uses of Clinoptilolite

Like chabazite, clinoptilolite has been used as a cheap desiccant and molecular sieve. As noted earlier, its selectivity for Cs has led to its use in aqueous nuclear waste treatment and its ability to remove NH_4^+ from water has been used on a plant scale (see Section. 5.3.2). An extensive literature describes its use in horticulture and agriculture as an amendment to soils and composts. Similarly, the benefits of its addition to animal feeds is well documented. These uses have been reviewed[40] and three conference reports also can be recommended for further details.[54–56]

Glossary

Chimeric (hybrid) protein: a nonnatural protein created when homologous regions of two homologous proteins are exchanged
Gag knuckle: this fold is composed of short (∼20 amino acids) Cys_2His_2 zinc fingers from retroviral gag proteins
Motif: a primary, secondary, or tertiary structural domain
Palindromic DNA-binding site: a DNA sequence that contains one inverted repeat composed of two half-sites of nucleotides
Zinc Knuckle: this fold group is composed of two short β-strands connected by a turn followed by a short helix or a loop, and it also may possess a unique turn with the consensus sequence CPXCG at either termini

Abbreviations

DBD = DNA-binding domain; HRE = Hormone response element; LIM = **L**in11, **I**sl1, and **M**ec3 (abbreviations for the genes in which the LIM domain was originally discovered); MT = Metallothionein; NCP = Nucleocapsid protein; PHD = Plant homeodomain; RING = Really interesting new gene; TFIIIA = Transcription factor IIIA; activator of transcription by RNA polymerase III; zf = Zinc finger.

1 INTRODUCTION

The local folding of small globular domains within gene regulatory proteins is required for sequence-specific DNA binding, an event that underlies gene expression in all kingdoms of life.[1] The formation of zinc-ligand coordination bonds provides the major driving force for the folding of these mini domains that lack an appreciable hydrophobic core.[2] Over the last two decades, an explosion in our knowledge of the diverse roles that the essential trace element zinc plays in DNA metabolism, chromatin remodeling, transcriptional regulation, nucleic acid packaging, and ribosome biogenesis has taken place.[3–7] Fueling this explosion is the structural characterization of zinc-containing nucleic acid-binding proteins at atomic resolution by X-ray crystallography and NMR spectroscopy. This chapter will survey these structural findings and develop unifying concepts that have emerged from these studies.

Zinc is found in all human body tissues with 30 to 40% found in the nucleus, 50% in the cytosol, and the remainder found in organelles, vesicles, and the cell membrane.[8] Zinc plays critical roles in the reduction of common infections, helps in the prevention of stunting growth, and supports neurobehavioral development among other attributes (*see* ***Nutritional Aspects of Metals & Trace Elements***).[9] Zinc is an essential trace element in all organisms, and the unique combination of structural and thermodynamic properties of zinc make it ideally suited for a diverse array of biological roles. These properties include its ready availability, Lewis acidity, high concentration of charge (atomic radius of 0.65 Å), lack of redox reactivity and stable oxidation state (2+). Zn(II) is a d^{10} transition metal ion that forms metal complexes of high thermodynamic stability that are often characterized by facile ligand exchange (*see* ***Zinc: Inorganic & Coordination Chemistry***).[5]

Zinc binds nearly exclusively to three types of amino acid side chains in proteins. These are cysteines, histidines, and carboxylates (Asp and Glu) with thiolate sulfurs and imidazole nitrogens by far the most common donor atoms. Zinc sites in proteins adopt a variety of coordination structures that differ in the number of ligands bound (coordination number), the type of ligands, metal-ligand bond lengths, dihedral ligand-metal-ligand bond angles, and, in some cases, second-shell interactions.[5] The Metalloprotein Database and Browser hosted by The Scripps Research Institute (http://metallo.scripps.edu/) reveals that among the approximately 3100 structurally characterized zinc coordination sites deposited in the Protein Data Bank (http://www.rcsb.org/pdb), the most prominent coordination number is four (1726), and the most common liganding pattern tetrathiolate (484), with tetrahedral or distorted tetrahedral coordination geometries by far the most prevalent for zinc sites classified as of April 2004.[10]

Zinc complexes in proteins perform structural, catalytic, and regulatory functions. Structural zinc sites typically adopt tetrahedral or distorted tetrahedral coordination geometries formed by four protein-derived ligands with no bound water molecules. Cysteines and histidines are by far the preferred ligands in such sites (e.g. zinc fingers; see Section 2).[11]

Catalytic and regulatory Zn(II) sites utilize the same amino acid ligands as structural sites, but include a greater percentage of carboxylate ligands derived from aspartate and glutamate, as well as solvent molecules (H_2O), which are almost always found in catalytic sites in enzymes (e.g. carbonic anhydrase) (*see* ***Zinc Enzymes***).[11] Cocatalytic sites, defined as catalytic metal sites that coordinate two metal ions via a bridging ligand(s) (e.g. phosphotriesterase), are formed by ligand sets similar to those found in catalytic sites, except that cysteine residues that typify structural zinc cluster sites (e.g. metallothioneins) (*see* ***Metallothioneins***) are never found as a bridging ligand in metalloenzymes (*see* ***Zinc Enzymes***).[11]

Structural zinc ions stabilize protein tertiary structure, protein–protein, and protein-nucleic acid interfaces. The zinc coordination bonds induce thermal stability and conformational rigidity to these important domains of proteins much like disulfide bonds do in oxidizing environments. In the absence of zinc, these protein domains are unfolded, exist in a predominantly random coil conformation, and are presumably subjected to rapid degradation and clearance by the cell. The most striking and seminal illustration of how 'structural zinc' stabilizes tertiary structure formation in DNA-binding proteins is in zinc finger (zf) proteins.[12] Classical C_2H_2 (Cys_2His_2) zinc finger domains, which mainly include DNA-binding proteins (they also mediate protein-RNA, protein–protein, and protein-lipid interactions) are small (~30 amino acid residues) domains that fold around one or more zinc ions, and are nearly exclusively found in eukaryotic organisms (see Sections 2.1–2.2).[13,14]

The number and complexity of structurally characterized zinc fingers has increased dramatically over the last ten years. In order to understand the seemingly endless collection of known zinc finger structures, a classification scheme was devised that combines all structures of functionally diverse proteins into well-defined fold groups, each of which is discussed here (see Section 2). Recent findings reveal that canonical C_2H_2 zinc finger domains in transcriptional regulatory proteins in eukaryotes are not exclusively involved in structural stability but have also been implicated in regulating the concentration of bioavailable zinc in cells (see Section 3.5).[15,16]

Suboptimal or toxic (above normal physiological levels) concentrations of intracellular zinc have adverse affects on many aspects of cellular metabolism (*see* ***Metalloregulation***; ***Metal Ion Toxicity***). Zinc is now known to function at the level of transcription by binding directly to regulatory proteins, that is, metal sensor proteins that repress, derepress, or activate the transcription of genes that encode metal transporters (importers/exporters) and/or metal chelators. This helps cells maintain homeostasis (*see* ***Metallochaperones & Metal Ion Homeostasis***), or an optimal steady-state concentration of zinc within the cytosol and other intracellular organelles.[3,17] Zinc sensor proteins and the determinants of their coordination chelates (number of ligands, types of ligands, and coordination geometry) are discussed as important factors that determine metal selectivity (zinc vs. other metal ions) in these families of related sensor proteins (see Section 3).

2 ZINC-CONTAINING TRANSCRIPTION FACTORS: STRUCTURAL ZINC SITES

2.1 The Zinc Finger Story

Structurally distinct 'zinc finger' (zf) protein classes have emerged over the past two decades where the sole common feature is that each employs multiple cysteine and/or histidine residues to coordinate tetrahedrally a Zn(II) ion in order to stabilize their folds.[13,18] Zinc finger proteins thus defined comprise ≈3% of the proteins encoded by the human genome making them, by far, the most common proteins in eukaryotes.[13] A recent analysis of the mouse transcriptome identifies 46 distinct conserved zf protein families that constitute 7.5% of the nonredundant full-length protein sequences in that organism.[19] The structure and properties of DNA-binding zinc fingers, particularly the classical C_2H_2 zfs (see Section 2.2 below) have been studied extensively and recently reviewed as to their structural properties and efforts at design, and myriad of biological functions including transcriptional activation and repression, DNA replication and repair, translation, programmed cell death, and metalloregulation.[14,18,20–23]

Zinc finger proteins have recently been classified into eight distinct structural groups distinguished by their tertiary structural folds around the zinc coordination complex and the spatial arrangement of secondary structural elements that contribute zinc ligands.[12] Table 1 lists representative members from each of six of these eight structural classes that are known to interact directly with nucleic acids. These are discussed in turn.

The first zinc finger domain discovered contained C_2H_2 motifs found originally in nine tandemly arranged ~30 amino acid residue repeats in the *Xenopus laevis* RNA polymerase III basal transcription factor IIIA (TFIIIIA).[24] In 1985, it was proposed that in the presence of zinc each of these repeats defined an independently folded mini-domain where the zinc ion was ligated tetrahedrally by two S^- (Cys) and two N^{ε} (His) side chains and the amino acids between the second and third ligands comprised the 'fingertip', which would interact directly with DNA.[24,25] All essential features of this seminal hypothesis have since proved to be correct. Figure 1 shows the crystal structure of the six N-terminal zinc fingers of *X. laevis* TFIIIA bound with 31 bp of the 5S rRNA gene promoter.[26] It is now known that much of the evolutionary and functional diversity of these canonical or classical C_2H_2 zinc finger proteins (Section 2.2) derives from the appendage of additional conserved domains to the zf domain to create modular proteins with new functionalities. An excellent illustration of this is the ubiquitous family

Table 1 Classes of zinc fingers

Classification	Fold/Motif[a]	Example(s)	Binding domain(s)	Structure
C_2H_2	$\beta\beta\alpha/C_2H_2$	TFIIIA, MTF-1, WT1, & Zap1	DNA, RNA, protein	Treble clef	$\beta\beta\beta\beta\alpha/C_4$[b] 	GATA-1 Nuclear Hormone Receptors (ER and GR) RING, FYVE, PHD	DNA DNA DNA, protein	
	(x2)	LIM domains	Protein	Zinc Ribbon	$\beta\beta\beta\beta\beta/C_4$ 	TFIIB, DNA Primase Ribosomal protein L31e	DNA, RNA	Gag knuckle	Truncated $\beta\beta\alpha/C_2HC$	Retroviral nucleocapsid	RNA	TAZ2-like domain	$\alpha\alpha/C_4$	DNA Polymerase III γ subunit TAZ1/TAZ2 domains of Protein CBP/p300	DNA	
Zn2/Cys6-like	$\alpha\alpha/C_6$[b] 	Gal4, Hap1, PUT3	DNA	
[a]*Yellow* spheres represent the positions of cysteine residues, and *blue* spheres represent positions of histidine residues; spheres showing gradients from *yellow to blue* represent positions predominantly occupied by cysteines and less frequently by histidines; spheres showing gradients from *blue to yellow* represent positions predominantly occupied by histidines and less frequently by cysteines. *Red* arrows represent β-strands, *blue* cylinders represent α-helices. [b]Interleaved zinc-binding sites in treble-clef motifs and Zn2/Cys6-like motifs are represented by *green* lines connecting the ligands that coordinate one zinc ion and *black* lines connecting ligands that ligate another zinc ion.

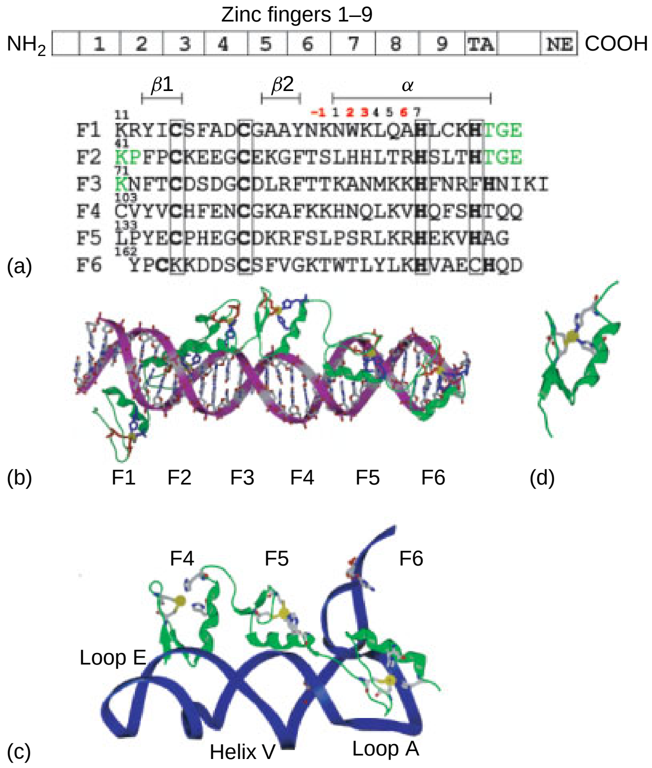

Figure 1 (a) A schematic domain structural representation of transcription factor IIIA (TFIIIA) from *Xenopus laevis* (top) and the primary structure of the N-terminal zinc fingers 1 to 6 with secondary structure assignments shown above the sequence (bottom). The metal-binding amino acids are in bold. Residues that possess a burgundy-shaded number above them (−1, +2, +3, and +6, corresponding to amino acid positions relative to the start of the α-helix in each $\beta\beta\alpha$ structure) are commonly involved in making base-specific contacts with the major groove of the DNA; (b) The X-ray crystallographic structure of the six N-terminal zinc fingers of *X. laevis* TFIIIA bound to 31 bp of the 5 S rRNA gene promoter determined at a resolution of 3.1 Å, with the zinc finger region represented in green and the DNA represented in blue;[26] (c) The X-ray crystallographic structure of the complex of fingers 4 to 6 of TFIIIA from *X. laevis* and 61 bases of 5S RNA derived from the central region of the complete nine-finger TFIIIA-5S RNA complex. Finger 4 interacts with the 'loop E' motif, finger 5 with helix V, and finger 6 with loop A.[29] (d) A ribbon diagram of a single $\beta\beta\alpha$ C_2H_2 zinc finger from the structure of TFIIIA. Conserved Cys and His residues donate coordination bonds to the zinc ion (*yellow* sphere)[26]

of Krüppel-associated box (KRAB) zf proteins, where the appended KRAB domain functions as a potent repressor of transcription.[27,28]

2.2 Classical Zinc Fingers (C_2H_2)

Each zinc finger forms a compact $\beta\beta\alpha$ structure (see Figure 1(d)) and basic and hydrophobic amino acids on the surface of the α-helix make specific contacts with the edges of the nucleotide bases in the major groove of the DNA.[13,14,18] Two or more C_2H_2 zinc fingers arranged in tandem are required to bind DNA with sequence specificity, and each finger is often separated by a conserved TGEKP linker.[13,21] One of the known functions of the linker is to cap the C-terminus of the preceding helix, but only in the DNA-bound conformation; in the unbound protein the linker is unstructured.[21,30] The classical C_2H_2 motif actually conforms to the consensus sequence (F/Y)-X-C-X_{2-5}-C-X_3-(F/Y)-X_5-ψ-X_2-H-X_{3-5}-H, where X represents any amino acid and ψ is a hydrophobic residue.[18] A single zinc ion is tetrahedrally coordinated between two cysteines at one end of a two-stranded antiparallel β-sheet (a β-hairpin) and two histidines found along one face of a C-terminal α-helix (Figure 1d).[18,21] The conserved hydrophobic amino acids form a mini-hydrophobic core stacked on top of the zinc coordination complex. Despite this, these fingers are essentially fully unfolded when zinc is not bound.[31] Therefore, the stability of these domains is largely derived from zinc coordination, which induces the proper architecture of this $\beta\beta\alpha$ structure. The structural paradigm of zf protein recognition of DNA is exemplified by the mouse transcription factor Zif268.[18] The primary site-specific contacts are made in the DNA major groove by the α-helix through primary hydrogen-bond interactions from helical positions −1, +3, and +6 to one strand of the DNA (Figure 1b). This is considered the sequence-specific recognition motif of DNA binding by C_2H_2 zinc fingers.[18,21]

Although the C_2H_2 zfs interact nearly exclusively with duplex DNA, there are also examples of classical C_2H_2 zfs that have been shown to interact with complex RNA and DNA/RNA heteroduplexes and mediate protein–protein interactions. One example is the Wilms' tumor suppressor protein (WT1), which binds both DNA and RNA and is thought to be involved in mRNA maturation.[21,32–34] The Ikaros family of transcription factors, which are essential regulators of lymphocyte development in vertebrates, is another example of zf proteins that interact with both proteins as well as nucleic acids.[13,21,35] Ikaros proteins contain two clusters of zf domains, with the N-terminal four-finger domain involved in DNA binding while the C-terminal two-finger cluster facilitates protein dimerization.[35] Interestingly, it has recently been shown that phosphorylation of Thr residues within the **T**GEKP linkers in Ikaros is inhibitory to DNA binding, potentially providing another level of regulatory control.[36]

The crystal structure of the central three-finger domain of TFIIIA (zf4-zf5-zf6), shown previously to provide major determinants for 5S RNA recognition,[37] complexed with 61 nucleotides of a truncated 5S RNA molecule, provides an opportunity to compare the determinants of specific DNA versus RNA recognition (Figure 1c).[29] In *Xenopus* oocytes, TFIIIA and 5S RNA form a 7S ribonucleoprotein (RNP) particle that constitutes the major storage form of this important ribosomal RNA. As stated above, the mode of DNA binding is quite well elucidated for TFIIIA, but the molecular basis of recognition of RNA was not. RNA molecules possess a more irregular structure than duplex DNA with a major groove that is too deep and narrow in a standard A-form

helical conformation to be accessible to the 'reading' helices of zf proteins. The structure reveals that zf4 and zf5 interact with the major groove sides of the 'loop E' motif and helix V, respectively, with zf6 bound to the conserved 'loop A' motif. Strikingly, zinc fingers 4 and 5 bind to 5S RNA in a manner that is superficially similar to that of the DNA complex; this is accomplished by a significantly widened major groove in these regions of the RNA. In contrast, the spatial relationship of fingers 5 and 6 in the RNA complex differs radically from that of DNA complex (compare Figure 1b vs. Figure 1c).[29]

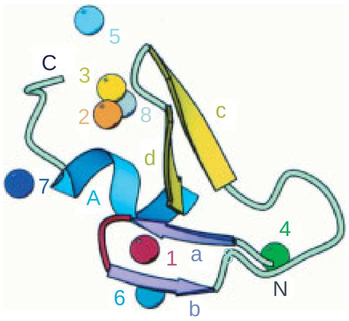

Figure 2 Ribbon representation of treble-clef zinc finger.[38] The protein ribbon corresponds to the structure of the Cys2 activator-binding domain of protein kinase C.[40] Examination of the structures of 42 treble-clef zinc fingers reveals that structural zinc ions are bound at up to eight distinct sites (displayed as spheres numbered from 1 to 8) in this fold. β-Strands and α-helices are labeled in lower and upper case letters, respectively. The short β-strands in the zinc knuckle region are shown in purple (a and b) with the zinc knuckle turn shaded red. The other two β-strands are colored yellow (c and d) and the α-helix is colored light blue (A). Metal ion 1 occupies the canonical treble-clef zinc site, with ions roughly corresponding to 2, 3, 5 and 8 corresponding to the second 'interleaved' zinc site found in RING, PHD, and FYFE zinc fingers (see Table 1). Metal ions labeled 4, 6, and 7 represent three additional sites accommodated by this basic fold. (Ref. 38. Reproduced by permssion of Oxford University Press)

2.3 Zinc Fingers: Treble-clef Fingers

The treble-clef motif is the underlying structural architecture of many zinc finger protein families and constitutes the second-most abundant zinc finger domain encoded by mammalian genomes, behind classical C_2H_2 zfs. Treble-clef zinc fingers include FYVE fingers, typically found in proteins that mediate the recruitment of proteins involved in membrane trafficking and cell signaling to phosphatidylinositol 3-phosphate-containing membranes; LIM domains, often found in adaptor proteins that interact with other proteins that enable integrin signaling within focal adhesions; nuclear hormone receptor-like fingers, hormone-dependent transcriptional activators; PHD fingers, found predominantly in chromatin regulatory proteins; and RING fingers, most commonly associated with ubiquitin protein ligases (Table 1). They are characterized by undetectable amino acid sequence similarity and an enormous diversity of biological function. Besides DNA binding, treble-clef finger proteins therefore mediate protein-RNA and protein–protein interactions in biological processes related to apoptosis, cell-cycle control and protein ubiquination, leading to protein degradation and turnover. In most instances, treble-clef motifs are derived from large, multidomain proteins.[12]

Coordination of each of the zinc ions in treble-clef fingers is either via four thiolate ligands (C_4), a Cys_3His, or a $Cys_2HisCys$ structure. The designation of this large family of proteins derives from the fact that when the Cα trace of a member of this class is viewed in a specific orientation, the polypeptide chain resembles a treble-clef sign found in musical notation.[38] The treble-clef finger consists of a β-hairpin (see Figure 2; containing the '*a*' and '*b*' β-strands) that incorporates a zinc-ligating C-X_2-C sequence, designated as a zinc knuckle, followed by a loop, and a second orthogonally positioned β-hairpin (containing the '*c*' and '*d*' β-strands) connected to a C-terminal α-helix (see Table 1 and Figure 2). A zinc knuckle is defined here as composed of two short β-strands connected by a turn followed by a short helix or a loop (it may also possess a unique turn with the consensus sequence CPXCG at either termini).[12] The last two zinc ligands (from a C-X_n-C sequence) are derived from the C-terminus of β-strand '*d*' and a residue from the immediately adjacent α-helix.[12,13,38,39] This domain is stabilized by the bound zinc ion and does not have a pronounced hydrophobic core.[38] Although the basic treble-clef motif contains a single zinc-binding site (corresponding to ion 1, Figure 2), many treble-clef finger proteins incorporate a second interleaved zinc-binding site within the same basic fold (e.g. RING, PHD, and FYVE finger domains, corresponding approximately to metal ions labeled 2, 3, and 8 in Figure 2), while others (e.g. LIM proteins) contain tandemly duplicated treble-clef motifs (Table 1). Strikingly, at least four additional distinct Zn(II) chelates can be accommodated by the basic treble-clef architecture (ions labeled 4, 5, 6, and 7 in Figure 2), suggesting considerable evolutionary pressure to maintain the functionality of this biologically important fold.

2.3.1 *Nuclear Hormone Receptor-like Zinc Fingers*

This subfamily within the treble-clef class is comprised of a large group of evolutionarily related nucleic acid proteins involved in transcriptional or translational regulation. This class of proteins include ribosomal proteins (S14, L24e, and L31e), the zinc-binding domain of the DNA repair factor XPA, and recombination endonucleases (VIII and I-TevI).[12,38] Nuclear receptor-like fingers also include GATA-1 and nuclear hormone receptor DNA-binding domain proteins.

Mammalian nuclear receptors regulate the expression or activation of target genes from promoter sequences that contain either a palindromic or a direct repeat DNA sequence collectively termed hormone response elements (HREs). Most nuclear receptors bind to HREs as either a homodimer

of steroid hormone receptors or heterodimers containing one retinoid X receptor (RXR) subunit and one nonsteroid hormone receptor subunit. Two highly conserved 66-residue core zf DNA-binding domains (DBDs) from two hormone receptor protomers make up the dimer.[41] Specific ligands recognized by these receptor proteins bind to C-terminal regulatory domains, known as the ligand binding-domain (LBD), which is connected to the N-terminal DBD by a hinge region.[41] Known ligands include sex steroids, for example, estrogen, progesterone, and testosterone, glucocorticoids, mineralocorticoids, bile acids, vitamin D_3, thyroid hormone, and retinoids.

The DBD of nuclear hormone receptors bind two zinc ions tetrahedrally through two conserved C_4 motifs. The N-terminal zinc site is a prototypical treble-clef zinc finger (Table 1) where the α-helix is positioned in the major groove of the conserved DNA half-sites.[13,38,41] The C-terminal zinc domain stabilizes the DBD dimerization interface. The structures of the glucocorticoid receptor (GR) and estrogen receptor (ER) homodimers on their cognate HREs were the first ones reported.[42,43] In the last ten years, structural studies together with biochemical and genetic data, on the DBD of RXR in combination with various nuclear receptor partners, as well as studies on the monomeric complex of NGFI-B, have helped decipher the mechanisms by which members of this class of zf proteins selectively bind their cognate DNA targets.[41,44–46]

2.4 Zinc Fingers: Zinc-Ribbon Motif

The zinc-ribbon motif consists of two structurally similar CPXCG zinc knuckles derived from two β-hairpins within a three-stranded antiparallel β-sheet (Table 1). The tertiary structural organization of the zinc-binding site bears a striking resemblance to the Fe-binding site in the electron transfer protein rubredoxin.[47] Some zinc-ribbon proteins are characterized by a long C-terminal β-hairpin that donates the third and fourth zinc ligands, thus the name ribbon.[12] The zinc ribbon is unique among zf proteins in that it completely lacks α-helical structure with all zinc-ligating residues derived from β-hairpins. The zinc ligation pattern is predominantly C_4 but some members contain C_3H coordination complexes.

The zinc-ribbon motif is found in a diverse group of proteins with limited sequence similarity and includes proteins involved in transcription (e.g. Transcription Factor IIB[47]) and translation (the G domain of the γ-subunit of the heterotrimeric translation initiation factor eIF2).[12,47,48] In TFIIB, the surface of the ribbon domain is conserved and is essential for the recruitment of RNA polymerase II (Pol II) to the Preinitiation Complex (PIC).[49] The GCM (glia cell missing) transcriptional regulators make novel use of a ribbon-like zinc complex to bind to DNA in an unusual way. Here, one edge of a five-stranded antiparallel β-sheet inserts into the major groove. The middle three antiparallel β-strands of the five-stranded sheet coordinate a zinc ion via two His and two Cys residues; this complex tethers the DNA-binding domain to a secondary distal domain that also contains a C_2H_2-like mixed α/β zinc finger.

In addition, three enzymes involved in DNA replication, including DNA primases, prokaryotic DNA topoisomerase I and some hexameric DNA helicases, are also classic zinc-ribbon proteins.[50] In bacteriophage DNA primases, mutations of the zinc-binding residues abrogate the synthesis of RNA primers for lagging strand DNA synthesis.[50] Strikingly, each subunit of the mini-chromosomal maintenance (MCM) protein, a heterohexameric helicase that initiates DNA replication in *S. cerevisiae*, contains an independently folded zinc-ribbon domain that appears to stabilize the dodecameric structure (a dimer of hexamers) of this replication complex.[51]

2.5 Zinc Fingers: Gag Knuckle

Gag knuckles are comprised of a zinc knuckle (two short β-strands connected by a turn) connected to a short α- or 3_{10}-helix or a loop (Table 1). They conform to the consensus sequence, Cys-X_2-Cys-X_{4-16}-His-X_4-Cys, originally discovered in retroviral *gag*-gene encoded nucleocapsid proteins.[52] Gag knuckles are more broadly defined by Grishin as $\approx$15 to 25 amino acid C_2H_2 or C_2HC modules that incorporate the zinc knuckle found in retroviral gag proteins.[12] The β-hairpin and α-helix of the gag knuckle is truncated relative to classical C_2H_2 zinc fingers, thus their designation as knuckles rather than fingers.[53] There are three subfamilies of gag knuckle proteins that carry out different biological functions and include retroviral nucleocapsid proteins, eukaryotic transcription factor IIA (TFIIA), and the reovirus outer capsid protein $\sigma 3$.

2.5.1 Retroviral Gag Knuckle

Retroviral nucleocapsid proteins (NCPs) are the major RNA-packaging proteins of animal retroviruses. The retroviral gag knuckle appends an N-terminal β-hairpin to one turn of a 3_{10}- or α-helix.[12] These are small ($\sim$50–100 residues), extremely basic proteins that usually possess two conserved knuckle domains that conform to a Cys-X_2-Cys-X_{4-16}-His-X_4-Cys sequence separated by a short (5–15 amino acid) linker. Retroviral gag knuckles recognize and bind to specific sequences of single-stranded RNA (ssRNA), which then allows for RNA encapsidation and replication of these viruses;[12,52] they also possess potent nucleic acid chaperone activity.[54] Gag knuckles are mostly found as two conserved domains separated by a linker of variable length and amino acid composition. This differs from the classical C_2H_2 zf proteins, where tandem zf domains are typically repeated more than twice and contain high sequence conservation in a large subset of linkers.[12]

2.6 Zinc Fingers: TAZ2 Domain-like

Transcriptional adaptor zinc finger (TAZ) domain proteins function by mediating protein–protein interactions between the basal transcriptional machinery and transcription factors.[12,21] This domain folds around three tetrahedrally coordinated zinc ions and adopts a novel triangular domain structure. The TAZ2 family is one of three distinct subfamilies of TAZ domain proteins, and includes the TAZ1 and TAZ2 domains found in the ubiquitous transcriptional coactivator CREB-binding transcriptional adaptor protein (CBP).[55] The ligation pattern contains three duplicated HCCC-type zinc-binding sites, and each site is formed by the C-terminus of an α-helix, a short loop, and the N-terminus of the next α-helix (Table 1).[12] Other members of this class include the zinc-binding domain of DNA polymerase III γ subunit from *E. coli* and the N-terminal domain of HIV-1 integrase. The ligation pattern for these proteins are C_4 and C_2H_2, respectively.[12]

It was recently shown that the catalytic core of *E. coli* RecQ, a helicase-primase and homolog of the human BLM protein, contains a single TAZ2 domain-like helix-loop-helix zinc-binding motif.[56] Mutations of the human gene, BLM, cause Bloom's syndrome in humans. The ligation pattern in RecQ is C_4, and the zinc-binding motif is formed by the N-terminus of an α-helix, a short loop, and the N-terminus of the next α-helix. The product of the potent SV40-tumor promoting oncogene, large T-antigen (LTg) also possesses a RecQ-like C_2H_2 TAZ2 zinc domain where the first two cysteines are derived from the N-terminus of an α-helix with the two histidines from the N-terminus of the next α-helix.[57] It has been suggested that the TAZ2-like zinc domain stabilizes the biologically active, hexameric form of this replicative LTg helicase.

2.7 Zn2/Cys6-like Finger

These DNA-binding proteins are unique among zf proteins, in that two tetrahedrally coordinated zinc ions are ligated by six conserved cysteines, with two bridging thiolates shared between the metal ions. This motif has been dubbed a binuclear cluster, reminiscent of metallothioneins, Cys-rich intracellular zinc chelators (*see* ***Metallothioneins***). The zinc-binding domains possess two ligands from a helix and two ligands from a loop (see Table 1).[12] These transcriptional regulators function as homodimers and are ubiquitous in fungi and notably absent in higher eukaryotes.[58] Structurally characterized binuclear cluster zf proteins include the *S. cerevisiae* transcriptional regulators Gal4, Hap1, and PUT3.[58]

2.8 Other zf Domains

A comprehensive compilation of zinc finger domains encoded by mammalian genomes (http://www.ebi.ac.uk/InterPro) contains 46 conserved zinc finger domains.[19] As mentioned above, the combinatorial diversity of these protein families arises from the modularity of the zf domain itself, which has been repeatedly fused to other conserved domains to create new proteins with new biological functions during evolution. Of particular note are two new motifs that have been recently identified in *enzymes* involved in chromatin remodeling and gene silencing. These are histone lysine (K) methyltransferases (HKMTs; e.g. *N. crassa* DIM-5 and human SET7/9) and sirtuins, NAD^+-dependent Sir2 (silent information regulator protein 2) protein (histone) deacetylases. Many HKMTs incorporate *in toto*, a Zn_3-Cys_9 triangular zinc cluster structurally superimposable on the β-domain of mammalian metallothioneins (*see* ***Metallothioneins***). Although relatively far from the active site and of unknown function, removal of zinc from this domain greatly inhibits histone methylase activity. Recent experiments suggest that a fourth C_4-Zn(II) binding site is assembled near the active site upon binding of the methyl donor substrate AdoMet; formation of this chelate appears absolutely essential for catalytic activity. Sirtuins contain a structural C_4 zinc ribbon-like motif, where the zinc ion is coordinated via two ligands derived from a β-hairpin and two derived from a loop between a β-strand and an α-helix rather than a second β-hairpin as in the classical zinc-ribbon motif (Section 2.4). Although far from the active site, in at least one sirtuin, *S. cerevisiae* Hst2, this zinc-binding module may well negatively regulate deacetylase activity by stabilizing assembly of a catalytically inactive homotrimeric enzyme.[59]

Additional proteins with novel zinc-binding domains include the SQUAMOSA promoter binding proteins (SBPs), which are plant-specific transcription factors that possess two zinc finger domains within a $\approx$65 residue globular domain. The N-terminal zinc finger somewhat resembles the classical $\beta\beta\alpha$ zinc finger (Section 2.2) and is followed by a C-terminal zinc ribbon-like DNA-binding domain (Section 2.4).[60] The N-terminal zinc finger consists predominantly of a C_3H ligation pattern while the C-terminal domain possesses an invariant C_2HC ligation pattern. These novel structures also suggest new modes of DNA recognition by zinc finger proteins.[60] Another zf protein characterized by an unclassified fold is the $\approx$70 amino acid tandem zinc finger (TZF) domain of the TIS11d protein, which regulates posttranscriptional control of mRNA stability by binding to class-II AU-rich elements (AREs) in the 3′ UTR of target mRNAs.[61] TIS11d contains two highly conserved CCCH zinc finger motifs with an invariant 18-residue linker. Although largely devoid of regular secondary structure, each CCCH zinc finger superficially resembles the retroviral Gag knuckle (Section 2.5), and contains a short α-helix after the first ligating cysteine, a turn of 3_{10}-helix between the second and third cysteine and another 3_{10}-helix located at the interface between finger 1 and the linker.[61]

3 REGULATORY ZINC IN METALLOREGULATORY PROTEINS

Transition metal ions, including Zn(II) are essential for survival, but become toxic at high intracellular concentrations (*see* ***Metal Ion Toxicity***). In all kingdoms of life, cells must therefore be capable of regulating the steady-state concentration or available pool of individual metal ions via the coordinate regulation of specific metal import and metal efflux or chelation systems. This metal homeostasis (*see* ***Metallochaperones & Metal Ion Homeostasis***) is established by metalloregulatory proteins that 'sense' when the concentration or pool of a particular transition metal ion in the cytosol or an intracellular compartment becomes either deficient or exceeds critical levels required for normal cellular metabolism (*see* ***Metalloregulation***). Through extensive biochemical, molecular genetic and more recently, whole genome sequencing efforts, a large number of known or putative metal-responsive regulator proteins have been identified, especially in eubacteria and archeabacteria. Four distinct subfamilies of prokaryotic metal-sensing transcriptional regulators have emerged from these studies and include the MerR, ArsR (or SmtB/ArsR), DtxR and Fur families of metalloregulators. Zinc-specific metalloregulators in each family have been discovered, and in some cases extensively characterized as to the structure of the coordination chelate, how individual family members recognize or detect a specific metal ion, and how metal binding positively or negatively allosterically regulates DNA binding and transcription of the resistance or uptake operons. These aspects of metal regulation in prokaryotes, and to a lesser degree, in eukaryotes, are discussed in turn.

3.1 MerR Family

The MerR family of regulators activate gene expression by distorting the operator DNA sequence and causing RNA polymerase to initiate transcription at an otherwise suboptimal promoter.[62] Members of this family are characterized by N-terminal winged-helix DNA-binding domains, followed by a long coiled-coil region. The C-terminal helical domain is the effector binding domain.[62] MerR orthologs that bind a wide range of inducers including metal ions, lipophilic drugs, nitric oxide and superoxide (induced by oxidative stress) are known. The paradigm of this family and hence where the name derives comes from the seminal studies of *merR* genes of transposons Tn*501* from *P. aeruginosa* and Tn*21* from *Shigella flexneri* R100 plasmid. In gram-negative systems, MerR regulates expression of the mercury resistance divergon (*merTP(C/F)AD(E)* and *merR*) from the major regulated promoter.[63] MerR has been shown to bind to the operator/promoter region of the *mer* operon that contains a 7-4-7 inverted repeat. MerR activates the transcription of the operon in the presence of Hg(II) and acts as a weak repressor in the absence of Hg(II).[62] A unifying feature of the family of MerR is that repression and activation requires the regulator to be bound on the −35 and −10 regions of the promoter. The −35 and −10 regions are separated by a longer spacer than normal (19 bp versus 17 bp). This suggested that the promoter structure was important to the regulatory mechanism. Activation distorts the DNA at the center of the operator to realign the −35 and −10 sequence, allowing RNA polymerase to transcribe the genes upon activation.[64] Insertions or deletions (1 to 2 bp) in the 19-bp spacer have been shown to abolish promoter activity or increase constitutive promoter activity, respectively, indicating the 19-bp spacer is essential for regulation.[62]

Although the structure of MerR has not yet been solved, the X-ray crystallographic structures of BmrR and MtaN, two MerR orthologs that regulate multidrug resistance in pathogenic bacteria have been determined.[65,66] More recently, the crystal structures of two *E. coli*-derived metal regulators from the MerR family have been reported. These include the zinc-specific regulator ZntR (to 1.9 Å resolution) (Section 3.2.1), and CueR, a Cu(I) sensor (to 2.2 Å resolution), which regulates the expression of the efflux pump CopA and periplasmic copper oxidase CueO in response to moderate copper stress (*see* ***Metal Ion Toxicity***; ***Metallochaperones & Metal Ion Homeostasis***). Au(I)- and Ag(I)-liganded complexes of CueR (to 2.5 and 2.1 Å resolution, respectively) have also been determined.[67] The metal coordination environment of these proteins is likely essential for determining metal specificity of MerR proteins.

3.1.1 *E. Coli ZntR: A Zn(II)-dependent MerR Family Regulator*

E. coli ZntR is mainly zinc inducible and regulates the expression of *zntA*, which encodes a Zn(II)/Cd(II)/Pb(II) ATPase. The ZntR operator is uniquely defined by a 20-bp sequence spacer between the canonical −35 and −10 regions of the promoter. ZntR exists as a dimer, binds two zinc ions per monomer (as determined by X-ray crystallography), and utilizes a MerR-like DNA distortion mechanism to activate the expression of *zntA*.[67,68] Strikingly, X-ray crystallography reveals a binuclear zinc site with each zinc ion bound in a tetrahedral coordination environment and an internuclear Zn–Zn distance of 3.6 Å.[67] One zinc ion (designated as A) is ligated by Cys114 and Cys124 of the metal-binding loop while the other zinc ion (designated as B) is ligated by Cys115 and His119 of the same metal-binding loop (Figure 3).[67] The two zinc ions are bridged by the oxygen atoms of a phosphate (or sulfate) anion and by Cys79′ from the other protomer.

This binuclear Zn(II) coordination complex in ZntR, coupled with the bound anion, was totally unexpected since Hg-MerR requires just one trigonally coordinated Hg(II) ion that bridges the MerR dimer to effect metalloregulation of the *mer* operon.[62] The extent to which occupancy of one or both metal sites in each of two symmetry-related metal-binding loops in ZntR regulates transcriptional activation has yet to

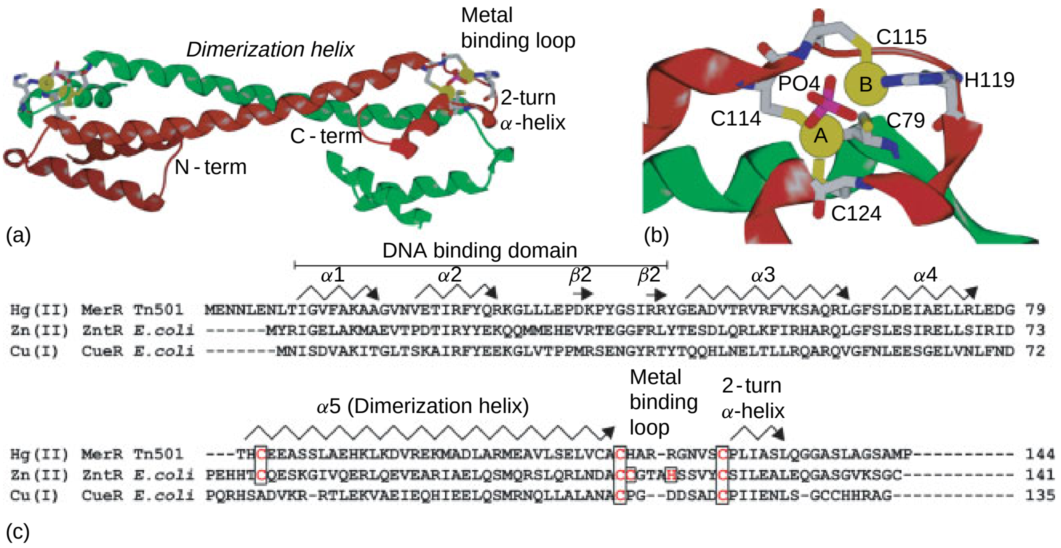

Figure 3 (a) Structure of the Zn_4ZntR dimer. The ribbon diagram shows one protomer in red and the other in green. The N-terminal ∼50-residue DNA-binding domains are not present in this structure.[67] The long α-helix is the dimerization helix while the metal-binding domain is formed by a metal-binding loop that connects the dimerization helix and two short C-terminal α-helices. (b) Close-up of the metal-binding domain of ZntR with two bound zinc ions shown as yellow spheres. Four zinc-ligating residues are derived from the red protomer (C114, C115, H119, and C124), while a phosphate (or sulfate) anion and the side chain of C79′ from the green protomer bridge the two zinc ions. (c) Sequence alignment of Hg(II)-specific Tn501 MerR, Zn(II)-specific *E. coli* ZntR, and Cu(I)-specific *E. coli* CueR.[67] Known metal-binding residues are colored red and are boxed. Secondary structure elements are represented above the sequence: β strands, horizontal arrows; α-helices, zig-zag arrows

be firmly established, although substitution of all five protein-derived zinc ligands reduces or abrogates the Zn(II) response in vivo.[69] Interestingly, inspection of the ZntR structure and sequence alignment of known ZntRs suggests that a C_3H(D) mononuclear, tetrahedral Zn(II) complex involving Cys114, His(Asp)119, Cys124 and Cys79′ could also be readily accommodated by ZntR. Interestingly, His29 and His53 are also required for metalloregulation, although these additional residues likely play a role in mediating DNA distortion by Zn(II)-ZntR.[69] Three of the four metal-binding cysteines in ZntR (Cys79′, Cys114, and Cys124) are conserved in Hg-sensing MerRs, and likely constitute the donor atoms to the subunit-bridging *tris*-thiolato Hg(II) complex. In Cu(I)-CueR, cysteines analogous to Cys114 and Cys124 form a linear S-Cu-S regulatory complex. Only in known zinc-sensing ZntRs are His29, His53 and His119 invariant or conserved. Hence, the metal selectivity of MerR family members appears to derive from differences in coordination number and type of metal ligands utilized by different proteins (see Figure 3), a finding exactly analogous to that previously demonstrated for two members of the ArsR/SmtB family, a zinc-sensing *S. aureus* CzrA versus the nickel-sensing NmtR (Section 3.2).[70]

As a further test of the inducer specificity of the metal-binding domains in MerR proteins, a chimeric protein has been characterized in which the N-terminal winged-helix DNA-binding domain (44 residues) of *Tn501* MerR was fused to the C-terminal 103 amino acids of ZntR and transcriptional activation measured from a *mer* operator/promoter that contained a 20-bp −10/−35 spacer uniquely characteristic of the *zntA* promoter rather than the wild-type 19-bp spacer in the *mer* operon.[71] This hybrid protein responded to Zn(II), but not Hg(II), consistent with the hypothesis that the C-terminal metal-binding domain of MerR proteins plays a major role in metal selectivity and adjustment of the appropriate degree of DNA distortion required by various operator-promoters.[62]

3.2 SmtB/ArsR Family: *S. Aureus* CzrA and *Synechococcus* SmtB

The SmtB/ArsR family consists of homodimeric ‘winged’ helix-turn-helix (HTH) transcriptional repressors that are specifically bound to their operator/promoter (O/P) DNA-binding sites in the metal-free apo state. Metal binding allosterically negatively regulates DNA binding and de-represses transcription.[72] Most of the O/P sequences of this family contain one or two imperfect 12-2-12 inverted repeats but little is known at the molecular level of how apo-repressor binds to these sites. The name of this family is derived from its two founding members, ArsR from *E. coli* and *Synechococcus* PCC 7942 SmtB. ArsR is an arsenic/antimony-responsive repressor of the *ars* operon that encodes an arsenate reductase, as well as proteins required for metal export.[72–74] SmtB functions as a zinc-responsive repressor that represses transcription of a divergently transcribed operon containing both the *smtA* gene (encodes a class-II metallothionein) and the *smtB* gene (Figure 4).[72,75,76]

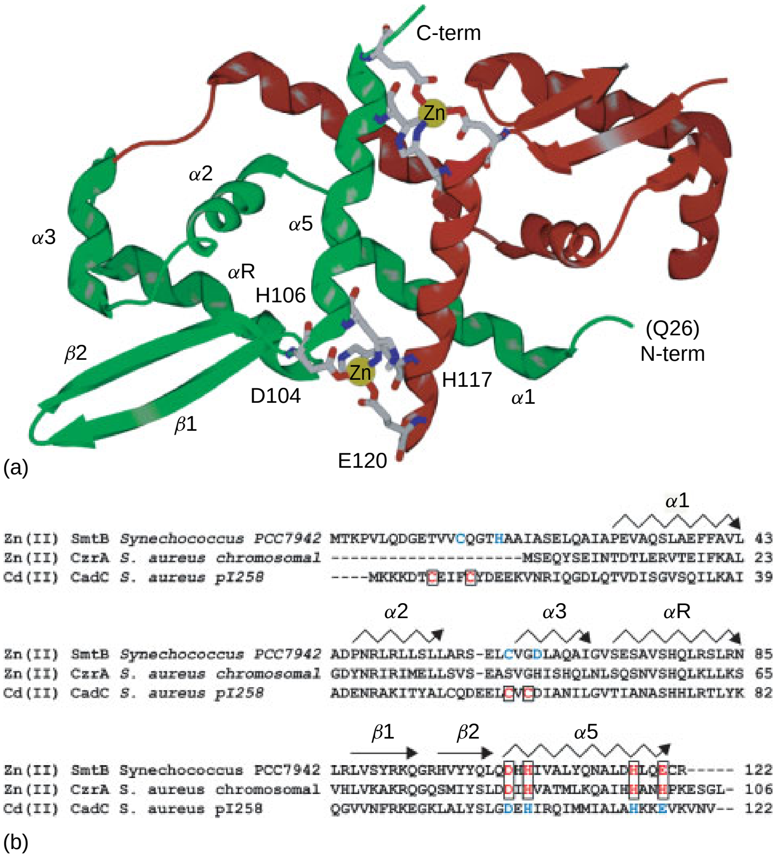

Figure 4 (a) A ribbon representation of the X-ray crystallographic structure of Zn_2 SmtB is shown with one protomer in green and the other in red.[77] Residues known to ligate the $\alpha5$ Zn(II) ions are shown. (b) Multiple sequence alignment of *Synechococcus* SmtB, *S. aureus* CzrA, and *S. aureus* pI258 CadC. Known metal-binding residues are boxed.[72] Residues shown to be involved in negatively allosterically regulating DNA binding are colored red. Blue residues are ligands to a second Zn(II) or Cd(II) but are *not* involved in metal sensing. $\alpha3N$ amino acids are the boxed and red cysteines in CadC. Secondary structure elements are as defined in Figure 3

Ten years of molecular genetic, biochemical, biophysical, and structural studies reveal that this family of metal-sensing transcriptional repressors generally possesses two well-characterized metal-binding sites (for a recent review see Busenlehner *et al.*[68]). They are termed the $\alpha3N$ site and the $\alpha5$ site. The $\alpha3N$ site is composed of cysteine residues from the N-terminal portion of the protein and a highly conserved ELCVCD motif in $\alpha3$ (Figure 4), initially termed the 'metal-binding box'.[72] The $\alpha5$ site is composed of histidines and carboxylate residues, and is found in the C-terminal portion of the protein. Not all members of this family contain both metal-binding sites. Some possess $\alpha3N$ only and others $\alpha5$ only, some have both sites, and a few have neither site (these proteins appear to possess a new, as yet to be characterized site).[72,78] The $\alpha5$ site interacts preferably with smaller divalent metal ions, for example, Zn(II), Co(II), and Ni(II), while the $\alpha3N$ site preferentially binds larger thiophilic metal ions such as Cd(II), Pb(II), and Bi(III). SmtB/ArsR proteins that possess both metal-binding sites have been shown to utilize only one site for regulation, not both sites. What factors determine which site is functional in a protein that possesses both sites is still unclear, but it is known that this selectivity of the allosteric response requires determinants outside of the primary metal ligands.[70,77,79]

3.2.1 *SmtB/CzrA*

Staphylococcus aureus CzrA is a Zn(II)/Co(II) sensing repressor. Like SmtB, CzrA metalloregulates DNA-binding through zinc binding to the $\alpha5$ site, which results in a quaternary structural conformational change that stabilizes a low affinity DNA-binding conformation.[70,77] Structural studies performed on apo- and Zn(II)-forms of CzrA and SmtB reveal that the $\alpha5$ metal-binding site is formed by a pair of ligands derived from the $\alpha5$ helix of one protomer, D84 (D104 in SmtB) and H86 (H106), and two derived from the $\alpha5$ helix of the other protomer, H97 (H117) and H100 (E120) (Figure 4).[77] The crystal structure of the Zn(II)-bound form of SmtB reveals an intersubunit hydrogen-bonding network that appears to link the metal-binding site ($\alpha5$) to the putative DNA-binding helix (αR). The Nε2 atom of His117 (the

nonliganding nitrogen of this histidine) is within hydrogen-bonding distance to the backbone carbonyl of R87 in the Zn(II)-ligated state (2.67 Å N-O), while in the apo-protein it is not (3.6 Å N-O distance). The residue adjacent to R87 is a conserved L88 that then donates a backbone hydrogen bond via its amide proton to the backbone carbonyl of a conserved L83 in the DNA recognition helix (αR) (Figure 4). Detailed hydrogen-deuterium exchange studies carried out with *S. aureus* CzrA by NMR methods are consistent with the formation of this hydrogen-bonding network in solution as well, with zinc binding to the α5 sites dramatically dampening internal motion throughout the dimer.[77] This work provides the first clear evidence of how metal binding allosterically regulates DNA binding in a prokaryotic metalloregulator at the atomic level.

3.3 DtxR Family: TroR

The DtxR family of regulators is named after its founding member DtxR from *Cornybacterium diphtheria*. DtxR and a homolog found in *M. tuberculosis*, IdeR, function as Fe(II)-dependent repressors that bind to a hyphenated palindromic sequence as a dimer.[80] DtxR negatively regulates genes required for iron acquisition, and expression of a major virulence factor, diphtheria toxin, in response to its corepressor iron. DtxR contains an N-terminal winged-helix ($\alpha\alpha\alpha\beta\beta\alpha$) DNA-binding domain followed by a helical dimerization domain; some DtxRs also contain a C-terminal Src homology 3 (SH3)-like domain that is rare in bacterial proteins.[81] At least 18 crystallographic structures of *C. diphtheria* DtxR and *M. tuberculosis* IdeR have been reported with a variety of divalent metal ions bound, in the presence and absence of DNA. While the coordination structures and functional importance of these bound metal ions is controversial, two distinct metal sites in DtxR/IdeR, termed site 1 and site 2, emerge from these studies. Metal site 1 adopts a distorted octahedral coordination geometry and is coordinated by three residues derived from the α4 (H79, E83) and α5 (H98) helices (Figure 5c), and two residues contributed by the C-terminal SH3 domain (E170 and Q173). Metal site 2 is the putative metalloregulatory site, and adopts a distorted pentacoordinate geometry formed by three closely spaced and invariant residues in the α5 helix (C102, E105, and H106) as well as M10 from helix α1 (Figure 5c).[81]

DtxR (IdeR) orthologs have recently been discovered that are involved in the regulation of genes that encode metal transporters apparently specific for other divalent metal ions, including Mn(II) and perhaps Zn(II). These include *Bacillus subtilis* MntR, highly specific for Mn(II), and *Treponema pallidum* TroR. *B. subtilis* MntR regulates the expression of two manganese transporters, the Nramp-type transporter MntH under high Mn(II) and the ABC-type transporter MntABCD under low Mn(II) conditions.[82,83] In high manganese, Mn(II)-MntR functions as a repressor by binding to operators upstream of the coding regions of both *mntH* and *mntABCD* operons. MntR is selective for manganese while DtxR is activated to bind DNA by various divalent metals including manganese in vitro.

Strikingly, the high-resolution crystallographic structure of Mn(II)-bound MntR (to 1.75 Å resolution) reveals a binuclear Mn(II) center, with the two Mn(II) ions bridged by two glutamates, E102 and E11, the latter unique to MntR, and a solvent molecule (Figure 5a).[83] The other ligands to the site A Mn(II) ion are H77 and E99 (C102 in DtxR) and two water molecules, creating a distorted octahedral coordination geometry.[83] Mn_B also adopts an octahedral geometry and is ligated by D8, which is M10 in Fe(II)-sensing DtxR, H103, and two solvent molecules, in addition to the bridging ligands E11 and E102.[83] Mn_B is roughly positioned in the same place as a Co(II) ion bound to metal site 1 in IdeR. In an effort to understand the molecular basis of metal ion discrimination between DtxR/IdeR and MntR, a D8M substitution mutant of MntR was functionally and structurally characterized. D8M MntR shows relaxed specificity for Mn(II) and is activated by both Fe(II) and Mn(II) in vivo.[84] The high-resolution crystallographic structure of D8M MntR (to 1.6 Å resolution) reveals why (Figure 5b): D8M MntR retains just one of the two Mn(II) ions and is coordinated by E11, H77, E102, and a solvent molecule (the introduced M8 is *not* ligated to the metal) in a distorted trigonal bipyramidal geometry, closer to the position of Mn_A in wild-type MntR.[83] These findings suggest that metal selectivity in the DtxR family is governed by the number and type of ligands bound to the metal, exactly analogous to findings in the MerR- and SmtB/ArsR-family regulators. Interestingly, the amino acid sequence of the putative Zn(II) regulator *T. pallidum* TroR lacks all N-terminal α1-derived metal-binding residues that play critical roles in DtxR/IdeR and MntR (Figure 5c); this might explain its reported ability to respond to Zn(II) versus other divalent transition metal ions (Section 3.3.1).

3.3.1 TroR

In 1997, Hardham *et al.* discovered a six-gene cluster termed the transport-related operon (*tro*) from *Treponema pallidum*.[85] Two genes of the operon include TroA, which encodes the solute-binding protein (SBP) component of an ATP-binding cassette transporter, and TroR, a DtxR-like metalloregulator.[85,86] TroR is similar to MntR in sequence (Figure 5c), and has been characterized as both a Mn(II)-specific,[87,88] and a Zn(II)-specific[85,89] regulator in vivo. Only limited metal-binding experiments have been reported for TroR, and there is currently no available structure. However, the crystallographic structure of Zn(II)-bound TroA,[86,90] the SBP whose expression is metalloregulated by TroR, may provide some insight as to the natural metal ligand(s) for TroR.

TroA coordinates a single Zn(II) ion in a pentavalent coordination geometry formed by H68, H133, H199 and D279(Oδ1 and Oδ2).[86] This coordination structure differs

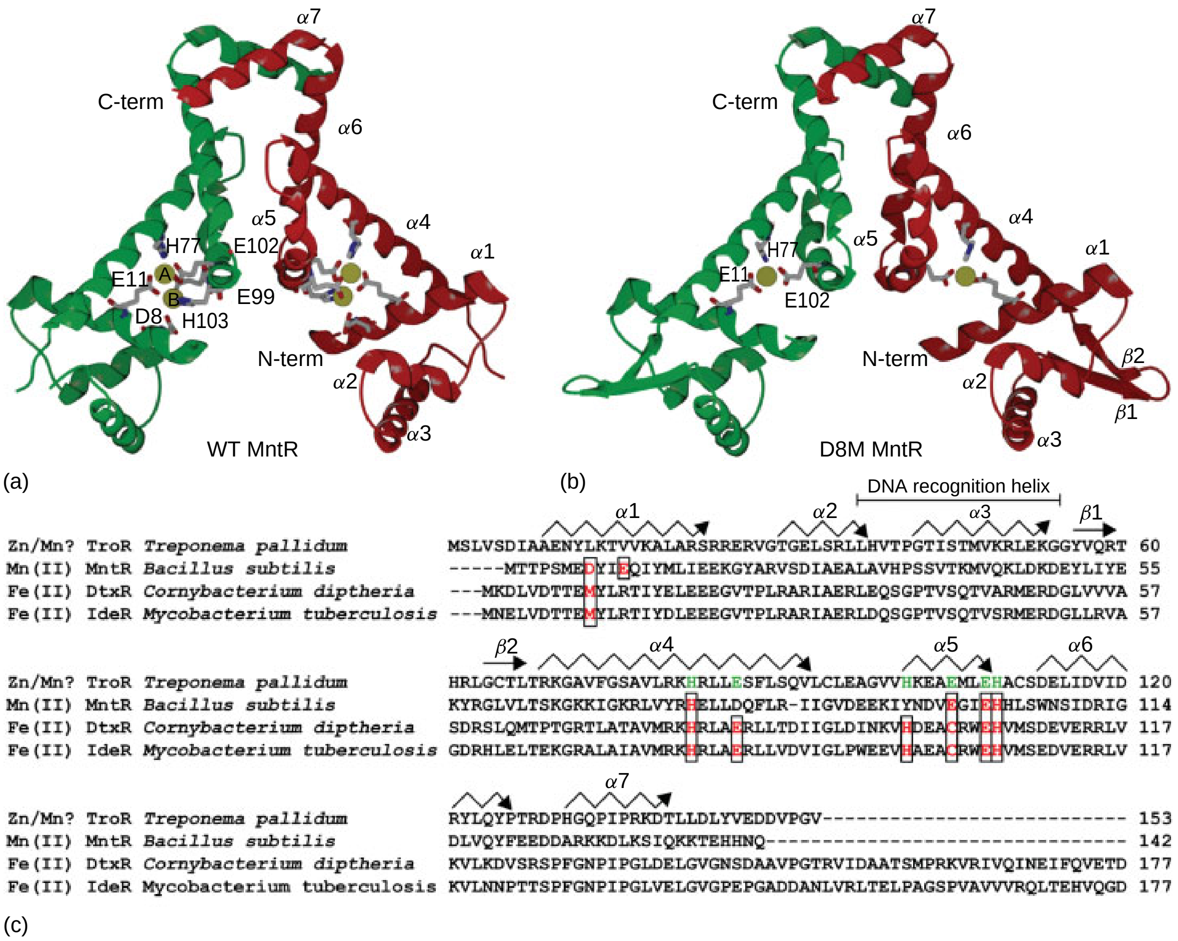

Figure 5 (a) Ribbon representation of the structure of wild-type *B. subtilus* MntR with two Mn(II) ions bound per protomer in a binuclear cluster. One subunit is shaded green and one in red. Residues E11, H77, E99, and E102 coordinate the Mn(II) ion designated as Mn_A while D8, E11, E102, and H103 coordinate the Mn(II) ion designated as Mn_B. The Mn(II) ions are bridged by bidentate interactions of E11, E102, and a solvent molecule; (b) structure of D8M MntR with one Mn(II) bound per protomer. One subunit is shown in green and the other in red. Residues E11, H77, and E102 coordinate the Mn(II) ion along with a solvent molecule (not shown); (c) sequence alignment of *T. pallidum* TroR, *B. subtilis* MntR, C. *diphtheria* DtxR, and *M. tuberculosis* IdeR with the secondary structure regions (based upon crystal structure of MntR) shown as above. Known metal-binding residues are colored red and boxed. Proposed metal-binding residues of TroR are shaded green. Note that the metal specificity of TroR (Zn vs. Mn) has not yet been firmly established (see text for details)

from that recently reported for Zn(II)-bound *Synechocystis* 6803 ZnuA, the SBP of the ZnuABC metal transporter, which is highly selective for Zn(II). In ZnuA, Zn(II) is bound in a distorted tetrahedral coordination geometry with just three protein-derived histidines, exactly analogous to H68, H133 and H199 in TroA, and a solvent molecule; the bidentate ligand D279 in TroA is conserved in ZnuAs. Although both ZnuA and TroA belong to the same cluster 9 family of ABC transporters, it has been argued that ZnuA preferentially binds Zn(II) over Mn(II) by providing just three protein-derived ligands, since Mn(II) complexes with low-coordination numbers are essentially inaccessible owing to ligand-field destabilization arguments and the well understood Irving–Williams series; Zn(II) with its full *d*-shell readily adopts four-coordinate complexes.[91] Since TroA apparently binds Zn(II) in a five-coordinate geometry, Mn(II) should bind to TroA with high affinity as well; this will effectively relax the metal selectivity of this transporter system. This is in fact the case since the measured metal-binding affinities of Zn(II) and Mn(II) ($K_d = 1.3 \pm 0.4\,\mu$M and $K_d = 1.0 \pm 0.2\,\mu$M, respectively) are identical within experimental error.[89] One would expect that the metalloregulator TroR would have evolved to sense both Zn(II) and Mn(II) as well.

3.4 Fur Family: Zur

E. coli Fur and homologs in other prokaryotes regulate the transcription of genes required for iron acquisition, including a host of distinct iron scavenging systems as well as the enzymes for siderophore biosynthesis (*see* ***Iron Transport: Siderophores***; ***Metalloregulation***).[80] In addition,

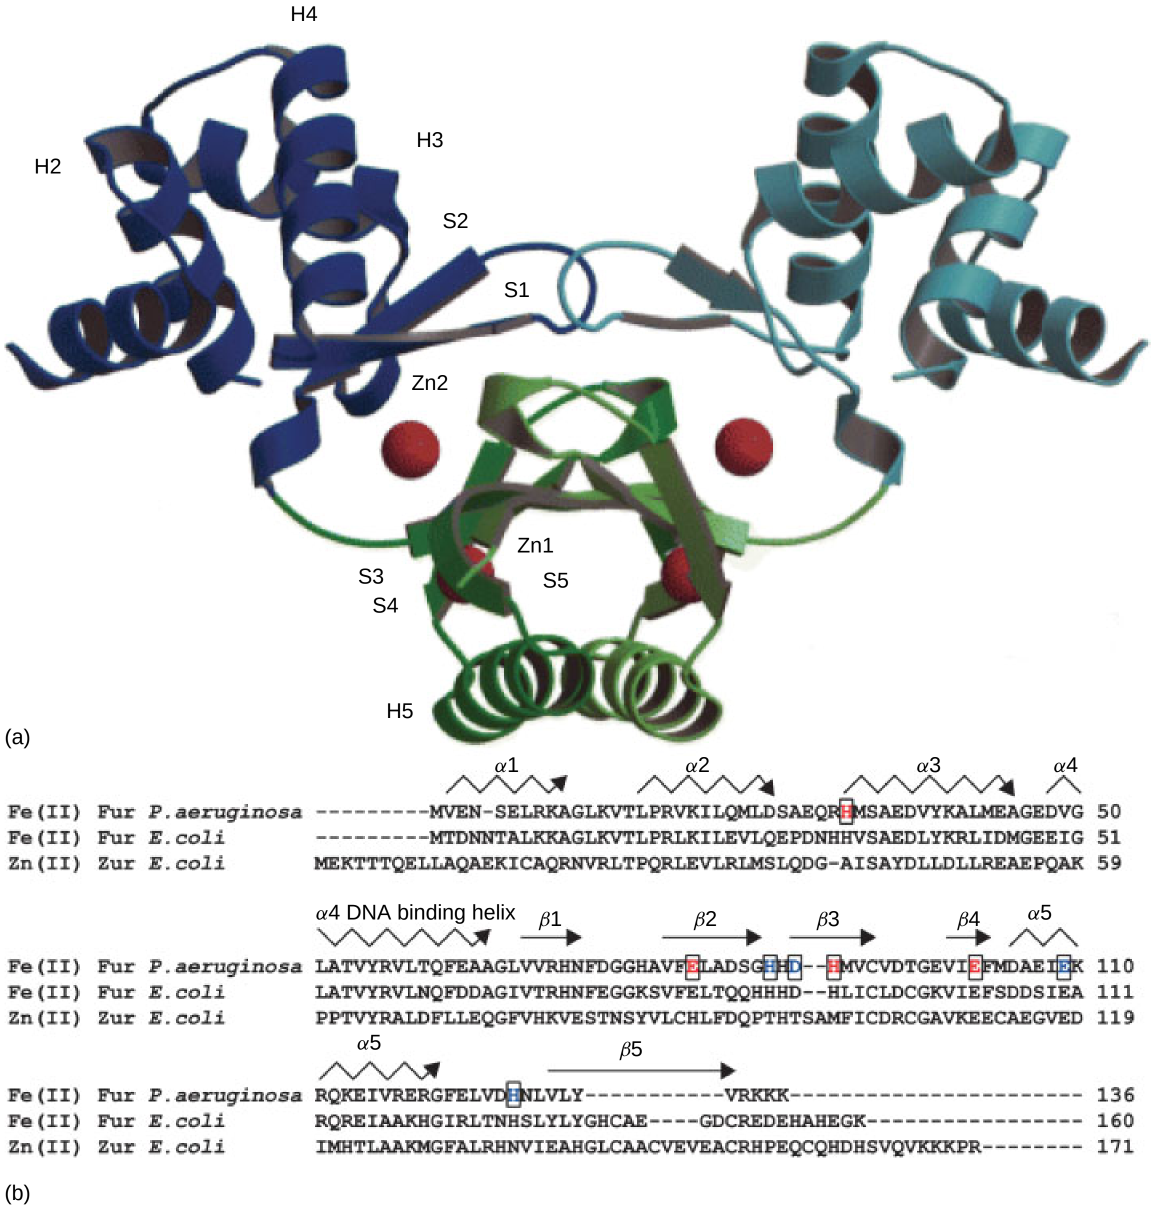

Figure 6 (a) A ribbon representation of the crystallographic structure of the Zn_4 *Pa* Fur dimer. Blue, DNA-binding domains; green, C-terminal dimerization domain (see text for details). Zinc ions are shown as dark magenta spheres. (Ref. 92. Reproduced by permission of Blackwell); (b) Sequence alignment of *Pseudomonas aeruginosa* Fur, *E. coli* Fur, and *E. coli* Zur using ClustalW (http://www.ebi.ac.uk/clustalw).[93] Known metal-binding ligands are boxed and the secondary structural elements are as above. Blue residues in *P. aeruginosa* Fur represent the proposed regulatory Fe-binding site; red residues in *P. aeruginosa* represent the proposed structural Zn binding site

the expression of key virulence factors in pathogenic bacteria are also regulated by Fur. The working model is that the iron-bound form of Fur binds to specific target sequences in the promoter of iron-regulated genes, collectively known as 'iron boxes', blocking access by RNA polymerase. Like the DtxR family regulators, iron functions as a corepressor of the expression of those genes linked to iron acquisition; in iron-starved conditions, these genes are constitutively expressed. The high-resolution crystallographic structure of *Pseudomonas aeruginosa* Fur complexed with Zn(II) (rather than iron) has recently been reported to 1.8 Å resolution, with a ribbon representation of the structure shown in Figure 6.[92] The global structure of the Fur homodimer is superficially similar to that of DtxR; in fact the winged-helix DNA-binding domains superimpose with a backbone rmsd of 1.8 Å from helix $\alpha2$-$\alpha4$ through the $\beta1$-$\beta2$ hairpin. The dimerization domain of each protomer is an α/β domain consisting of a 3-stranded β-sheet topped by the C-terminal $\alpha5$ helix. Dimerization results in a six-stranded β-barrel capped by an antiparallel coiled-coil formed by the $\alpha5$ helices.

Two metal ions are bound per protomer for a total of four metal ions per dimer, designated Zn1 and Zn2. Zn1 is coordinated by residues located exclusively in the dimerization domain and adopts a distorted octahedral geometry with four protein-derived ligands (H86, D88, E107 and H124), and includes one bidentate carboxylate (D88) and a well-ordered water molecule. Zn2 bridges the DNA-binding and dimerization domains and adopts distorted tetrahedral coordination geometry (H32, E80, H89 and E100).[92] Fe(II) exchange experiments and characterization of the resulting Zn/Fe hybrid protein by X-ray absorption spectroscopy reveals that Zn1 is readily exchanged with Fe(II) and adopts a coordination complex that is isostructural with Zn1, with coordination of Zn2 unchanged. Therefore, Pohl *et al.* argue that in *Pa* Fur, the regulatory metal site corresponds to Zn1 located exclusively in the dimerization domain, while Zn2 is an unusual structural Zn(II) site, which forms part of the long-range allosteric pathway of communication between the regulatory sites and the DNA-binding domains of PA Fur. It seems plausible that metal binding to site 1 might globally alter the orientation of one subunit relative to the other, stabilizing a high-affinity binding conformation. All Fur homologs contain the full complement of metal sites structurally characterized in *Pa* Fur.

Interestingly, many Fur homologs, including *E. coli* Fur, contain two pairs of cysteine residues not present in *Pa* Fur. One pair is C92 and C95, just C-terminal to H86 and D88 of the Zn1(Fe) site and H89 of the Zn2 site, and N-terminal to E100 of Zn2 site in *Pa* Fur; *Pa* Fur contains a residue analogous to C92 only, which does not participate in metal binding (see Figure 6b). In addition, most Fur homologs contain a short C-terminal extension that contains a C-X_4-C sequence that is not present in *Pa* Fur (Figure 6(b)). X-ray absorption studies of *E. coli* Fur suggest at least one sulfur-containing Zn(II) coordination complex; spectroscopic studies of mutants suggest that C92 and C95 ligate this Zn(II) ion in the formation of a structural $S_2(N/O)_2$ complex, although this remains to be definitely determined.[93,95]

3.4.1 E. Coli Zur

Zur is a recently discovered Fur ortholog (27% sequence identity) that regulates the expression of a divergently transcribed operon that encodes the high-affinity zinc uptake system, *znuBC* and *znuA*, in a highly Zn(II)-specific fashion.[96,97] The high-resolution structure of Zur is not yet available and the molecular basis for metal ion discrimination by *E. coli* Zur remains unclear. However, it is possible to speculate on metal selectivity on the basis of an amino acid sequence alignment and limited spectroscopic findings reported for the Zn(II) and Co(II) metalloderivatives of *E. coli* Zur. Zur binds two metal ions per subunit and four per dimer in two spectroscopically distinguishable tetrahedral sites.[98] One Zn(II) ion, ZnA, is tightly bound in an $S_3(N/O)$ coordination environment and is refractory to metal exchange with Co(II). This site is likely analogous to the structural Zn2 site in Fur homologs that contain the C92-X_2-C95 cysteine pair. The other site, ZnB, is readily exchanged with Co(II) and is characterized by tetrahedral $S(N/O)_3$ coordination geometry, in striking contrast to the octahedral, putative Fe(II)-sensing Zn1(Fe) site of Fur.[98] Although the four donor atoms to this putative Zn(II)-sensing site remain unknown, at least two cysteine residues just C-terminal to the $\alpha 5$ helix in *Pa* Fur appear to be uniquely conserved in all functionally characterized Zur proteins (Figure 6b); one of these may well correspond to the thiolate donor in the ZnB site. Regardless of the details, these comparative structural studies of Fur and Zur emphasize the recurring theme that the primary determinant for metal selectivity in metal sensor proteins is coordination number and geometry, with a lesser role played by the nature of the donor atoms. This is exactly in accord with the conclusions reached by the Fierke group from a careful investigation of the metal affinities and structural studies of an extensive panel of carbonic anhydrase mutants (*see* ***Zinc Enzymes***).[99]

3.5 MTF-1 and *S. Cerevisiae* Zap1

Eukaryotic cells, like prokaryotes, have evolved efficient mechanisms to govern metal ion homeostasis, except that the regulatory logic is far more complex than simple regulation of DNA binding. In eukaryotes, metalloregulation of intracellular (cytoplasmic-nuclear) trafficking, posttranslational modification, protein–protein interactions and DNA binding are all possible and have been documented to occur in some cases. Two zinc finger proteins are known to play major roles in regulating zinc homeostasis in eukaryotes. They are *S. cerevisiae* Zap1, which controls the expression of a number of genes (>40) involved in zinc accumulation and storage, and vertebrate metal-response element (MRE)-binding Transcription Factor 1 (MTF-1). MTF-1 up-regulates the transcription of genes encoding metallothioneins, small cysteine-rich metal-sequestering proteins, ZnT-1, a cytoplasmic efflux pump, and other genes in response to heavy-metal (Zn/Cd) and oxidative stress in mammals. Both proteins possess multiple tandem C_2H_2 zinc fingers (7 zf's in Zap1 and 6 zf's in MTF-1), a subset of which appears to metalloregulate DNA-binding upon zinc binding (Figure 7).[15,100–102] A cluster of five zinc fingers near the C-terminus of Zap1 mediates high-affinity binding to an 11-bp zinc-response element (ZRE), while fingers 1 to 4 of MTF-1 play this role on the 12-bp MRE.[101–103]

A popular metalloregulatory model proposes that these or other remaining zinc fingers might regulate gene expression in response to fluctuations in bioavailable zinc concentration. In Zap1, zinc fingers zf1 and zf2 appear to play a direct role in zinc sensing by negatively regulating activation domain 2 function as the intracellular zinc concentration rises (see Figure 7).[16] In MTF-1, the precise mechanism of Zn(II)-activation of MRE-binding has been far more elusive, although recent experiments suggest that zinc fingers zf1, zf5, and zf6 stabilize the interaction of MTF-1 with chromatin-embedded

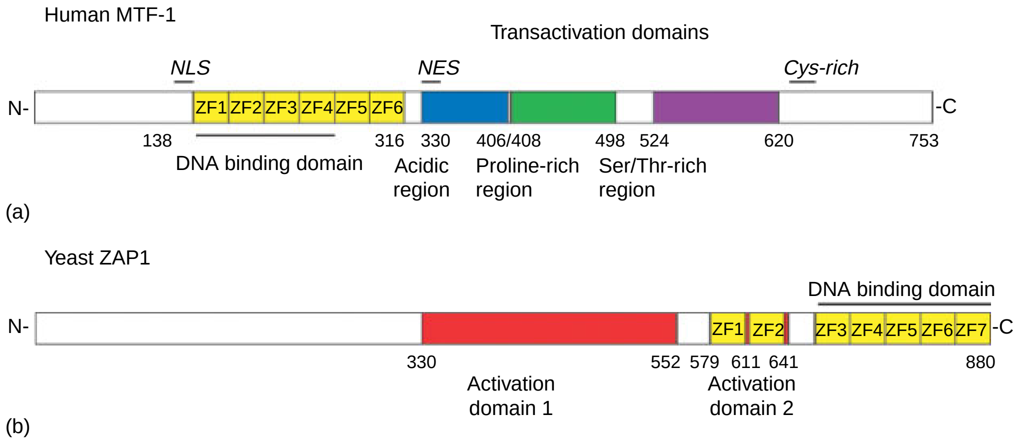

Figure 7 (a) Domain organization of human MTF-1 in which zinc finger domains are colored yellow and denoted by ZF (zinc finger). The acidic, proline-rich, and Ser/Thr-rich transactivation domains are indicated. *NLS*, nuclear localization signal; *NES*, nuclear export signal; *Cys-rich*, a cysteine cluster that functions in metal-inducible transcriptional activation;[104] (b) Domain organization of *S. cerevisiae* Zap1. Transactivation domains are indicated as is the DNA-binding domain (zf3-zf7)[16]

MREs.[100,105] Interestingly, all six zinc fingers of hMTF-1 bind Co(II) with equilibrium affinities that are more similar than different ($K_{Co} \approx 2 \times 10^6 - 5 \times 10^7$ M^{-1} at pH 7.0),[106] despite the vastly different reactivities of the cysteine thiolates of C-terminal fingers zf5 and zf6 toward an exogenous alkylating reagent, that is, these fingers exhibit an enhanced kinetic lability relative to primary MRE-binding fingers. Likewise, a peptide corresponding to the regulatory fingers (zf1-zf2) of Zap1 binds Zn(II) with the same apparent affinities as a DNA-binding finger pair (zf3-zf4) ($K_{Zn} \approx 10^9$ M^{-1}) despite more rapid metal dissociation rates for the zf1-zf2 pair.[16] These findings suggest that zinc metalloregulation of gene expression in eukaryotic cells might be under kinetic, rather than thermodynamic control (see Section 4). Recently, it has been shown that a conserved cluster of four cysteines (^{632}**C**Q**C**Q**C**A**C**^{638}) located just C-terminal to the Ser/Thr-rich transcription activation domain of hMTF-1 (see Figure 7) is required for activation of transcription in the presence of zinc and cadmium in vivo.[104] These findings suggest that other domains outside of the zinc fingers themselves in MTF-1 play a role in metal inducibility. MTF-1 and Zap1 utilize their zinc fingers to bind DNA with high affinity and help regulate the expression of genes involved in metal sequestration and/or transport. Exactly how these domains regulate transcription in response to changes in intracellular zinc concentration still requires clarification.

4 PERSPECTIVES/CONCLUSIONS

As summarized in this chapter, zinc-containing nucleic acid-binding proteins are ubiquitous in nature and play integral roles in all aspects of nucleic acid metabolism, including DNA replication, recombination and repair, transcriptional activation/repression and chromatin remodeling, translational regulation, mRNA stability, ribosome dynamics and biogenesis. Although the molecular structures of these zinc coordination complexes are remarkably diverse and encompass all α-, all β- and mixed α/β-domains (Table 1), the common feature is a tetrahedral coordination geometry formed by four protein-derived ligands, two or more of which must be cysteine thiolates. Formation of the zinc coordination complex directs the folding of what are often mini domains that typically lack a hydrophobic core, thereby functionally stabilizing protein–protein and protein-nucleic acid interfaces. The classification of these zinc finger proteins into distinct fold groups begs the question of how many additional novel structures of zinc finger proteins might exist. Section 2.8 lists several proteins that do not precisely adhere to the structural classification scheme summarized in this chapter. However, global examination of their structures seems to suggest that as new zinc finger or zinc fingerlike domains are characterized, they will likely have some similarity to existing fold groups already described.

Is there additional functional currency that comes with the specific utilization of thiolate-rich Zn(II) coordination complexes to fulfill these myriad of important roles? One possibility may lie in the distinctive features of Zn-thiolate chemistry itself.[107] There is emerging evidence in support of the idea that zinc sites in nucleic acid-binding proteins are susceptible to rapid, and in some cases, reversible inactivation via formation of disulfide bonds between metal-ligating cysteines, with concomitant expulsion of the Zn(II) and local unfolding, under conditions of oxidative stress. For example, cysteine thiolates are readily *S*-nitrosylated when intracellular NO concentrations in mammalian cells rise; in at least one case, increasing NO gives rise to transient increases in intracellular zinc levels that is detectable by zinc-selective intracellular dyes.[108] In addition, *S*-nitrosylation of the RING finger domain

(Section 2.3) of a ubiquitin E3 ligase *parkin* is positively linked to neurodegenerative loss of dopamine neurons in Parkinson's disease.[109] A similar perturbation of zinc pools by heavy-metal xenobiotics, for example, Cd, in mammalian cells has also been proposed.[40] These and other findings suggest a strong link between intracellular zinc levels and various stress responses and the progression of human disease perhaps mediated in part by zinc release from metallothioneins, with Zn-thiolate coordination bonds a 'composite' redox sensor, rather than the metal ion itself, which obviously does not change oxidation state.[107] Such a redox sensor might also transiently disable fundamental processes devoted to DNA replication, DNA recombination, transcription initiation and regulation, and ribosome biogenesis until a full-scale redox stress response could be mounted by the cell.

Interestingly, metalloregulatory zinc sites in prokaryotic and mammalian metal sensor proteins, like structural zinc finger complexes, often contain thiolate ligands as well; in fact, homologous SmtB/ArsR sensors *Synechococcus* SmtB and *S. aureus* CzrA are currently the lone exceptions to this trend (Section 3.2.1) In these systems, zinc coordination number, rather than ligand type, appears to dictate metal selectivity among closely related orthologs from different metal sensor families (Section 3). The common structural feature is that metalloregulatory zinc sites, like structural zinc finger sites, are rigorously four-coordinate, but may be characterized by perhaps one weakly bound metal ligand that would enable ligand exchange and zinc transfer to acceptor proteins in establishing metal resistance.[94] This may be particularly important for zinc sensors since the thermodynamic stabilities of these zinc regulatory proteins are high (pM and fM zinc dissociation equilibrium constants for SmtB and ZntR/Zur, respectively).[110,111] This makes it unlikely that zinc will move from donor to acceptor, be it protein, metallothionein or small molecule (reduced glutathione), via the solvent and may instead be directly transferred from donor to acceptor in a process characterized by an equilibrium constant near one that might be kinetically facilitated by transient docking and rapid ligand exchange. This would have the effect of maintaining zinc homeostasis even upon challenge with toxic concentrations of the metal in the absence of large thermodynamic gradients of 'free' zinc inside the cell or within other intracellular compartments. Obtaining a mechanistic understanding of zinc homeostasis and trafficking within living cells in normal versus stressed states will surely prove to be an exciting area of future work in the general area of zinc and nucleic acid-binding proteins.

ABC = ATP-binding cassette; ADA = Adenosine deaminase; ADAM = A distintegrin and metalloprotease domain; ADH = Alcohol dehydrogenase; Apo2L or TRAIL = Apoptosis-inducing ligand 2; BIR = Baculovirus Inhibitor of apoptosis repeat; BHMT = Betaine-homocysteine methyltransferase; BRCT = Breast cancer tumor suppressor protein C-terminous; CA = Carbonic anhydrase; CAM = γ-carbonic anhydrase; C1 = Cysteine-rich domain; CH1 = Cysteine/histidine rich domain; CPD A = Carboxypeptidase A; CDA = Cytidine deaminase; CTAD = C-terminal transactivating domain; CRP = Cysteine-rich protein; CRIP = Cysteine-rich intestinal protein; DBD = DNA-binding domain; e/aIf2 = Eukaryotic/archaeal Initiation Factor; EDTA = Ethylenediaminetetraacetic acid; eNOS or NOS-3 = Endothelial nitric oxide synthase; H_4B = Tetrahydrobiopterin; HIF = Hypoxia-inducible factor; HIV = Human immunodeficiency virus; HMTase = Histone methyltransferase; HLA-DR = Class II major histocompatibility molecule; huIFN = Human interferon; KSR = Kinase suppressor of Ras; IAP = Inhibitor of apoptosis; iNOS or NOS-2 = Inducible nitric oxide synthase; IUB = International Union of Biochemistry; MEROPS = System for classification of peptidase sequences; *mt* = *Methanobacterium thermautotrophicum*; MCM = Minichromosome maintenance; MHC = Major histocompatibility complex; Mip = Macrophage infectivity potentiator protein; MMP = Matrix metalloproteinase; MPD = 2-methyl-2,4-pentanediol; NAD = Nicotinamide adenine dinucleotide; NADH = Reduced nicotinamide adenine dinucleotide; NADP = Nicotinamide adenine dinucleotide phosphate; NGF = Nerve growth factor; nNOS, NOS-1 = Neuronal nitric oxide synthase; PDE = Phosphodiesterase; Peptidase = Enzyme acting on peptides; PINCH = Particularly interesting new Cys-His protein; PLBP = Periplasmic ligand-binding protein; PMI = Phosphomannose isomerase; PTS = Signal transducing protein; PsaA = Pneumococcal surface antigen; Proteinase = Enzyme acting on proteins; RS = tRNA synthetase; SAM = S-adensoyl-L-methionine; SEA, B etc. = Staphylococcal enterotoxins type A, B etc; SPEA, C etc. = Streptococcal pyrogenic exotoxins type A, C etc; SET = Su(var), Enhancer of zeste, Trithorax; SHBG = Sex hormone binding-globulin; SMEZ = streptococcal mitogenic exotoxin; Sir2 = Silencing information regulator 2; SOD = Superoxide dismutase; TCR = T-cell receptor; TNF = Tumor necrosis factor; TACE = Tumor necrosis factor-α-converting enzyme; TSST = Toxic shock syndrome toxin; VanX = Dipeptidase of vancomycin-resistant pathogenic *Enterococci*; VDR = Vitamin D-Receptor; XAFS = X-ray absorption fine structure; XIAP = X-linked inhibitor of apoptosis protein.

1 INTRODUCTION

The importance of zinc to growth and development in all forms of life was first established through zinc deficiency studies of microorganisms followed by those in plants and animals (*see* ***Nutritional Aspects of Metals & Trace Elements***).[1] The involvement of zinc in a wide variety of metabolic processes including carbohydrate, lipid, protein, and nucleic acid synthesis and degradation paralleled the technical advances in analytical methods that could detect the presence of zinc in minute amounts coupled with advances in the methodology for protein isolation and purification.

The molecular characterization of zinc sites in biological systems came first through replacing the spectroscopically silent zinc with the chromophoric metal cobalt. These studies in conjunction with kinetic studies gave information on the importance of the metal site to protein function. Structural studies of the entire protein obtained by X-ray diffraction and NMR now give detailed information of the metal ligands and the coordination geometry of the metal site. X-ray absorption fine structure, XAFS, permits visualization of the zinc site directly in the solution and crystal states and enhances the ability to identify the manner in which zinc is involved in the function of the protein.[2] The combination of all of these approaches allows formulation of how the zinc influences protein function that can be tested by a combined approach including mutagenesis and rapid kinetics. Finally, the ability to determine primary protein structure through translation of DNA sequences in combination with our increasing knowledge of zinc-binding sites permits prediction of new zinc-binding sites and thereby protein function without even having an expressed protein.[3,4]

Zinc is the only metal to have representatives in all six of the International Union of Biochemistry, IUB, classes of

enzymes. The function of these enzymes is therefore related to the chemistry of zinc, which is quite versatile. It has a remarkably adaptable coordination sphere that allows it to accommodate a broad range of coordination numbers and geometries. If zinc retains a positive charge after ligating to protein side chains, it can act as a Lewis acid in catalysis. If a zinc-bound water is converted to hydroxide, the zinc site can act as a base or nucleophile in catalysis. In this sense, the zinc sites are amphoteric. The oxidation/reduction properties of its neighboring transition metals is a major cause of their ligand exchange rates, amphoteric properties, and coordination geometries. Since zinc has a filled d-shell, it does not have oxidation/reduction properties, thus providing a stable metal ion species in a biological medium whose redox potential is in constant flux.

Our first attempts at classifying the manner in which zinc binds to enzymes was made on the basis of the zinc ligands and coordination geometries of from one to three dozen zinc enzymes during the period 1988 to 1993 (Figure 1). This led to the recognition of three types of zinc-binding sites: *catalytic*, *cocatalytic*, and *structural*.[5,6] As of 2003, the structural characteristics of more than thirty dozen zinc sites have been reported, the great majority of which still fit into the original classification (see below). A new type of zinc-binding site, *protein interface*, has become apparent during the past few years.[3,4] In this case, zinc-binding sites are formed through ligands supplied from amino acid residues residing in the binding surface of two protein molecules.

2 SOME GENERAL FEATURES OF ZINC-BINDING SITES

The secondary support and scaffolding in combination with the direct ligands of the zinc allows fine tuning of the role of the zinc and its neighboring amino acids in the protein function. The following general observations pertain to the structural properties of zinc-binding sites found in enzymes and other zinc-binding proteins.[4] (1) Nearly all the zinc sites contain at least one secondary structural element. (2) β-sheets supply ligands to a wide variety of zinc-binding sites. (3) Ligands frequently come from the first, last, or 1 or 2 amino acids before or after a β-sheet or α-helix. (4) Small loop regions (6 amino acids) between two types of secondary structure can also supply the ligands. This may allow more freedom in the coordination properties of the zinc site. (5) Short spacers of one generally use a β-sheet to supply the ligands while a spacer of three uses an α-helix. (6) An α-helix is used to supply the short spacer ligands most frequently in hydrolytic enzymes (in particular, the metalloproteases). (7) His ligands are often H-bonded to carboxyl groups of Asp or Glu or carbonyl groups of a variety of amino acids. (8) Hydrophobic amino acids likely are involved in stabilizing the zinc-binding site through orientation of the ligands.

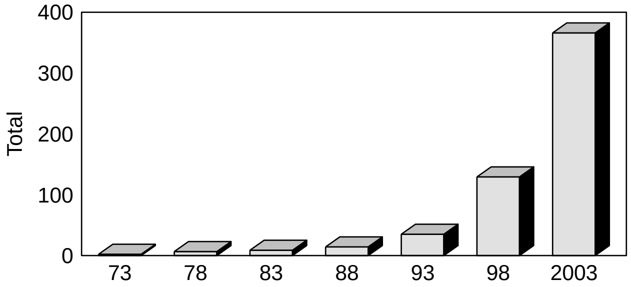

Figure 1 Time course of structural determination of zinc-binding sites in enzymes

3 CATALYTIC ZINC SITES

There are today about 12 dozen 3-dimensional structural references of *catalytic* zinc sites encompassing all six classes of enzymes (Table 1). The hydrolase enzyme class (III) has the greatest number of representatives. A catalytic zinc generally forms complexes with any three nitrogen, oxygen, and sulfur donors of His, Glu, Asp, and Cys with His being the predominant amino acid chosen. Histidine (usually the NE2 nitrogen) may be chosen because of its capacity to disperse charge through H-bonding of its nonliganding nitrogen. The overall sequence length of such sites can be as small as 11 amino acids as is observed in the zinc endoprotease families with the zinc site signature HExxHxxGxxH/D and the 5-aminolevulinic acid dehydratase enzymes (Table 1). The zinc ligands are separated by comparatively short and long amino acid spacers. While in principle the third ligand could be supplied from either the C- or N-terminal side of the first two ligands, the C-terminus is preferred by a ratio of about 5 to 1. The great majority of the short spacers contain one to three amino acids (Table 1). The length of the short spacer is often dictated by the ligand support structure: 3 for an α-helix and 1 for a β-sheet. In the case of the oxidoreductases, the involvement of H-bonding interactions between residues in the short spacer (for example, His47 and/or His51 in ADH) and the cofactor reduced nicotinamide adenine dinucleotide (NADH) may have led to the extension of the 'short' spacer to 17 to 29 (versus a long spacer of 82 to 106).

The coordination number for such sites is usually 4 or 5 and the geometry in the free state is frequently distorted-tetrahedral or trigonal-bipyramidal. Water is always a ligand to the catalytic zinc. The zinc-bound water can be directly involved in catalysis by its ionization or it can be activated through polarization by a neighboring amino acid residue acting as a general acid/base (Figure 2). The zinc can function as a Lewis acid by a substrate ligand displacement by the water or expansion of the coordination shell. The chemical nature of the three protein ligands, their spacing and secondary

Table 1 Catalytic zinc sites[a]

[a]The amino acid spacer between ligands L_1 and L_2 is X, that between L_3 and nearest ligand L_1 or L_2 is Y, and that between L_3 and L_4 is Z. The symbol N indicates that L_3 is located on the amino (N) side of L_2. If no letter is present, L_3 is located on the carboxy-terminal side of L_2. The subscripts α, β refer to the α-or 3_{10} helix and β-sheet structure that supplies the ligand. The subscript L denotes an amino acid sequence of ≤ 6 residues between two structural elements. The subscripts a and b indicate the ligand is either one (or two) residues after or before the secondary structural element.

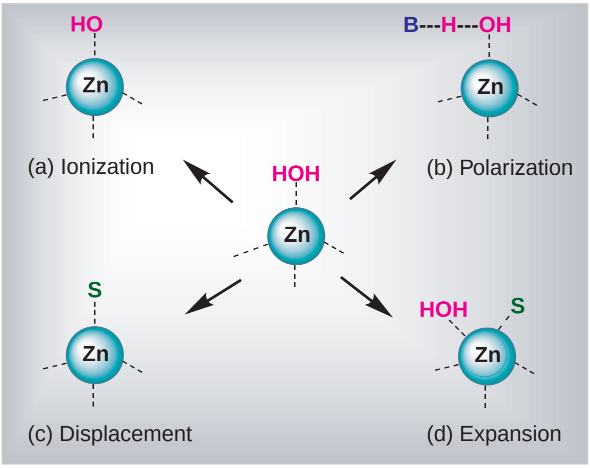

Figure 2 The role of the zinc and its bound water in catalysis. The water can ionize either (a) without or (b) with the help of an adjacent base, B, supplied by an amino acid residue. The zinc-bound water can also (c) be displaced by substrate, S or (d) the coordination sphere be expanded upon interaction with substrate

interactions with neighboring amino acids in conjunction with the vicinal properties of the active center created by protein folding are all critical for the various mechanisms through which zinc can be involved in catalysis.

3.1 Scaffolding of the Catalytic Zinc Sites

In considering how tightly the zinc will bind to the protein site, how readily it can be released from the protein, and its effect on protein function one must not only take into account the first shell ligands but the scaffolding of these sites. The scaffolding encompasses not only the type of secondary structure supplying the ligands, but also the effects of amino acid residues on the metal ligands. These amino acids are sometimes thought of as the 'outer or second' shell of ligands. Indeed comparative structural studies of the metal sites in four of the first known zinc enzymes, carbonic anhydrase, carboxypeptidase A, alcohol dehydrogenase, and thermolysin led to the identification of carbonyl and carboxyl 'orienters', or amino acids that formed H-bonds to the ligands to the metal.[7]

Many of the catalytic and structural zinc-binding sites contain His imidazole and Glu or Asp carboxyl groups as ligands to the zinc. The tight binding and often slow off rates for zinc from such sites is not expected based on the binding constants for imidazole and acetate binding to zinc. The pK_1 values for acetate and imidazole of $\sim$1.5 are not particularly strong.[2] Binding three imidazole groups and an acetate to a zinc would then be expected to have an overall binding constant of 10^5–10^7. However, the binding constant for zinc to the Thr199Glu mutant carbonic anhydrase II[8] that contains 3 His and 1 Glu as ligands is 5×10^{13}. The fact that so many catalytic zinc sites bind zinc with picomole binding constants, yet have imidazole and acetate as their ligands likely reflects their proximity and restricted mobility in the protein. A regular form of secondary structure can supply some of the correct orientation needed for good ligand binding to zinc. However, the stability and the function of the metal site is also likely influenced by the outer shell of residues in the vicinity of the metal-binding site. The secondary interactions of the ligands with ionic groups of the side-chain groups of the outer shell amino acid residues or the carbonyl oxygen of the backbone peptide chain may be critical to the formation and stabilization of the zinc sites containing oxygen, nitrogen, and sulfur ligands.

3.1.1 *Carbonic Anhydrases: Hydrophilic Orienters*

Examination of the effect of the orienters or indirect ligands on stability of the zinc-binding site and catalysis has been most thoroughly examined in the carbonic anhydrase α-class of enzymes.[9,10] There are currently X-ray crystal structures for catalytic zinc-binding sites of 5 of the mammalian α-carbonic anhydrases (Figure 3). The zinc ion is coordinated by the imidazole side chain of His94, His96 and His119 in all of these mammalian carbonic anhydrases. The three His ligands

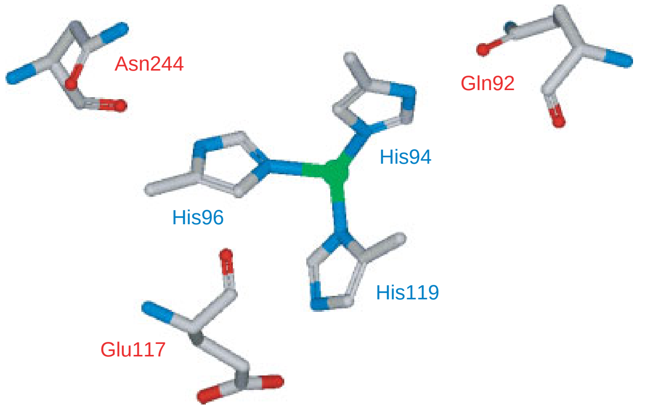

Figure 4 Catalytic zinc-binding site of human carbonic anhydrase II (pdb# 1CA2[12]) showing the zinc ligands NE2 of His94 and His96 and ND1 of His119 and their oxygen atom 'orienters' from Gln92, Ans244, and Glu117 respectively. Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

of these enzymes readily allow formation of zinc hydroxide, which can then add OH^- to CO_2 to form HCO_3^-. The amino acids adjacent to these zinc ligands are also highly conserved compared to the rest of the protein.[3] Thus, while the similarity scores for this set of proteins is between 60 to 99% the metal-binding site ligand sequence (9 amino acids used for each region) is above 90% for the majority of the sequences. In terms of identity of amino acids the overall structures are 35 to 95% identical while the metal-binding site sequences are 60 to 100% conserved. One of the reasons for this is that H-bonds are formed between Gln92 amide nitrogen and His94 and between the Glu117 carboxyl group and His119 (Figure 4). These interactions likely stabilize zinc binding and influence the function of the zinc in catalysis. In addition, the backbone carbonyl of Asn 244 accepts a H-bond from His96 and the hydroxyl group of Thr199 accepts a hydrogen bond from the zinc-bound water.[11] These residues are also conserved in all the carbonic anhydrase I-V enzymes.

Secondary ligand interactions are postulated to be involved in strengthening the metal complexation and/or modulating the nucleophilicity of the zinc-bound water.[13] Both interactions occur in the case of carbonic anhydrase based on the examination of functional and structural consequences of mutating the orientating residues Gln92, Glu117, Asn244 and Thr199.[11,14,15] The results indicate the zinc affinity is reduced by about a factor of five- to ten-fold when a native H-bond is eliminated. The effects also appear to be additive. Thus, the combined mutations of Gln92Ala and Glu117Ala leads to a 40-fold increase in the dissociation constant for zinc while the individual mutations lead to 4- and 10-fold increases, respectively.[11] The weakened binding of zinc is largely accounted for by an increased off-rate constant for zinc dissociation.

These secondary protein interactions would also be expected to affect the charge on the zinc. The interaction of hydrogen donating or accepting groups to the zinc ligands might therefore modulate the pK_a of the catalytic zinc-bound water resulting in changes in the nucleophilicity of the water and the ease at which it can expand its coordination shell or allow the zinc-bound water or hydroxide to be displaced. The pH dependence of the carbonic anhydrase II catalyzed hydrolysis of *p*-nitrophenylacetate was used to examine this postulate. In the wild type enzyme, it is characterized by a pK_a of 6.8, which is believed to reflect the ionization of the zinc-bound water molecule.[11] In the case of the Gln92Glu mutation in carbonic anhydrase II, a neutral hydrogen bond acceptor is replaced by a negatively charged acceptor. The positive charge on the zinc should therefore be reduced, which in turn should make the ionization of the water more difficult. The results of the functional studies confirm this relationship since the kinetically determined pK_a for the water increases by 0.7 units for this mutation.[11]

The reverse effect is expected for a mutation that removes this negative charge since this should increase the charge on the zinc leading to a lower pK_a for ester hydrolysis. Replacing Glu117 with Asp led to a slight decrease of 0.2 units consistent with a less favorable interaction of the Asp117 carboxylate with the His119 imidazole group. However, the results with Glu117Ala did not agree with the expectations. The pK_a values for the native and Glu117Ala mutant are 6.8 and 6.9 respectively. The value for the Ala mutant was expected to be lowered by as much as 1 unit owing to the loss of the anionic interaction with the His ligand. The X-ray studies found a chloride ion binding in the crystalline Glu117Ala mutant in the region of the Glu-117 carboxylate-His-119 interaction of the native enzyme.[15] The kinetic assays didn't contain any chloride ions but did use 0.1 M sulfate for controlling ionic strength.[11] If sulfate can bind in the same region as chloride, His119 may still have an interaction with an anionic species.

However, inspection of the X-ray structure of the native enzyme suggests another explanation (Figure 5). There are

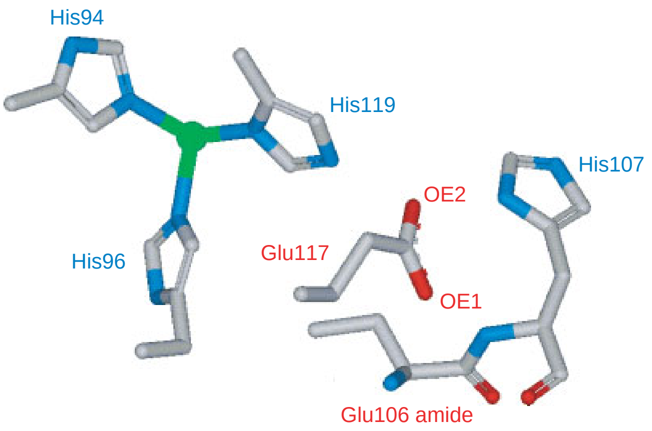

Figure 5 H-bonds to the side-chain carboxyl group of Glu117 of human carbonic anhydrase II (pdb# 1CA2[12]). Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

several potential H-bonds for the carboxyl group of Glu117 with other amino acids in its vicinity in the native enzyme. Thus, the OE2 of Glu117 is 2.57 Å and 2.93 Å from the NE2 of His119 and ND1 of His107, respectively (pdb # 1CA2[12]). In addition, the OE1 of Glu117 is 2.83 Å and 2.87 Å from the amide NHs of both His107 and Glu106. This intricate pattern of H-bonds would be expected to reduce the effect of relaying negative charge to the zinc ligand His119. Removal of this carboxyl group would therefore not be expected to change the charge on the His ligand in agreement with the results. The loss of the extensive H-bonding network to this ligand might be expected to be reflected in a relaxing of the conformation of this ligand, which could in turn lead to an increased off-rate for zinc dissociation. This is in fact what occurs for mutations of this ligand in contrast to the same mutations for His94 that does not have as extensive H-bonding network. Thus, the conversion of His94Ala leads to a 2-fold increase in the off-rate constant for zinc dissociation, while that for His119Ala leads to a 300-fold increase.[11] It is also of interest to note that a new H-bond is gained in the mutation of Gln92Glu. In this case, the OE1 oxygen of the carboxyl group of Glu92 is 2.94 Å from ND1 of His94 and is 3.01 Å from the amide NH of Phe93. This would tend to reduce the effect of relaying negative charge to the zinc and might place more constraint on the zinc ligand, His94, in the mutant enzyme. The fact that the zinc off-rate constant is now 6-fold slower than that of the native enzyme[11] is consistent with the increased H-bonding network found in the mutant enzyme.

3.1.2 Carbonic Anhydrase: Hydrophobic Orienters

The hydrophobic residues at positions 93, 95 and 97 are also highly conserved for this family of enzymes (Figure 3).[3] These residues are generally Phe for positions 93 and 95 and Trp for 97. The aromatic residues would be expected to restrict the motion of the His ligands and/or provide an environment of low dielectric constant that would enhance electrostatic interactions.[16] A cassette mutagenesis technique was used to select CA II enzymes mutated at positions 93, 95 and 97 that retained high zinc affinity.[17] The best variant enzymes contained Ile, Phe, Leu, and Met at position 93; Ile, Leu, and Met at position 95 and Trp or Val at position 97 in general agreement with what is found for this class of enzymes. When small hydrophilic residues are introduced at these positions, the zinc affinity decreases. Thus, the Thr-**His**-Ser-**His**-Val mutant compared to the native Phe-**His**-Phe-**His**-Trp enzyme has a 110-fold increased K_D for zinc essentially owing to an increase in the off-rate constant of 400-fold. The k_{cat}/K_m for the CO_2 hydrase and esterase activity is decreased 90- and 30-fold, respectively, but the pK_a for esterase activity doesn't change. The better zinc-binding and higher catalytic efficiency correlate with the combined volume of the residues at positions 93, 95, and 97.[17]

The effect of these amino acids on the zinc dissociation rate constant was also examined. Replacement of the hydrophobic amino acid by Ser at any position increased the zinc off-rate constant. The results suggested replacing the large aromatic residues at positions 93, 95, and 97 with smaller residues may increase the conformational mobility of the β-strand, permitting the adjacent histidines that coordinate zinc (His94 and His96) additional flexibility.[18] The variants with the slowest dissociation rate constant retain Trp at position 97. Comparison of the properties of the variants Ile 93 Met 95 Trp 97 and Ile 93 Met 95 Val 97 shows the affinity constant values for zinc are comparable, whereas the zinc dissociation rate constant increases 10-fold for substitution of Trp 97 with Val in agreement with the postulate of the aromatic residues anchoring the β-strand to reduce the conformational flexibility of His94 and His96 metal ligands.[18] The reason Trp97 is able to do this better than a Phe residue may be due to its indole NH. Inspection of the X-ray structure of the native enzyme (pdb # 1CA2[12]) indicates this NH is within H-bonding distance (2.75 Å) from the backbone amide carbonyl oxygen of Met241 (Figure 6). This amino acid is the last residue of a short (3-residue) β-strand and two amino acids removed from Asn244 that H-bonds His96 through its side-chain amide group. Disruption of this H-bond may therefore have an added effect on the increased zinc off-rate constants whenever Trp97 is replaced by other amino acids.

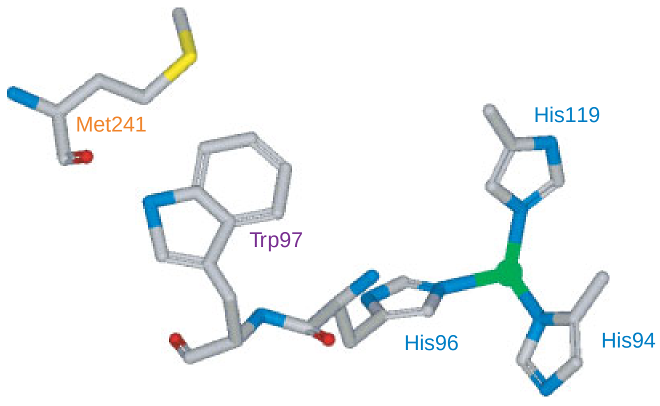

Figure 6 Amide of Met241 of human carbonic anhydrase II H-bonds to the indole NH of Trp100 (pdb# 1CA2[12]). Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

The results of studies of the cobalt- and copper-substituted mutants have indicated these hydrophobic residues may be important to retaining a tetrahedral geometry for the zinc site.[18] The correlation of the additive hydrophobicity of the amino acids bordering the metal ligands to copper binding strength is the reverse of that observed for zinc and cobalt. The lower their collective hydrophobicity the better the copper binding. The mutant enzyme Thr93Ser95Val97 binds copper 8×10^5 times more tightly than zinc. The inactive copper-substituted native enzyme has a bipyramidal geometry.[19] The results suggest the hydrophobic cluster of amino acids orients the His ligands to stabilize a distorted-tetrahedral geometry and to destabilize the bipyramidal geometry observed when copper binds.[18]

Although copper binds tighter than zinc to all forms of the enzyme tested, zinc stabilizes the protein fold better as judged by solvent-induced denaturation experiments. In addition the dissociation rate constant for zinc is about 100 times slower than copper suggesting the zinc is kinetically trapped once folding has occurred. This may thus be a physiological means by which metal ion specificity is achieved.[18]

3.1.3 *Metalloproteases*

The closely linked family of carboxypeptidases, CPD, and large group of proteases sharing an HExxH zinc signature serve to illustrate the variation in the level of scaffolding even in such closely related enzymes.[20] The CPD A family includes the A1-A5, B, B3, and U (R) enzymes (MEROPS M14A family)[21] while the CPD E family contains the D, E, X1, X2, and Z enzymes (MEROPS M14B family).[21] Both carboxypeptidase subfamilies show strong conservation of the ligands to the zinc (Table 1) and have an Asp residue from the C-terminal side of the first His ligand that H-bonds to its nonmetal bound NH (Table 2). This residue is conserved in 90 of the 92 sequences reported. This interaction will likely stabilize the zinc-binding site and make the ionization of the zinc-bound water more difficult since the negative charge on the carboxylate oxygen will be transmitted to the metal through the aromatic imidazole ring. The M14 subclasses of carboxypeptidases differ in some likely important aspects in their secondary ligand shell. The residues on each side of the second ligand, L_2, of the short spacer for the CPD A class are Arg71 and Trp73. The Arg residue is invariant in 56/56 sequences and the Trp residue in 53/56 (3 are His) sequences. In the case of the CPD E class, the L_2 minus one residue is Asn or Asp in 34/36 sequences while the residue equivalent to Trp73 varies considerable and is generally much smaller (15Val, 9Ala, 5Thr, 5 Pro, 1E, and 1 W). Trp residues can often stabilize the zinc binding to its ligands (see above) so its replacement by relatively small amino acids could destabilize zinc binding and/or increase the off-rate constant for zinc. The replacement of the positive Arg residue by a negatively charged Asp or neutral Asn residue would also effect the charge in the active site, which in turn could effect specificity and function of the enzyme.

A large number of the catalytic zinc sites in metalloproteases have either two His and a Glu or an Asp or three His ligands (Table 1). It is therefore generally assumed these sites behave the same with respect to the stability and catalytic function of the metal. However, the scaffolding differs even in relatively closely related family groups (Table 2). Thermolysin, neprilysin, mono-zinc aminopeptidases (represented by leukotriene hydrolase), matrix metalloproteinases, snake venoms (ADAMS), astacin and serriatia all have an HExxH metal-binding sequence containing the catalytic group Glu. Nevertheless, they all differ in the type of H-bonding interactions that occur with the His ligands of the short spacer (Figure 7).

The catalytic zinc site of thermolysin contains His142 and His146 from the short spacer and Glu166 from the long spacer arm. In this case two other conserved amino acids from the long spacer arm make interactions with the ligands from the short spacer arm. Thus, the carboxamide group of Asn165

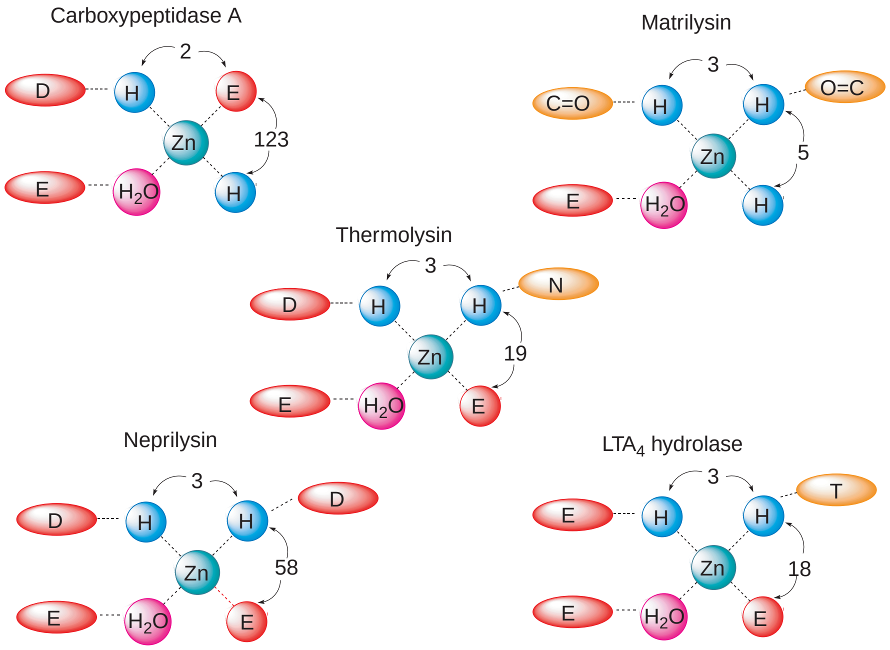

Figure 7 Scaffolding in catalytic sites of the metalloproteases, carboxypeptidase A (M14A), thermolysin (M4), matrilysin (M10A), neutral endoprotease (M13), NEP, Leukotreine Hydrolase,LTA_4 (M1)

[a]X-ray structures (Table 1) and the sequence information in the MEPORS 1.7 database[21] are source of information.

H-bonds His146 and the carboxylate of Glu170 H-bonds the NH of His142. Both residues are highly conserved (Table 2). In the neprilysin family, two acidic (Asp) amino acids that are supplied by the short and long spacer arms serve this function. The replacement of the Asn amide H-bonding group observed in thermolysin by an Asp carboxylate group in neprilysin should change the charge on the zinc.

A bifunctional zinc metalloenzyme, Leukotriene A4 hydrolase, catalyzes the rate-limiting step in the biosynthesis of leukotriene B4, a classical chemoattractant and immune-modulating lipid mediator.[22] It also acts as an aminopeptidase and is inhibited by aminopeptidase inhibitors. It has been placed in the aminopeptidase M1 class[21] based on it sequence similarities to aminopeptidases. It uses the carboxylate of Glu235 and the OH of Thr321, residing in the C-terminal arm of the third ligand, to H-bond to the first two His ligands (Table 2). The Thr likely H-bonds through the oxygen to the NH of the His ligand, which should remove charge from the zinc but not as much as a carboxylate. Thr321 is conserved in all 11 of the identified leukotriene enzymes but in the greater M1 class this residue is not highly conserved being Ala in several. The Glu325 residue in LTA4 hydrolase is also conserved in 11/11 sequences while in the greater aminopeptidase class this residues is Glu in several, replaced by Asp for the Ala aminopeptidases and varies greatly for 30 members of the141 sequence-postulated aminopeptidases.

A superfamily of metalloproteases, encompassing the protease classes[21] M10A&B and M12A&B use backbone amide carbonyls to H-bond the first two His ligands (Table 2). The amide carbonyl of the residue 3 amino acids away from the second His ligand on its C-terminal side H-bonds this His in all the subclasses. It is a highly conserved Leu for members of M10A&B and either a Phe/Ile or Met for the majority of the members of the M12A&B (Table 2). The first His is also H-bonded by an amide carbonyl of a hydrophobic aliphatic amino acid with spacers characteristic of each subclass of protease, varying from 16 to 53 amino acids away. The use of amide carbonyls to H-bond the His ligands would increase the positive charge on the zinc compared to the use of one or two carboxylates for the thermolysin and neprilysin families (Table 2). This in turn could favor the ionization of the zinc-bound water and the use of hydroxide as a nucleophile.

Similar scaffolding interactions occur in the cocatalytic sites of aminopeptidases as well (Table 2). A second type of interaction occurs in many of these sites. When only one of the oxygens of an Asp or Glu ligand binds the metal the other oxygen forms a H-bond with a Ser or Gln or its isosteric amino acid His. The particular type of interactions are again highly conserved and characteristic of the class of peptidase.

These secondary ligand interactions will likely effect the stability of the zinc site, the dissociation rate constant for zinc and the manner in which zinc participates in catalysis. Thus disruption of these interactions could lead to weakened metal binding and inactivation of the enzyme. If the secondary ligand changes the charge on the catalytic metal, it will change the capacity of the metal to act as a Lewis acid catalyst as well as effect its ability to influence the ionization of the metal-bound water.

3.2 Inhibition of Zinc Enzyme Catalysis

Since the zinc-bound water is one of the most critical components of the catalytic zinc site, there are three ways that one can envision inhibiting the metalloenzyme. Thus inhibition should occur if a potential inhibitor can displace the water by binding directly to the zinc, or remove the zinc ion from the protein or bind a second zinc ion to the catalytic zinc-bound water and/or another catalytic group (Figure 8).

3.2.1 *Inhibition of Catalysis by Removing the Zinc-bound Water or the Zinc*

The importance of zinc enzymes in both normal and pathological processes makes them targets for drug design. The active-site zinc in these enzymes is a particularly attractive target because the strength of a chelator-metal interaction increases the potency and specificity of an inhibitor. Zinc metalloprotease inhibitors are usually designed to inactivate the enzyme by displacing the zinc-bound water and forming a stable ternary complex with the enzyme and active-site zinc. The success of this approach with the angiotensin-converting enzyme (ACE) inhibitor Captopril ([2S]-N-L-3-mercapto-2-methyl-propionyl-L-proline) on the treatment of hypertension[23] led to the design of many types of metal-binding agents that displace the metal-bound water and in addition are designed to mimic the transition state of the enzyme. Popular groups are hydroxamates and thiolates for the C-terminal side, phosphoryl goups for the N-terminal side

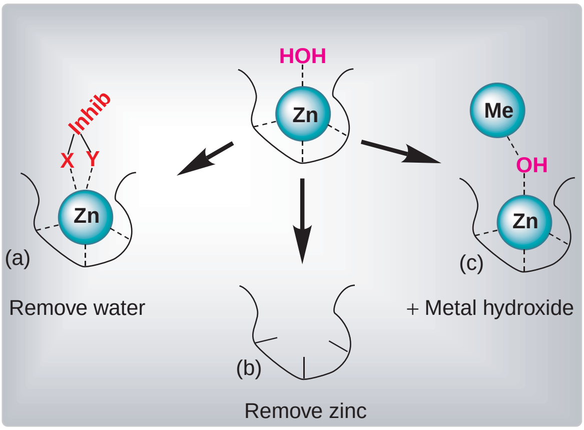

Figure 8 Inhibition of zinc metalloenzymes is accomplished by: (a) an Inhibitor displacing the zinc-bound water, (b) removing the metal, or (c) bridging an inhibitory zinc to the catalytic zinc

and carboxyalkyl and phosphinic acids as transition state or tetrahedral intermediate mimics.[24] Specificity can be built into the inhibitor on either side of the metal-binding ligand. Many of the crystal structures of zinc enzymes reported in the literature are in fact ternary complexes where the zinc-bound water has been displaced by the inhibitor. An excellent source of information on natural metalloprotease inhibitors is the MEROPS protease database.[21]

While there has been extensive research on inhibitors that bind by displacing the catalytic zinc-bound water, relatively little is known about the molecular mechanisms of how a metal-binding agent or chelator removes zinc.[25,26] In most cases, the zinc dissociation rate constant for the metalloenzyme is the controlling factor for such inhibition. D-penicillamine (D-PEN), a drug used for many years in the treatment of rheumatoid arthritis and Wilson's disease (*see* ***Metal-related Diseases of Genetic Origin***), was recently shown to be capable of catalyzing the removal of the metal from zinc proteases.[27] It is a member of the Cys family of amino acids. It differs from D-Cys by the presence of two methyl groups on the β-carbon. D-Cys inhibits carboxypeptidase A by displacing the zinc-bound water as might be expected since it contains a sulfhydryl binding group.[28] D-PEN in marked contrast inhibits by increasing the zinc dissociation rate constant for CPD by 420-fold and then acting as the receptor of the freed zinc ion.[27]

Complete removal of zinc and thus inactivation of the enzyme can be accomplished in these systems at low D-PEN concentrations if a secondary scavenger chelator is added to the system. Such chelators bind metal that has been released from the enzyme but do not participate in the release.[25,26] In the case of carboxypeptidase A, μM thionein (apo-metallothionen; *see* ***Metallothioneins***) inhibits catalysis by only about 10% over a 15-min period consistent with its action as a secondary chelator.[3] However, in the presence of 250 μM D-PEN and μM thionein total inhibition is achieved in less than 15 min. D-PEN accelerates zinc equilibration between carboxypeptidase A and thionein (Scheme 1). This is accomplished by D-PEN catalyzing the release of Zn from the enzyme. Since D-PEN is in vast excess over both the enzyme and thionein, the enzyme-released zinc would be expected to bind to D-PEN first. However, since thionein binds zinc more tightly than D-penicillamine and can accept 7 moles of zinc per mole of thionein, it should be the ultimate acceptor of the released zinc.

Consequently, the *in vivo* potency of D-PEN as a zinc enzyme inhibitor can be augmented by coadministration

$$\text{EZn} + \text{D-PEN} \rightleftharpoons \text{D-PEN}\bullet\text{E}{\sim}\text{Zn} \qquad [1]$$

$$\text{D-PEN}\bullet\text{E}{\sim}\text{Zn} \rightleftharpoons \text{Zn}^{2+} + \text{D-PEN}\bullet\text{E} \qquad [2]$$

$$\text{Zn}^{2+} + \text{D-PEN} \rightleftharpoons \text{Zn(D-PEN)}_2 \qquad [3]$$

$$\text{T} + \text{Zn(D-PEN)}_2 \rightleftharpoons \text{Zn}_7\text{T} + \text{D-PEN} \qquad [4]$$

Scheme 1

of secondary chelators or through the presence of natural chelators such as thionein or other metal-binding species. From a physiological perspective, such a mechanism of inhibition would be essentially irreversible, given the minuscule levels of *free* zinc believed present in the body.[29]

3.2.2 Inhibition of Enzyme Catalysis by Zinc

Investigations into the metalloenzyme nature of an enzyme frequently involves an attempt to inhibit it with a chelator, followed by reversal of any inhibition by adding excess metal.[26] If excess zinc doesn't reverse the inhibition, it may be due to the fact that zinc can inhibit the zinc enzyme. A considerable amount of anecdotal information exists that zinc inhibits zinc enzymes but how it accomplishes it is not well established. The most thorough study of its mechanism of inhibition is on CPD A.[30,31]

A combination of steady-state and presteady sate kinetic and spectral and chemical modification studies led to a mechanistic scheme in which inhibition occurs through the binding of the zinc-monohydroxide species to the active EH species of the enzyme (Scheme 2).[2] The pH independent constant for the inhibition by zinc is 0.71 μM. The derived pK_a of 6 for the inhibition studies agrees with the corresponding value obtained in peptide hydrolysis experiments for the group, EH_2, whose ionization leads to formation of the catalytically active form of the enzyme.

The ionizable ligand, EH_2, is assigned to Glu270, since chemical modification of this residue with CMC (1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide) decreases the binding affinity of carboxypeptidase A for zinc and lead by more than 60- and 200-fold, respectively.[31] A bridging interaction between the Glu270-coordinated zinc hydroxide is implicated by the ability of Zn and Pb to induce a marked increase in the visible absorption spectrum of the cobalt enzyme within 20 ms of mixing 10^{-4} M Zn or Pb with 10^{-4} M cobalt enzyme.[31]

Based on the spectro-kinetic and chemical modification studies, a binding mode for the inhibitory zinc ion was proposed to account for its inhibition (Figure 9).[30] The zinc-monohydroxide ion binds to the ionized carboxylate of Glu270 and displaces the zinc-bound water. The inhibitory zinc bridging interaction explains both the loss of metal binding upon chemical modification of Glu270 or lowering pH as well as the increase in absorbance in the cobalt enzyme upon binding lead or a zinc ion. Removal of the Glu270 carboxylate through protonation or chemical modification should decrease inhibitory metal binding. Replacement of the catalytic cobalt-bound water molecule with the hydroxide anion should lead to an increase in visible absorbance (as is observed when azide binds to the metal). A water molecule and a chloride anion complete the zinc inhibitory site since chloride enhances the inhibition by zinc and lead. The K_i values for the charge-neutral Zn(OH)Cl and Pb(OH)Cl are both about 5×10^{-7} M.[30] If the inhibitory

$$Zn^{2+} \overset{K_1}{\rightleftharpoons} ZnOH^+ \overset{K_2}{\rightleftharpoons} Zn(OH)_2 \overset{K_3}{\rightleftharpoons} Zn(OH)_3^- \overset{K_4}{\rightleftharpoons} Zn(OH)_4^{2-} \qquad [5]$$

$$EH \cdot ZnOH^+ \overset{K_{I,\,lim}}{\rightleftharpoons} EH + ZnOH^+ \qquad [6]$$

$$EH_2 \overset{K_{EH_2}}{\rightleftharpoons} EH + H^+ \qquad [7]$$

Scheme 2

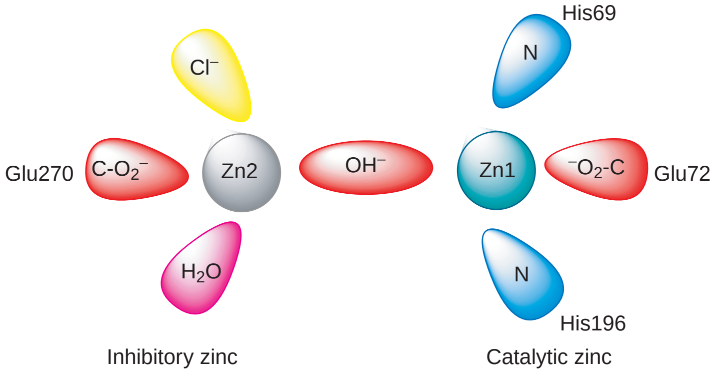

Figure 9 Schematic of inhibitory zinc-binding site in carboxypeptidase A

metal-monohydroxide complex is charge-neutralized by a multidentate ligand that can bind to other active-site residues, an even lower inhibition constant can be anticipated. Such inhibitory complexes could be very important to regulatory processes and/or toxicological processes involving Pb or other heavy metals with zinc enzymes.

This mode of zinc inhibition is confirmed in its entirety by two different crystallography studies of carboxypeptidase A.[32,33] A 1.7 Å structure of the crystalline carboxypeptidase A that was dialyzed versus 0.33 mM $ZnCl_2$ reveals a second zinc bound in a distorted tetrahedron composed of the carboxylate of Glu270, a water molecule, a chloride ion and a hydroxide ion.[32] The hydroxide forms a 114° angular bridge between the inhibitory and the catalytic zinc ions. The inhibitory zinc holds the hydroxide at the same location as the catalytic zinc-bound water molecule in the uninhibited enzyme. Superposition of the benzylsuccinate inhibitory complex on the $ZnOH^+$ inhibited complex demonstrates that the carbonyl group of the inhibitor and the inhibitory zinc ion are almost the same indicating the second zinc ion should interfere with proper positioning of the substrate.[32] This is consistent with the competitive inhibition observed with both zinc and lead.[30]

A similar type inhibitory zinc-binding site is observed in crystals of thermolysin.[34] The features have been compared to those for carboxypeptidase A.[32] The inhibitory zinc to catalytic zinc distance is 3.2 Å for thermolysin and 3.3 Å for carboxypeptidase A. A water/hydroxide bridges the two sites with a similar geometry, 116° in thermolysin and 114° in carboxypeptidase A. In thermolysin, the coordination sphere is completed by Tyr157, His231 and one of the carboxylate oxygens of Glu166. The latter is particularly interesting since it is the third ligand to the catalytic zinc as well. This inhibitor site therefore resembles the cocatalytic sites seen in many hydrolytic enzymes (Table 3). It therefore means the structural detection of multiple metal-binding sites should always be accompanied with functional studies to discern whether the metal site is active or inhibitory.

This type of inhibitory zinc binding is also observed in other zinc enzymes. The zinc-dependent UDP-3-O-acyl-N-acetylglucosamine deacetylase (LpxC) catalyzes the first committed step in the biosynthesis of lipid A, the hydrophobic anchor of lipopolysaccharide (LPS) that constitutes the outermost monolayer of gram-negative bacteria.[35,36] The catalytic zinc is bound to the NE2 nitrogens of His79 and His242, and an oxygen of the carboxyl group of Asp238 (Table 1).[35,36] (Note the spacing of the first amino acids differs in these studies owing to the numbers given). Mutation of Glu78 to Ala removes zinc inhibition of the enzyme.[36] Based on this finding and the earlier studies of carboxypeptidase A,[30–32] the authors proposed the inhibitory zinc bridges to the catalytic zinc by a water/hydroxide ion. Addition of excess zinc to the crystalline enzyme leads to the observation of two

[a]The amino acid residue that bridges the two-metal sites is shown in ***italic bold face***. When the symbol H_2O is given this may represent from one to three metal-bound water molecules. R is the distance between the metal atoms. When Trp is listed as a ligand, the α-amino and a amide carbonyl are the ligands. See footnote of Table 1 for the definitions of other terms.

zinc ions bound in the active site in much the same fashion as is observed in the metalloproteases discussed above.[35] The postulated inhibitory zinc ion binds 3.4 Å from the catalytic zinc (pdb 1P42). The second zinc binds in a tetrahedral coordination geometry to a solvent molecule, the NE2 nitrogen of His265, and an oxygen from the carboxyl groups of Glu78 and the fatty acid inhibitor, myristic acid.[36] The binding of the inhibitory zinc to the carboxylate of the myristic acid is reminiscent of the binding of similar inhibitory complexes in carboxypeptidase A.[31] The invariant residues, Glu 78 and His265, of the enzyme LpxC are believed to play the same roles in catalysis as Glu166 and His231 do in thermolysin on the basis of the structure of the inhibitory zinc site.

Examination of the crystals of yeast cytosine deaminase shows a second zinc ion coordinated to the active site by a bridging water/hydroxide ion to the catalytic zinc ion. This zinc ion has three other water molecules bound to it some of which have very short (~1.8 Å) bonds to the second zinc.[37] This may represent an inhibitory zinc ion that has bound to the protein with more than one hydroxide ion coordinated to the zinc.

Zinc also inhibits a variety of nonmetalloenzymes.[3] Inhibition constants in the nM range are observed in some cases. In these situations it is possible that the zinc could be involved in regulating the activity of the enzyme. Thionein has been demonstrated to reverse the inhibition glyceraldehyde-3-phosphate dehydrogenase by zinc ions, suggesting the possibility that thionein (apo-metallothionien; *see* ***Metallothioneins***) can be involved in a regulatory capacity with zinc as its partner.[38]

The fact that zinc inhibits enzymes has also been used to design new serine protease inhibitors.[39,40] The type of zinc ligand is important to the inhibition. Thus the zinc-bound bis(5-amidino-2-benzimidazolyl)methane, BABIM, and derivatives of it inhibit several human serine proteases with an inhibition constant of 1 to 25 nM. Zinc increases the inhibition by the agent up to 10 000 times. For example, the K_i for BABIM inhibition of trypsin decreases from 19 µM to 5 nM in the presence of 100 nM zinc ions at pH 8.2.[39] The crystal structure of trypsin cocrystallized with BABIM and zinc shows zinc tetrahedrally coordinated to two nitrogens of BABIM and two of the catalytic triad residues, His57 and Ser195. This type of zinc-binding site is quite similar to that observed for the inhibition of zinc proteases by zinc ions. Thus, the inhibitory zinc is bridging two catalytic components His57 and Ser195 for trypsin and Glu270 and a zinc-bound hydroxide for carboxypeptidase A. In these enzymes, the zinc hydroxide and serine oxide are the nucleophiles and the glutamate carboxyl group and His imidazole are the general acid/base catalysts. Prostrate specific antigen, PSA, or prostrate kallikrein is a serine protease that is inhibited by zinc and mercury ions.[41] One of the three zinc-binding sites in the crystalline enzyme is to Asp91, His101 and His234 and a water molecule. It has been postulated that zinc binding could distort the catalytic triad through minor movements of His101 since it is next to catalytic triad residue Asp102.

3.3 Specific Zinc Enzymes

The large number of this class of enzymes makes it difficult to cover the properties of each specific member in any detail. Many have been commented on in other general reviews on this class of enzymes.[3,4] However, some brief comments will be made on some newer members.

3.3.1 Alcohol Dehydrogenases

The ligand nature of the catalytic zinc site varies considerably for the overall grouping of the dehydrogenases but is quite constant for the subfamilies (Table 1). The dimeric mammalian ADHs are NADH-dependent and have two Cys and one His as ligands to a catalytic zinc site (Table 1). The crystal structures of several tetrameric bacterial ADHs have been reported recently. The medium chain alcohol dehydrogenases from thermostable *Thermoanaerobacter brockii*, TBADH,[42,43] originally isolated from a Yellowstone Park hot spring, its mesophilic counterpart *Clostridium beijerinckii*, CBADH,[44] and the archaeon ADH from *Aeropyrum pernix*[45] are all NADP(H) dependent while the archaeon SsADH from *Sulfolobus solfataricus*[46] is NADH-dependent. The catalytic zinc sites of the former NADP(H)-dependent enzymes all have the Cys and His ligands separated by a spacer of 21 to 24 amino acids similar to other ADHs (Table 1). They differ in that the third ligand is now an Asp residue rather than a Cys. All have water as the fourth ligand.

The catalytic zinc site of the NADH-dependent archaeon SsADH is closer to the dimeric ADHs in that it has a Cys as its third ligand. The presumed fourth ligand water is not found, however. The Glu residue next to the second His ligand is now bound to the zinc.[46] The carboxylate oxygens of the equivalent Glu residue in the other tetrameric ADHs are 4 to 7 Å removed form the zinc (pdb files 1KEV, 1H2B, 1YKF). In CBADH this Glu residue is a zinc ligand in the Nicotinamide adenine dinucleotide phosphate (NADP)-free form of the enzyme.[42] However, the distance between the carboxylate oxygen and the zinc increases from 2.35 to 3.94 Å upon binding the coenzyme. In the human $\chi\chi$ alcohol dehydrogenase, ADH, the equivalent residue, Glu68 is observed 2.9 Å and 2.0 Å from the catalytic zinc in the A and B subunits respectively.[47] In other human and horse ADHs, the carboxylate oxygens are at least 4.7 Å from the catalytic zinc atom. The binding of the Glu to the zinc in this case may be a reflection of the involvement of Glu68 in the displacement of water in a late step-in catalysis as predicted by molecular dynamics calculations.[47,48]

3.3.2 Sorbitol Dehydrogenases

The Glu residue that is sometimes seen as a ligand in the ADHs is also a ligand in some of the structures of the

sorbitol dehydrogenases (SDH) (Table 1). This enzyme and aldose reductase form the polyol pathway that interconverts glucose and fructose. Overproduction of the coenzyme NADH by SDH may play a role in diabetes-induced dysfunction in sensitive tissues.[49] Human SDH is a tetramer that has a catalytic zinc coordinated by Cys44, His69, Glu70 and a water molecule in both the apo and NAD^+ complex.[49] The inhibitor CP-162,572 coordinates the zinc through the N1 nitrogen of its pyrimidine ring and an oxygen of its hydroxymethyl substitutent causing the dissociation of Glu70. The inhibitor forms hydrophobic interactions to NADH and likely sterically occludes substrate binding.

The silverleaf whitefly, *Bemisia argentifolii* ketose reductase (BaKR), is tetrameric, with the monomer having a very similar fold to the alcohol dehydrogenases (ADHs).[50] The catalytic zinc ion is tetrahedrally coordinated to Cys41, His66, Glu67, and a water molecule in the enzyme form lacking its coenzyme NADP(H) as is seen in the hSDH. The residue equivalent to the third Asp ligand in the tetrameric ADHs is Glu152 in BaKR. The carboxylate of this residue hydrogen bonds the zinc-bound water. Glu152 has been reported to be the third ligand in rat SDH in place of the Glu67 observed in hSDH and BaKR.[51]

The sequence of *Bacillus stearothermophilus* glycerol dehydrogenase (GlyDH) indicates that it is a member of the third grouping of ADHs, the so-called iron-containing alcohol dehydrogenase family. However it has a strict dependence on zinc for activity.[52] It catalyzes the oxidation of glycerol to dihydroxyacetone (1,3-dihydroxypropanone) with concomitant reduction of NAD^+ to NADH. The catalytic zinc is bound to the NE2 nitrogens of His274 and His256, an oxygen of the carboxylate of Asp173 and a water molecule.[52] The ligand nature of the catalytic zinc site is similar to the tetrameric ADHs but the first cysteine ligand is now replaced by a histidine (Table 1).

3.3.3 Hydrolases

This is the largest class of zinc enzymes. The detailed description of the properties of just the metalloprotease group is a major section of a new handbook of proteases.[53] This perspective will therefore only highlight the results of a few novel findings in recent 3-dimensional structures.

Angiotensin-converting enzyme (ACE) plays a critical role in cardiovascular function by catalyzing the cleavage of the carboxy-terminal His-Leu dipeptide from angiotensin I to produce a potent vasopressor octapeptide, angiotensin II. Inhibitors of hypertension were designed in the 1970s on the basis of an assumed mechanistic homology with carboxypeptidase A. Such inhibitors are a first line of therapy for hypertension, heart failure, myocardial infarction, and diabetic nephropathy.[54] Much effort has been put into obtaining a crystalline structure of the enzyme. However, this was not accomplished until very recently when the X-ray structure of human testicular ACE and its complex with one of the most widely used inhibitors, lisinopril (N2-[(S)-1-carboxy-3-phenylpropyl]-L-lysyl-L-proline; also known as Prinivil or Zestril) was reported at 2.0 Å resolution.[54] Analysis of the three-dimensional structure of ACE shows that it bears little similarity to that of carboxypeptidase A, but instead resembles neurolysin[55] and *Pyrococcus furiosus* carboxypeptidase[56] zinc metallopeptidases that have little sequence similarity to ACE. The active site of testicular ACE corresponds to the C-terminal domain of somatic ACE.[57] The somatic ACE contains active sites in its C-and N-terminal domains, which presents new opportunities in drug design.[58]

Mycothiol (1-D-myo-inosityl 2-(N-acetyl-L-cysteinyl) amido-2-deoxy-alpha-D-glucopyranoside, MSH or AcCys-GlcN-inositol (Ins)) is the major reducing agent in actinomycetes, including *Mycobacterium tuberculosis*.[59] The biosynthesis of MSH involves a zinc-dependent deacetylase, MshB, that removes the acetyl group from the precursor GlcNAc-Ins to yield GlcN-Ins. The 3-dimensional structure reveals a protein that folds in a manner resembling lactate dehydrogenase in the N-terminal domain. The catalytic zinc-binding site is in the N-terminal domain occupying a position equivalent to that of the NAD^+ coenzyme of lactate dehydrogenase. The zinc ion binds to the ND1 nitrogen of His13, the NE2 nitrogen of His147, a carboxylate oxygen of Asp16 and two water molecules. One of the waters is hydrogen-bonded to Asp15. This residue would therefore be in the position of the Glu residues believed to be the general acid/base catalyst in many metalloproteases. This would be the first instance in a metallohydrolase where an Asp residue would be the acid/base catalyst. In addition to the zinc providing electrophilic assistance by allowing substrate to displace the second water molecule, the imidazole of His144 is in a position to form a hydrogen bond to the oxyanion of the tetrahedral intermediate.[59]

The deamination mechanism of *E. coli* cytidine deaminase (CDA) is believed to be similar to that of *E. coli* adenosine deaminase (ADA).[60,61] However, the zinc-binding site of the ADA contains 3 His residues while that of CDA contains two Cys and one His residue (Table 1). Examination of the structures of transition state analogs show that the inhibitor complex is stabilized by a zinc hydroxide and an adjacent carboxyl group of an Asp or Glu residue in the active site. The differences in zinc ligands and tertiary structures of the dimeric ADA and CDA have led to the proposal that the common features in the transition state stabilization have arisen from convergent evolution.[60] The variation in the zinc-binding site in this functional class of enzymes is also evident in the tetrameric *Bacillus subtilis* cytidine deaminase that has three Cys ligands, Cys89, Cys86, and Cys53[62] in agreement with sequence alignment that led to the proposal of the three Cys ligands.[63]

3.3.4 β-Carbonic Anhydrases

The β-class of carbonic anhydrases includes CAs from plants, algae, bacteria, and archea.[64,65] The higher plant and

unicellular green algae use the β-CAs for photosynthetic CO_2 fixation. The three-dimensional structures *Pisum sativum* β-CA,[66] *Porphyridium purpureum* β-CA,[67] and *Methanosarcina thermophila* β-CA[68] show that this group of carbonic anhydrases has a strikingly different catalytic zinc coordination site from the mammalian class (Table 1). In all cases, the catalytic zinc is coordinated by two Cys and a His as was anticipated by XAFS studies of the spinach CA.[69,70] Two of the ligands, His87 (NE2) and Cys90, are supplied by a loop region and a β-sheet, respectively and are separated by a short spacer of two (Table 1). The third ligand, Cys32 (*M. thermophila* β-CA numbering), is supplied by a β-sheet from the N-terminal side. The structure reported for the *P. purpureum* β-CA[67] has an additional Asp coordinated to the zinc and no bound water molecules. On the basis of this structure, it was proposed that this β-CA and possibly the γ-class of CAs do not use a zinc hydroxide mechanism in their function.[67] However, in the other two reported structures the fourth ligand is a solvent molecule (acetate) for *P. sativum* β-CA[66] and a water molecule for *M. thermophila* β-CA.[68] The putative Asp ligand exists in all three enzymes in a highly conserved loop region C-terminal to the third Cys ligand (CysXAspSerArg). In the enzymes in which the Asp is not a ligand, the Arg guanidinium group is hydrogen-bonded to the Asp carboxyl group preventing it from coordinating the zinc.[68] The zinc-coordinated water molecule in the *M. thermophila* β-CA has therefore been displaced by either an acetate carboxylate in the *P. sativum* β-CA or the carboxylate of Asp151 in the *P. purpureum* β-CA. Further studies will be needed to determine what is the function of the Asp residue in question. However, comparison of the α- and β-CA catalytic zinc sites is of interest in this regard. The positive charge on the zinc in the β-CAs should be reduced by the replacement of two His imidazole ligands by Cys sulfur ligands. The ionization of the zinc-bound water molecule might therefore need the assistance of a neighboring carboxyl group as is postulated in metalloproteases.[2,20,71] A role for Asp151 in catalysis rather than zinc binding could be inferred from the results of a mutation of this residue to an Asn in spinach β-CA.[72] The resulting enzyme still binds zinc but retains little CO_2 hydratase activity.

The γ-class of CAs has one structural representative from *Methanosarcina thermophila*.[73,74] While it retains three His ligands as in the α-class, the spacing characteristics change (Table 1). The resulting trimeric enzyme forms a zinc site from the interface of its subunits (*see* 6.1.2 and Table 5).

3.4 Mechanisms of Zinc Enzymes Containing Catalytic Zinc Sites

A number of representatives from the enzymes containing catalytic zinc sites have been extensively studied by both functional and structural means. This group of zinc sites is too large for this perspective to do justice to this voluminous body of work on so many enzymes. However, there are several recent sources of information on the properties of these enzymes and their mechanism of action. The Handbooks on Metalloproteins[75,76] are particularly good sources for a number of the zinc enzymes having catalytic zinc sites. The large class of metalloproteases is extensively covered in the Handbook of Proteolytic Enzymes,[53] including a separate chapter on their mechanism of action.[20]

4 COCATALYTIC ZINC SITES

Cocatalytic zinc sites occur in metalloenzymes where two or three metals are closely spaced to bring about catalysis. There are over five dozen representatives of this type of zinc site with the great majority belonging to the Class III hydrolases (Table 3). The fact that many zinc enzymes required more that one metal for full activity was known for many years. However, the location of these metals relative to one another was often in debate. Prior to structural analyses these metal atoms were often referred to as a combination of a catalytic zinc site and a ‘modulating’ or ‘regulatory’ zinc.[77] The metal can usually be removed from a catalytic zinc site without a major effect on the structure of the protein. However, cocatalytic metal sites are often formed from ligands that extend over a large portion of the protein structure. It is therefore not unreasonable that enzymes containing two or more metals in the absence of a structure have been described as having one catalytic metal and a second metal that has structural and/or regulatory effects on activity. Thus far, three-dimensional structures of these enzymes show the metals are always in close proximity.

The alkaline phosphatase family contains three metals in the active site while the rest of the cocatalytic zinc sites contain two metals (Figure 10) (Table 3). Some of these sites contain metals such as copper, iron, and magnesium in combination with zinc. Combinations of Cu(II)/Zn are seen in the superoxide dismutase (SOD) family (*see* ***Copper Proteins with Type 2 Sites***), Zn/Mg are seen in alkaline phosphatase family and lens aminopeptidase, and Fe(III)/Zn in the purple acid phosphatase family.

The bridging of two of the metal sites by a side-chain moiety of a single amino acid residue, usually Asp, and sometimes a water molecule is a novel characteristic of these sites.[6] In principle, any sp^2 center containing two nucleophilic atoms should have a bridging potential. Thus, the carboxylate oxygens of Asp or Glu, or of a carboxylated lysine, LysCO-2, or the ring nitrogens of the imidazole group of His are found to bridge such sites. This bridging interaction of the amino acid requires the metals to be in close proximity to each other. The distance between the metals in these sites depends on the bridging amino acid. In the case of an Asp, Glu, or LysCO-2 carboxylate, it is generally between 3 and 4 Å (Table 3). In the case of a His imidazole group the distance increases to about 6 Å.

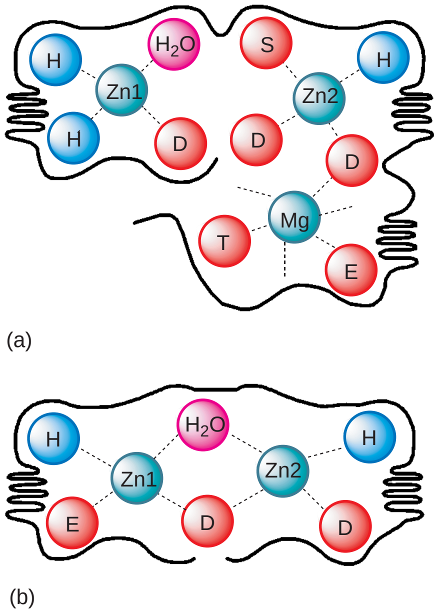

Figure 10 Schematics of three-metal cocatalytic sites (a) represented by *E. coli* alkaline phosphatase,[78] and two-metal cocatalytic sites (b) represented by *Aeromonas proteolytic* amino peptidase.[79] The one-letter codes D, E, and H are given for the amino acids Asp, Glu, and His respectively

Asp and His predominate as ligands in cocatalytic zinc sites where the frequency is Asp $\simeq$ His > Glu. These sites also occasionally contain unusual zinc ligands such as amide carbonyls provided by Asn, Gln, and the peptide backbone; hydroxyl groups from Ser, Thr, and Tyr and the amine nitrogen of Lys or the N-terminal amino group of the protein. Perhaps remarkable is the low utilization Cys ligands in these metal sites. Since the ligands to cocatalytic zinc sites often come from nearly the entire length of the protein, the metals may be also important to the overall fold of the protein as well as catalytic function. The secondary structure of the protein plays a major role in providing the ligands to these sites. Some of the families use almost exclusively β-sheets to provide the ligands while other families use all α-helices (Table 3). In many cases ligands are provided by amino acids residing 1 or 2 residues before or after a β-sheet or an α-helix. The zinc ions are often pentacoordinate and arranged in a trigonal-bipyramidal geometry.

4.1 Mechanism of Cocatalytic Enzymes

The bridging amino acids and H_2O likely have critical roles in catalysis. Thus, their dissociation from either metal atom during catalysis will change the charge on the metal promoting its action as a Lewis acid or allowing interaction with an electronegative atom of the substrate. In addition, a released bridging ligand can participate transiently in the reaction as a nucleophile or general acid/base catalyst. The flexibility of the arm supplying the bridging ligands (e.g. one carbon, C, for Asp and His, 2 C for Glu or 5 C/N for LysCO-2) would be expected to influence the stability and reactivity of the two-metal sites. Thus, it can be envisioned for cocatalytic sites in hydrolytic enzymes that substrate binding involves one zinc site acting as a template for substrate binding while the other zinc provides hydroxide for nucleophilic attack on the sp^2 center of the ester or amide bond of the substrate. In the next step the roles of the metals can be reversed. In this manner, the metal atoms and their associated ligands play specific roles in each step of the reaction that works to bring about catalysis. The ligands in these sites, in particular, the histidines, are often involved in further hydrogen-bonding interactions with other amino acids. These interactions should effect the charge on the metal and the stability of the metal complex thus fine tuning catalysis and the stability of the metal sites.[3,20]

The reader is referred to the following sources of further information on the specific cocatalytic enzymes: superoxide dismutase,[80] and the reduced form,[81] alkaline phosphatases,[78,82] nuclease P1,[83] purple acid phosphatase,[84,85] amidohydrolase,[86,87] leucine aminopeptidase,[88] general comments on the mechanisms of the phosphatases[89] and aminopeptidases,[89,90] and other cocatalytic zinc enzymes.[76]

5 STRUCTURAL ZINC SITES

The early structural studies of metalloenzymes led to the suggestion that metal atoms that have a catalytic role would be composed of ligands from different parts of the polypeptide chain whereas ligands to metal atoms in structural sites would be close together. We now know that both types of zinc sites generally contain at least two ligands that are separated by a short spacer.[4,91] In addition, while many structural zinc sites are composed of ligands from a relatively short sequence in the protein, this is not always the case as might be anticipated from inspection of disulfide structural elements that often come from vastly separated regions of the protein primary structure.

The role of structural zinc sites is likely two-fold. They maintain the structure of the protein in the immediate vicinity of the metal site. In this manner it may influence enzymatic activity by providing active-site residues involved in catalysis and/or effecting the chemical environment of catalytic groups through interaction with amino acids originating from within its metal-binding spacers. However, in many cases, these metal sites also effect the overall stability of the protein as judged by temperature and pH criteria.

While zinc can readily form four-, five-, and six-coordinate complexes, structural zinc sites in proteins have 4 protein ligands and no bound water molecule. This type of coordination is also observed in many of the *Protein Interface* zinc sites.[3,4] The first zinc enzymes recognized to have a

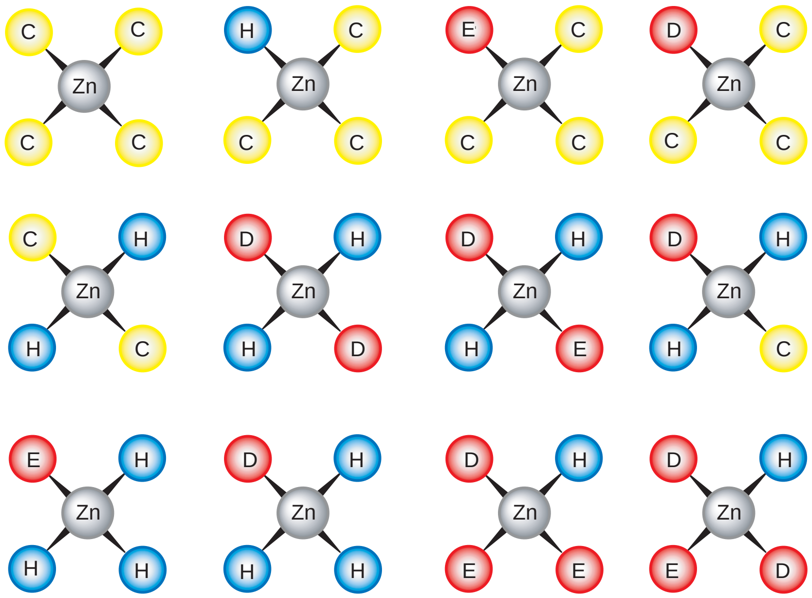

Figure 11 Schematic of the four-coordinate zinc sites observed thus far in terms of the type of bound ligands. The one-letter codes C, D, E and H are given for the amino acids Cys, Asp, Glu, and His, respectively

structural zinc site were horse liver alcohol dehydrogenase, ADH,[92] and the regulatory subunit of *E. coli* aspartate carbamoyltransferase.[93] In both cases the zinc is bound to four cysteines in a relatively short linear sequence of 15 to 33 amino acids, respectively. There are today more than eleven dozen structural zinc sites with representatives in all six enzyme classes defined by the International Union of Biochemists. The ligands to these metal sites are provided by protein sequences as small as 10 amino acids and as large as 212 amino acids but the majority fall within the range of 15 to 40 amino acids (Table 4). There is nearly always one short spacer separating two amino acids in these sites. The ligands are frequently supplied from within or just before or after a β-sheet secondary structure. Several ligands are supplied by a short amino acid sequence of 3 to 6 amino acids (loop) between two peptide regions of regular (β-sheet or α-helical) secondary structure. The majority of these loop regions are composed of two β-sheets. While the sulfur of a Cys is by far the preferred ligand for such sites, it is also found in combination with an imidazole nitrogen of His, and/or a carboxylate oxygen from Asp or Glu. The second most prevalent ligand is histidine.

The presence of His and/or Cys in the same zinc-binding site frequently gets some form of a ‘zinc-finger’ nomenclature (*see* ***Technetium: Organometallic Chemistry***). Based on only ‘loose’ criteria, some of the sites listed here are still referred to as zinc-finger domains,[94] even if they do not fit the criteria of having DNA-binding properties and/or the ligand nature (2His/2Cys), sequence length (~30 amino acids) and presence of both α-helix and β-sheets in the zinc-binding site associated with a classical zinc finger.[95] Several reviews exist on the expansion of this nomenclature in the area of zinc protein sites interacting with nucleic acids (*see* ***Zinc: DNA-binding Proteins***).[96–100]

The expansion of this nomenclature thus far deals mainly with the type of secondary structure present in combination with Cys and His ligands. However, even if one considers only the four main amino acid ligand donors, Cys, His, Asp and Glu, there are 22 permutations of a zinc bound to these four ligands, 12 of which have been observed in zinc enzymes and zinc proteins (Figure 11, Tables 4–6). Several other features of the site can also be important to the resulting influence of the zinc ion. These include the type of secondary structure, outer shell interactions, how many short spacers occur and the order of the ligand donors. This is likely the reason for the frequent use of the word novel in describing new zinc-binding sites owing to the difficulty in classifying the site in terms of the relatively small number of proposed names such as zinc-box, -bundle, -cluster, -finger, -knuckle, ribbon, -ring, etc. The one feature they have in common is the presence of four protein ligands and no coordinated water molecule.[4,5,91]

5.1 Structural Sites Involved in Function

Some of these sites can effect function in zinc proteins as well as stabilizing structure. The hydrolase class of zinc enzymes are good examples of this action.[91] In this case, one or more amino acid residues within the active site may be provided by the amino acid spacers between zinc ligands (Figure 12). The side chain of these amino acids may be involved in substrate binding, bond cleavage or modulating the chemical environment of the active site. In addition, other active-site residues are often provided by

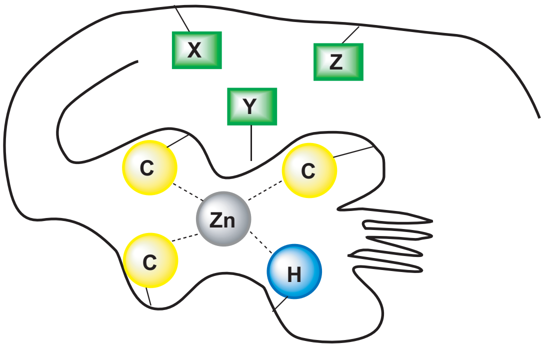

Figure 12 Schematic of a structural zinc-binding site that provides active-site residues from amino acids located within the metal-coordination spacers. Other active-site residues are often provided by the peptide sequence N-terminal to the structural zinc site. The symbol Y can represent more than one amino acid. (Table 4)

the peptide sequence N-terminal to the structural zinc site. Some structural zinc sites that exert influence on function are given below.

5.1.1 *Formamidopyrimidine-DNA Glycosylase Family*

The bacterial formamidopyrimidine-DNA glycosylase (alias Fpg or MutM) is a bifunctional base-repair enzyme (DNA glycosylase/AP lyase) that removes a wide range of oxidized purines from oxidatively damaged DNA.[101] The crystal structures of the Fpg (MutM) enzymes from *Thermus thermophilus*,[102] *Lactococcus lactis*,[101] *Escherichia coli*,[103] *Bacillus stearothermophilus*[104] and the sequence similar endonuclease VIII (Nei) from *E. coli*,[105] all share the same type of structural zinc-binding site at the end of the C-terminus of the proteins. This zinc site is composed of four cysteine sulfur ligands (Table 4). The first three cysteines are supplied by two β-sheets. The zinc site influences the function of the enzyme through an amino acid located within its metal-binding spacer. The guanidinium group of an Arg residue from within the large central coordination spacer makes two H-bonds with the p^{-1} and p^0 phosphates of the pyrimidine cleavage site of the substrate. In addition, several other binding interactions come from the N-terminal side of the zinc-binding site.

5.1.2 *Rhinovirus-2 Proteinase*

The human 2A proteinase from the common cold (rhinovirus) is structurally related to the cysteine proteases.[106] Its active site contains a characteristic catalytic AspHisCys triad. This proteinase also contains a structural zinc-binding site in the N-terminus of the protein composed of Cys52, Cys54, Cys112 and His114 as ligand donors (Table 4). Two β-sheets supply the last three amino acids. The site is believed to be structural since it is not accessible to other ligands and is unlikely to have any functional role in RNA binding. Chelation and site-directed mutagenesis studies indicate the zinc is essential for formation of an enzymatically active form of the enzyme.[107,108] The zinc-depleted enzyme shows mostly unchanged secondary structure as determined by CD spectroscopy, but not a fully denatured random coil as obtained by the presence of guanidinium hydrochloride.[109] The zinc may therefore be stabilizing a local conformation of the protein that is critical for activity.

This zinc site likely influences enzymatic function through its effect on local conformation. In this case, the crucial catalytic residue Cys106 is supplied from within the large central coordination spacer and the other members of the triad, His14 and Asp35, come from the N-terminal side of the zinc-binding site.

5.1.3 *Endonucleases*

The enzyme from *Physarum polycephalum* is a homodimer containing two zinc sites per monomer of 324 amino acids.[110] The two zinc sites originate in the N-terminus of the protein spanning residues 41 to 138. The first zinc site is formed from Cys41, Cys100, Cys105 and His110 supplied by three β-sheets while the second zinc uses Cys125, Cys132, His134 and Cys138 as ligands that are supplied from a largely unstructured region of the protein except for one short α-helix (Table 4). The two zinc ions are separated by 15.3 Å. Both sites contain 3 Cys and 1 His ligand although the order of ligand coordination is different. The second zinc site may play a role in stabilizing the dimer interface since the indole rings of Trp 125 from each monomer are stacked against each other.[110] Neither site is involved in DNA-binding since both are 15 to 17 Å from the substrate complex. However, the active-site His98 amino acid is one residue away from the second Cys ligand in the first zinc site.

5.1.4 *Matrix Metalloproteinases*

The matrix metalloproteinase (MMP) class of enzymes contain a non-Cys zinc-binding site that has the characteristics of a structural zinc site, that is, four ligands, and no metal-bound water (Table 4). This site contains three His and an Asp residue in a linear sequence spanning 28 amino acids (Table 4).[111,112] The site is highly conserved in the MMPs, occurring in the great majority of sequence-identified MMPs (125/138 sequences in MEROPS 1.7 data set)[113] and has a signature of $HX_1DX_{12}HX_{12}H$. As is likely the case for many structural metal sites, this site may be indirectly effecting the activity of the enzyme. Although this zinc is separated by 12 Å from the catalytic zinc site, the amino acids adjacent to the third and fourth ligands (His) to the ‘structural’ zinc site provide a number of hydrophobic residues that border the catalytic Glu residue. These regions contain LeuAla and AlaPhe/Tyr sequences on the two sides of one His and an Ala and Phe adjacent to the other His. These residues could provide a hydrophobic environment for the catalytic Glu carboxylate

Table 4 Structural zinc sites[a]

[a]See footnote of Table 1 for the definitions of terms. [b]A ? means the ligand is in question.

group of the MMPs and thus raise its pK_a, allowing it to play a role in stabilizing the transition state in catalysis.[2] The properties of the structural zinc site in the MMPs and in other similar sites may therefore influence function indirectly through effects on local conformation or local environment.

5.2 Zinc Clusters Class II: Histone Lysine Methyl Transferases

Histones undergo extensive posttranslational modifications such as acetylation, phosphorylation, and methylation on their N-terminal peptides that extend out of the nucleosome. Such modifications have been proposed to be part of a histone code that is recognized by cellular factors that influence gene expression.[114] Some of the SET (Su(var), Enhancer of zeste, Trithorax) domain proteins,[115] in combination with a cofactor S-adensoyl-L-methionine (SAM), are enzymes that methylate lysine 9 of histone H3. These enzymes contain minimally a histone methyltransferase (HMTase) catalytic domain that includes the conserved SET domain flanked by cysteine-rich pre- and post-SET motifs.[116,117] A zinc cluster-type binding site, Zn_3Cys_9, is believed to be important to the structural stability of the pre-SET domains of the histone lysine methyl transferases, DIM-5[116] (the gene product of *Neurospora crassa* defective in methylation gene, *dim-5*),[118] and the *Schizosaccharomyces pombe* cryptic loci regulator 4, Clr4.[117] A fourth zinc site has been found in the *Neurospora*

crassa Dim-5 enzyme bound to four Cys residues (Table 4).[119] This zinc is 39 to 43 Å from the zinc cluster.

The zinc cluster sites have several features in common with the β-domain three-metal clusters of eukaryotic metallothioneins (*see* ***Metallothioneins***). All of these clusters can be viewed as simple hexagons in two dimensions (Figure 13). The hexagon is composed of alternating zinc ions and bridging Cys ligands. Each zinc has two other nonbridging Cys sulfurs ligated to it. In each case there is a short spacer of 7 amino acids between two of the bridging Cys ligands. However, the spacers to the third bridging Cys are much larger for the histone methyltransferases. This is due to large inserts of 28 and 46 amino acids between the fifth and sixth cysteines in the Clr4 and DIM-5 HMTases, respectively, compared to 1- and 3-amino acid spacers for the human,[120] mouse,[121] and sea urchin[122] metallothioneins, respectively. The spacing characteristics of the last four cysteine ligands in the HMTases is highly conserved compared to that of the first five cysteine ligands. A search using the motif [YFIK]ECX$_3$CXCX$_3$CX$_2$R leads to only 46 proteins, many of which are suspected to be HMTases.[91] The majority of the putative large spacers between the fifth and sixth Cys ligands are between 24 and 29 amino acids while two are 46 and 66 amino acids. The resulting variation in the putative spacing of the first five Cys residues is given by the subscripts in the sequence: $CX_{1-2}CX_{2-6,8}CX_{3-7}CX_{0-1}C$.

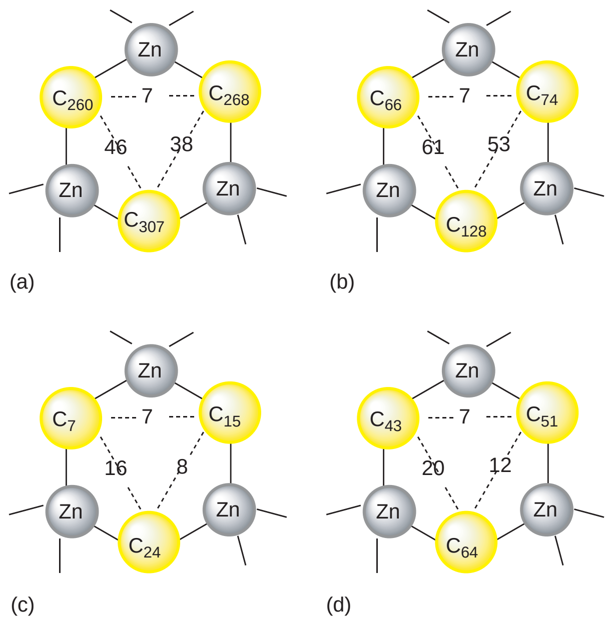

Figure 13 Properties of some zinc cluster sites observed in zinc enzymes and metallothionein. The bridging Cys residues as well as their spacing are identified for (a) *Schizosaccharomyces pombe* Lysine methyltransferase Clr4,[117] (b) *Neurospora crassa* Histone H3 methyltransferase DIM-5,[116] (c) β-domain of human metallothionein-2,[120] and (d) β-domain of sea urchin metallothionein MTA.[122] The PDB numbers are respectively: 1MVH, 1 ML9, 1MHU, and 1QJL

6 PROTEIN INTERFACE ZINC SITES

Thus far, we have considered how zinc can directly influence enzyme structure and function through its action in catalytic, cocatalytic, and structural zinc-binding sites formed from intramolecular ligands in monomeric proteins or in a subunit of a multi-subunit protein. However, zinc can also bind to the interface of protein molecules and form all of the zinc-binding sites mentioned above. In this capacity, it may also influence the quaternary structure of proteins. Zinc binding to ligands supplied from protein molecules at their interface contact surface has been observed in increasing numbers in the last few years.[3,4,123] These interactions can lead to dimers or trimers of the same protein or link two different proteins through the intermolecular ligands. The amino acid residues His, Glu, and Asp primarily supply the ligands to these sites but Cys-containing sites are also found (Table 5). The ligands are generally contributed by some form of secondary structure with β-sheets predominating. The most common types of these sites are formed from either each protein molecule providing two zinc ligands or one protein moiety providing three ligands and the second providing one as in the case of the nitric oxide synthase family and superantigens, respectively (Figure 14).

The resulting zinc-binding sites can function as catalytic zinc sites as in γ-carbonic anhydrase[74] or structural-like sites as in the proposed superantigen-MHC class II complexes[124] or cocatalytic-like sites as in the zinc-sensing transcriptional regulator ZntR.[125]

6.1 Protein Interface Catalytic Zinc Sites

While one might anticipate the binding of zinc between protein molecules to indirectly effect protein function by a number of means, it is perhaps most remarkable that these interactions can lead to catalytic zinc sites. This can occur even when all of the elements are in each monomer of the enzyme. In other cases, the intermolecular zinc site may be involved in placing the enzyme in the proper physiological place to exercise its function.

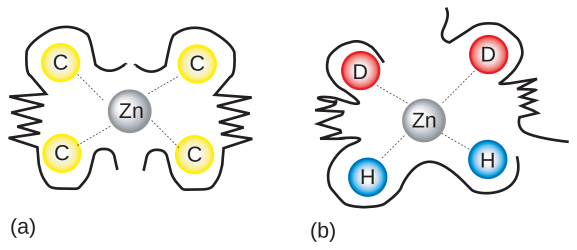

Figure 14 Protein interface zinc sites are formed at the interface of two proteins with generally four amino acid ligands binding to the zinc ion. The most common forms supply (a) two amino acid ligands from both protein moieties or (b) three amino acids ligands from one protein moiety and one ligand from another

6.1.1 γ-Carbonic Anhydrase: Trigonal-Bipyramidal Zinc Site

The carbonic anhyrases are classified broadly as α, β and γ enzymes. X-ray structures exist for all three forms (Tables 1 and 5). The catalytic zinc sites are highly conserved for each class of enzymes but differ markedly when the classes are compared. The α-class of enzymes contain two His ligands separated by a short spacer of one, a third His ligand supplied from the C-terminal side of the protein and one water molecule to complete the tetrahedrally bound zinc (Table 1). The β-class of enzymes contain a zinc site formed from a Cys and His ligand separated by 2 amino acids and another Cys ligand supplied from the N-terminal side of the protein (Table 1). The first member of the γ-class of carbonic anhydrases, CAM, was isolated and characterized from the methanogenic archaeon *Methanosarcina thermophila*.[126] Both the α and γ classes of enzymes have three histidine ligands supplied by β-sheet secondary structures in the catalytic zinc site (Tables 1 and 5). However they differ in the length of their short spacers (one versus four). This in turn allows the second His of the trimeric CAM enzyme to become part of the zinc-binding site in an adjacent monomer rather than bind to its own active-site zinc. The crystal structures of the native zinc enzyme and the cobalt-substituted enzyme show the metal-binding site is formed from His81 (ND1) and His122 (NE2) of one monomer and His117 (NE2) of another monomer.[73,74] In contrast to the tetrahedral zinc site observed in the α-class of enzymes that have only one zinc-bound water molecule (Table 1), the zinc CAM contains two water molecules in a trigonal-bipyramidal coordination geometry while the cobalt CAM contains three bound waters in an octahedral geometry. Both of these crystalline geometries are consistent with results obtained from XAFS studies performed in the solution state.[127]

6.1.2 Human Glyoxalase I: Square Pyramidal and Octahedral Zinc Sites

Another remarkable catalytic zinc site is found in human glyoxalase I where the C-terminal domain of one monomer interacts with the N-terminal domain of a second monomer to form two zinc-binding sites at the interface of the subunits.[128] The active-site zinc is coordinated by four protein residues and one water molecule in a square pyramidal coordination geometry. The base of the pyramid is formed from Gln33 and Glu99 of one subunit, Glu172 from the second subunit and a water molecule. The apex of the pyramid uses His126 from the second subunit. Such a geometry could be viewed as octahedral with one axial ligand missing. The results of EPR (cobalt enzyme)[129] and XAFS (zinc enzyme)[130] studies suggest a distorted octahedral coordination in solution. The sixth ligand site may be a water molecule. Another remarkable feature of this metalloenzyme is that while zinc binds tighter than Mg (3×10^{-11} vs 1×10^{-6} M) the Mg enzyme is fully active.[131] The octahedral metal-coordination geometry and the functional replacement of Zn by Mg is unusual for catalytic zinc sites. These results raise the possibility that Mg is the functional metal *in vivo*.

Mutagenic studies of the zinc ligands of the human enzyme suggest that the metal ligand Glu172 may be directly involved in catalysis.[132] Thus, both the E172Q and Q33E/E172Q double mutant still bind zinc but the catalytic activity is decreased by 10^5 and 10^8 fold, respectively. Crystallographic results of the enzyme complexed with a transition state analog S-(N-hydroxy-N-p-iodophenylcarbamoyl)glutathione, HIPC-GSH, that mimics the enediolate intermediate that should form along the reaction pathway are consistent with this hypothesis.[133] In this structure, the two oxygen atoms of the hydroxycarbamoyl moiety displace two zinc-bound water molecules that are observed in a possible product-like complex of S-p-nitrobenzyloxycarbonylglutathione, NBC-GSH. In addition the Glu172 carboxylate oxygen-Zn distance has increased from 2.0 Å to 3.3 Å in the HIPC-GSH complex indicating it is no longer a ligand to the zinc. The resulting coordination of the zinc thus changes from square pyramidal in the transition state-like complex to distorted octahedral in the product-like complex. The zinc ion is envisioned to play a Lewis acid role in catalysis by directly coordinating the enediol intermediate and the freed zinc ligand Glu172 is proposed to facilitate proton transfer between the adjacent carbon atoms of the substrate.[133]

6.1.3 E. Coli Glyoxalase I: Trigonal-Bipyramidal Zinc Site

While the human and *E. coli* enzymes have similar amino acid sequences and three-dimensional structures, they do not have the identical protein ligands. Nickel is believed to be the native metal in the *E. coli* glyoxalase I enzyme (*see* ***Nickel Enzymes & Cofactors***).[134] The nickel is bound octahedrally to His5 (NE2) and Glu56 (OE1) from one monomer, His74 (NE2) and Glu122 (OE1) from the other, and two water molecules.[135] Structure and function studies of *E. coli* glyoxalase I have shown the active nickel, cobalt, and cadmium enzymes have octahedral geometry while the zinc enzyme has trigonal-bipyramidal coordination and is inactive.[135] The zinc coordination site contains four protein ligands plus a single water molecule. In contrast, the metal-coordination sites in the active forms of the enzyme includes two water molecules bound to the metal ion, suggesting that this may be a key feature of the catalytic mechanism.

6.1.4 E. Coli Pdxa: Octahedral Zinc Site

Pyridoxal 5′-phosphate is an essential cofactor for many enzymes responsible for the metabolic conversions of amino acids. The fourth step in its synthetic pathway in *Escherichia coli* is catalyzed by the divalent metal ion-dependent enzyme 4-hydroxythreonine-4-phosphate dehydrogenase (PdxA), which converts 4-hydroxy-l-threonine phosphate (HTP) to 3-amino-2-oxopropyl phosphate.[136] The

enzyme active site is located at its dimer interface, within a cleft between two subdomains and involves residues from both monomers and two zinc ions. Each zinc ion is bound to NE2 nitrogens of His166 and His266 from one monomer and the NE2 nitrogen of His211 of a second monomer and 3 water molecules in an octahedral coordination geometry (Table 5). These histidines are strictly conserved in 74 members of this family of enzymes. The amino and hydroxyl groups of the substrate, HTP, bind to the zinc ion in a pentacoordinate manner by replacing the three water molecules.[136]

6.1.5 *E. Coli L-histidinol Dehydrogenase: Octahedral Zinc Site*

L-histidinol dehydrogenase (HisD) catalyzes the last two steps in the biosynthesis of L-histidine: sequential NAD-dependent oxidations of L-histidinol to L-histidinaldehyde and then to L-histidine.[137] HisD functions as a homodimer and requires the presence of one zinc ion per monomer. The x-ray structure of *E. coli* HisD in the presence of zinc, NAD^+ and the substrate, L-histidinol, shows the zinc bound to the side-chain amide carbonyl of Gln259, the NE2 nitrogen of His262 and Asp360(OD2) of one monomer and the NE2 nitrogen of His419 of the other monomer and the substrate ND1 nitrogen and its amino group in a octahedral coordination geometry.[137] The role of zinc in this case is to position the substrate for catalysis. Since the NE2 nitrogen of His237 is within H-bonding distance of the histidinol OH, it likely participates in acid-base catalysis.

6.2 Protein Interface Structural-like Zinc Sites

There are a number of protein interface sites that have the properties of an enzyme structural zinc-binding site in that they are composed of four protein ligands and no water molecules. These sites may be involved in local protein conformation or be involved in stabilizing quaternary structure. The metal ion acting in this manner is not directly involved in the function of the protein but may still play an indirect role in aligning critical components of the protein for its intended function.

6.2.1 *Zinc-binding Sites in Superantigens*

Streptococcus pyogenes and *Staphylococcus aureus* secrete a number of enterotoxins and pyrogenic exotoxins, respectively. These toxins are known as superantigens, since they simultaneously form complexes with the major histocompatibility class II (MHC-II) molecules and T-cell receptors (TCRs) enabling them to activate a number of T-cell lymphocytes.[124,138,139] Thus, superantigens stimulate up to 20% of the T cells while only 0.0001% to 0.001% T cells are stimulated upon normal antigen presentation. The massive T-cell activation leads to cytokine release and systemic shock. The staphylococcal enterotoxins (SE) A, B, C1-C3, D and E, toxic shock syndrome toxin (TSST-1), the streptococcal pyrogenic exotoxins (SPE) A, B, Cs, G, and H, the streptococcal mitogenic exotoxins, SMEZ and SMEZ-2 are the best structurally studied superantigens thus far (Tables 5 and 6).

Zinc is believed to be an important factor in the mechanism of T-cell activation. Thus binding of staphylococcal enterotoxin A and enterotoxin E to HLA-DR1 is completely abolished by low concentrations of Ethylenediaminetetraacetic acid (EDTA).[140] This binding is completely restored by the addition of a 2 μM excess of Zn^{2+} but not by Ca^{2+}, Mg^{2+} or other metal ions. Studies using EDTA ± $ZnCl_2$ show zinc-dependent binding of *Streptococcus pyogenes* exotoxin (SPE-C), SPE-G, SPE-H and SMEZ and SMEZ-2 to the MHC class II molecule HLA-DR1 (affinities of 15 to 36 nM).[138] On the basis of these criteria, the superantigens SEB and the toxic shock syndrome toxin TSST do not show zinc-dependent binding to the MHC class II molecule.

Two distinct zinc-binding sites are apparent from the reported structures of the superantigens (Tables 5 and 6). These zinc sites contain at least three protein ligands with each site having short and long spacers. The third ligand comes from the N-terminal side of the second ligand. In one case the short spacer is one (Asp (OD1)-X-His (NE2)) with both ligands coming from a β-sheet, located in the C-terminal side of the protein. The third ligand is either an Asp or His residue located 33 to 39 amino acids away: SEA,[141,142] SEC3,[143] SED,[144] and SEH[145] (partial) and SPE-C,[146] SPE-H, and SMEZ-2[147] all contain this type of zinc-binding site (Tables 5 and 6). The second type of zinc-binding site has a short spacer of 3 and contains two His ligands in the N-terminal side of the superantigen with the third ligand located 27 to 34 amino acids away: SEC2,[148] SEA[149] (2nd Zn site) and SPEA and SPEA1[150,151] contain this type of site. The fourth ligand in these sites is quite variable. It may come from a neighboring protein molecule, from within the same molecule or be a bound water molecule. The variability in the fourth ligand could be due to the fact that this ligand should come from the MHC class II molecule. His81 of the β chain of the DR1 molecule has been proposed to be this ligand based on the fact that mutation of this ligand disrupts HLA-DR1 binding to SEA but not SEB or TSST-1 that do not bind zinc strongly.[152]

A somewhat similar zinc-binding site was observed in crystals of rat submaxillary gland tonin that had been grown in a zinc-containing mother liquor.[153] The zinc binds to the NE2 nitrogens of His97, His99, and the catalytic His57 of one molecule and Glu148 of an adjacent one. The presence of zinc was reported to inhibit the enzyme at pH 6.5. The structure of the zinc-binding sites in the dimeric form of psoriasin (S100A7) also contains three His and one Asp ligand.[154] This 22.7 kDa homodimeric protein belongs to the S100 class of calcium-binding EF-hand proteins (*see* ***Calcium-binding Proteins***). Two zinc-binding sites occur per dimer through the formation of a tetrahedral site consisting of the N-terminal

Table 5 Protein interface zinc sites[a]

His17 (NE2) and Asp24 (OD1) of one monomer and His86 (NE2) and His90 (NE2) of the other. This binding site is apparently weak since it is reported to have a dissociation constant of 100 µM.

The finding of zinc binding at the interface of two enterotoxin molecules in several of the superantigens (Table 5) could mean that zinc influences the function by forming dimers of the superantigen. SED crystallizes as a Zn^{2+}-dependent dimer with two high affinity zinc sites located between the C-terminal β-sheets of the two monomers.[144] Each zinc is tetrahedrally coordinated by His118 from one SED molecule and Asp182, His220 and Asp222 from the other. Thus, in the case of SED it has been suggested that zinc binding could induce dimer formation and each monomer could bind to the MHC class II molecule.[144] This type of zinc ligation and zinc-mediated dimerization occurs in several SECs, but not in most staphylococcal enterotoxins. The potential importance of zinc in SEC-mediated pathogenesis was investigated by site-directed mutagenesis by replacing the SEC zinc-binding ligands with alanine.[143] The SEC mutants were unable to bind zinc and failed to form dimers. However, it was concluded that zinc binding was not essential for T-cell stimulation, emesis, or lethality although in general the mutants were less pyrogenic.

6.2.2 *Nitric Oxide Synthase*

Although His, Glu, and Asp residues are frequently used in forming these protein interface sites, Cys-containing sites are also observed. A zinc ion is tetrahedrally coordinated to a pair of symmetry-related Cys residues near the bottom of dimer interface of the bovine endothelial nitric oxide synthase, eNOS or NOS-3 (Table 5) (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***).[155] The Cys ligands, Cys96 and Cys101, are part of a small three-stranded antiparallel β-sheet that orientates the Cys ligands in the same direction directly across the antiparallel strands. The zinc site is further stabilized by H-bonds between the Cys ligands and the backbone amide NH of Leu102 and Gly103 as well as a H-bond of the amide NH of Cys101 to the carbonyl of Asn468. The zinc is positioned equidistant from each heme (21.6 Å) and each tetrahydrobiopterin, H_4B (12 Å). Ser104, 2 amino acids removed from one of the Cys ligands, H-bonds directly to the pterin side-chain hydroxyl group. The metal center is believed to act in a structural capacity to maintain the integrity of the pterin-binding site. It is also centered in the most electropositive region of eNOS. It could therefore provide a binding site for the electronegative reductase domain. In

addition, if one of the Cys ligands has nucleophilic capacity it could undergo S-nitrosylation.[156] A precedent for this is the DNA repair protein *Escherichia coli* Ada in which a zinc-bound Cys can be methylated irreversibly in the DNA complex.[157] The nitrosylated Cys might then release zinc, which may be controlled by the redox status in situ.[158]

These Cys residues are conserved in 20 mammalian e, i, and n-NOS enzymes, suggesting that the site may occur in all forms of NOS.[155] The crystal structures of the *E. coli* expressed human endothethial, eNOS,[159] the human inducible form iNOS or NOS-2,[159,160] mouse iNOS[161] and the rat neuronal nNOS or NOS-3[162] all have this same zinc-binding site in agreement with the sequence analysis.

6.2.3 *Shaw T1*

A highly conserved zinc protein interface Cys/His site occurs in the N-terminal, cytoplasmic tetramerization domain (T1) of voltage-gated K^+ channels.[163] The crystal structure of the *Shaw* T1 tetramers reveals a four-layered protein scaffolding. Within layer 4 on the proposed membrane side of the tetramer, there are 4 zinc ions coordinated by a His and two Cys from one monomer and one Cys from another. The zinc is tetrahedrally coordinated by Cys102 and Cys103 from layer 4 and His75 (ND1) from layer 3 of one monomer and Cys81 from layer 3 of another monomer. This site ($CysCysX_{20}CysX_5His$ of one monomer) is conserved for 62 members of the *Shaw*, *Shab*, and *Shal* T1 domain sequences but not for the *Shaker* T1 domain.[163] The physiological function of this zinc site is unknown.

6.2.4 *Human Tyrosine Kinase Lck complexes with CD4 and CD8*

The Sarc family tyrosine kinase Lck transduces signals that are required for normal T-cell lymphocyte development and antigen-dependent activation of mature T cells.[164] It does this by associating its N-terminus with the cytoplasmic tails of T-cell coreceptors CD4 and CD8α in a zinc-dependent manner. The solution structures of ternary zinc-CD4-Lck and zinc-CD8α-Lck complexes were determined by using peptides of the appropriate regions of the proteins.[164] In each case, zinc binds to Cys23 and Cys29 of Lck and completes its tetrahedral coordination by binding to two Cys residues of CD4 (Cys420 and Cys422) or CD8α (Cys194 and Cys196). The zinc is thus used to clasp the T-cell receptors to Lck. Other similar structural elements also are observed in this binding process.

6.2.5 *Zinc-his/Glu Sites at Protein Interfaces*

There are several His/Glu combinations that lead to zinc binding at the interface of proteins (Table 5). A number of these zinc sites are symmetry related. Thus zinc binds between Glu139 (OE1) and His178 (NE2) in one molecule of the asymmetric crystal unit of the 4 phenylimidazole-bound *Sulfolobus solfataricus* cytochrome P450 and their symmetry residues in another molecule.[165] The functional importance of a dimer and zinc's contribution to its stability is not known. However, no zinc was added in the crystalline procedure. A His/Glu site with a short spacer of 3 is observed in the dimer interface of mouse survivin (Table 5).[166] The human survivin does not form a similar intermolecular zinc site.[167]

In crystals of the high molecular weight form of nerve growth factor 7S NGF, a zinc is tetrahedrally bound between His82 (NE2) and Glu75 (OE1) of the α-subunit and His217 (NE2) and Glu222 (OE1) of the γ-subunit.[168] The binding of zinc to this interface is consistent with the observation that zinc enhances the stability of the 7S complex.

6.3 Zinc Sites Induced by High Zinc Concentrations in Crystallization Solutions

Zinc is often used in crystallization buffers because it appears to aid in formation of high quality crystals. Since the zinc concentrations used to obtain the crystals is in the range of a few mM to over 100 mM these sites often may not be of physiological significance. The effect of zinc on protein function and/or structure should be correlated to the concentration needed to observe zinc binding to the crystalline enzyme. However, the fact that zinc has the property of making better protein crystals may reflect its ability to perform inter-protein interactions under physiological conditions where the concentration of water may not be 55 M and the amount of zinc needed for the binding maybe much less. The great majority of these zinc sites use His, Asp, and Glu as ligands.

The human pathogen *Legionella pneumophila*, the etiological agent of the severe and often fatal Legionnaires' disease, produces a major virulence factor, termed macrophage infectivity potentiator protein (Mip), that is necessary for optimal multiplication of the bacteria within human alveolar macrophage.[169] The interaction of the C-terminal FKBP (binds drug FK506) domains of adjacent Mip dimers in the crystal lattice is mediated by two zinc ions, which were added for crystallization and enabled the solving of the structure. The NE2 nitrogen of His205 from one Mip C-terminal domain and Glu164(OE1) from a neighboring molecule and two water molecules one of which bridges to a second zinc ion that binds to Glu130(OE1) of the first Mip molecule and two water molecules complete the tetrahedral coordination of each zinc ion. Zinc is not an intrinsic part of the Mip protein and does not influence the enzyme's peptidylprolyl isomerase activity.[169] The authors reason its sole function is to form the observed crystal contact.

The crystals of the human interferon-α_{2B} dimers, huIFN-α_{2B}, obtained in the presence of 40 mM zinc acetate[170] show the most extensive interactions occur in the vicinity of the zinc-binding site. This site is formed from adjacent Glu residues 41 and 42 located on a 3_{10} helix. A distorted-tetrahedral zinc coordination sphere is completed

by the identical glutamates from a two-fold symmetry-related molecule. However, gel permeation studies indicate huIFN-α_{2B} is a monomer up to 50 μM and the presence of 1 mM Zn does not shift the equilibrium toward a dimer.[170]

A tetrahedral zinc-binding site between symmetry-related monomers in the cytochrome C reductase is composed of a His and an Asp ligand in one monomer, a His ligand from the second monomer and a chloride ion.[171] Since there is no known effect of zinc in this system, the site is considered to be an artifact. Five tetrahedral zinc-binding sites are observed in symmetry-related molecules of granzyme B in complex with a peptide analog, AC-IEPD-CHO.[172] These zinc coordination sites are believed to be artifacts of using zinc in the crystallization buffer since zinc is not required for substrate binding.

Zinc (6–10 mM) is used to aid in crystallization of chicken tropomodulin.[173] The resulting crystals contain a zinc-binding site at the interface of two protein molecules in the crystal lattice (Table 5). It is not known what effect zinc has on the protein function in solution. When the crystals of *Urtica dioica* agglutinin isolectin I are grown in 100 mM zinc acetate, the C-terminal domains binds two zinc ions at the sugar binding site.[174] Thus, His47 of one protein molecule and His67 of a second one bind the first zinc while Asp 75 of molecule one and His47 of molecule two bind the second zinc ion. The effect of zinc under more physiological conditions is not known.

7 ZINC-BINDING PROTEINS

Structural studies in recent years have revealed a number of zinc-binding sites in proteins of diverse function. In compiling Table 6, a number of DNA-binding proteins have been left out since there are several good sources of information on these zinc sites, which usually contain Cys and His ligands (*see* ***Zinc: DNA-binding Proteins***).[96–100,175,176]

The great majority of these zinc sites are formed from four protein side-chain ligands to yield a tetrahedral binding site. Their function may therefore be related to the local and/or overall structure since the sites span from 22 to 227 amino acids. As in the case of structural zinc sites in enzymes (Table 4), the vast majority of the sites contain at least one short spacer. The residues generally are supplied from β-sheets or reside within one or two residues of such a secondary structure (Table 6). The amino acids, His and Cys, are the predominate suppliers of ligands but several sites are made up of combinations of His, Asp, and Glu residues. Some examples of the group will be highlighted herein since the properties of a number of the listed proteins have been detailed elsewhere.[4]

7.1 LIM Domain Proteins

Two consecutive zinc-binding sites spanning 50 to 54 amino acids with the zinc ions located between 16.5 Å and 18.0 Å occurs in a number of proteins of diverse physiological function (Table 6). The zinc-binding sites are often referred to as zinc fingers but they are not involved in DNA-binding and their purpose appears to be a structural one. The name LIM comes from the identification of tandem copies of a Cys-rich motif that was present amino-terminal to the homeodomains in the proteins encoded by the *Caenorhabditis elegans* genes lin-11, isl-1 and mec-3 (*see* ***Zinc: DNA-binding Proteins***).[177] NMR studies have determined the structural properties of several of the LIM domains (Table 6). These tetrahedral zinc sites contain four protein ligands that are mainly Cys residues in combination with His and Asp residues. The N-terminal zinc site is highly conserved having a zinc signature of CCHC. The C-terminal site is more variable with the last two ligands being various combinations of Cys with His or Asp. No bound water molecules are found in these sites. The first and third ligands usually are supplied from a β-sheet structure. The second ligand resides in a loop region between two β-sheets while the fourth ligand may come from an α-helix, or β-sheet region of the protein (Table 6).

These domains are often found as repeats in proteins that are involved in diverse biochemical processes. The LIM domains are thought to function as protein interaction modules, mediating specific contacts between members of functional complexes and modulating the activity of some of the constituent proteins.[178] Group 1 of the LIM proteins contain the LIM homeodomain (LHX), LIMK (LIM kinases) and LMO (rhombotin) subfamilies.

LMO2 and LMO4 are members of a small family of nuclear transcriptional regulators that are important for both normal development and disease processes. LMO2 is essential for hemopoiesis and angiogenesis, and inappropriate overexpression of this protein leads to T-cell leukemias.[179] LMO4 is developmentally regulated in the mammary gland and has been implicated in breast oncogenesis.

Group 2 of the LIM domains contains the Cys-rich Proteins (CRP) and Cys-rich Intestinal Protein (CRIP) subfamilies that have tandem repeats of zinc-binding sites containing the ligands CCHC and CCCC (Table 6). The structures of the chicken,[180] quail,[181,182] and rat[183,184] proteins are determined by NMR. These proteins have a role in the contractile machinery of muscle. Three vertebrate CRPs (CRP1-3) are associated with the actin cytoskeleton, and one has been shown to be required for striated muscle structure and function in muscle differentiation and function.[180]

The PINCH (Particularly Interesting New Cys/His rich protein) is a widely expressed adapter protein that contains five LIM domains that belong to group 3 of the LIM domain subfamilies.[185] PINCH is found in focal adhesions, large cellular complexes that link extracellular matrix to the actin cytoskeleton and has been implicated as a platform for multiple protein–protein interactions that mediate integrin signaling within focal adhesions.[186]

7.2 BIR Domain Proteins

Another repeating zinc-binding site defines a domain in a protein that is an inhibitor of apoptosis, IAP. Apoptosis is a physiological cell suicide program that is essential to the development and maintenance of healthy tissues.[187] Thus, malfunctioning cells are targeted for destruction. Disruption of this process is implicated in cancer, auto immune, and immunodeficiency diseases. The IAP family members contain a protein segment of about 80 amino acids, named the baculovirus IAP repeat (BIR), domain since it was first observed in apoptosis suppressors in the genome of baculoviruses. BIR domains have been found in mammalian, fly, nematode, yeast and virus proteins.[187] One of the first described members of the family was Survivin, a relatively small 16 kDa protein. Both the human and mouse proteins contain a zinc-binding site in the N-terminal, BIR-like domain.[166,167] The zinc binds to Cys57, Cys60, His77 (NE2) and Cys84 in both human and mouse proteins (Table 6).

The X-ray structures of several of these proteins shows a highly conserved zinc-binding site spanning 28 amino acids with the spacing characteristics of $Cx_2Cx_{16}Hx_2C$ (Table 6). The first two Cys ligands are supplied by a β-sheet and loop region between two β-sheets, while the third His ligand resides in an α-helix and the last Cys ligand is in a loop between two α-helices.

Proteins containing these domains have been shown to inhibit caspases.[187] At least 8 members of the mammalian family of IAP proteins containing two to three copies of the BIR domain have been identified.[188] These BIR domains may function differently in the inhibition of the caspases. The third BIR repeat, BIR3, of the X-linked protein, X-linked inhibitor of apoptosis protein (XIAP) binds to monomeric initiator caspase-9 to form a heterodimer and thus prevents caspase-9 from forming its functional dimer, resulting in loss of enzymatic activity.[188]

The crystal structure of the BIR2 domain of XIAP in complex with caspase-3 reveals the inhibitor makes limited contacts through its BIR domain to the surface of the enzyme, and most contacts to caspase-3 originate from the N-terminal extension.[189] The mechanism of inhibition is likely due to blocking substrate binding.

The mitochondrial protein Smac/DIABLO promotes apoptosis by eliminating the inhibitory effect of IAPs through physical interactions.[190] The crystal structure of Smac/DIABLO complexed with the BIR3 domain of XIAP indicate the relief of inhibition by the IAP protein occurs mainly through the N-terminal four residues (Ala-Val-Pro-Ile) in Smac/DIABLO. The N-terminal Ala binds in a hydrophobic pocket of BIR3, that makes five hydrogen bonds to neighboring residues on BIR3.

The inhibitor of apoptosis protein DIAP1 suppresses Dronc-dependent cell death in *Drosophila melangaster*, with the second BIR domain (BIR2) playing an important role.[191] DIAP1 is an E3 ubiquitin ligase. The BIR2 domain of DIAP1 recognizes a 12-amino acid residue sequence in Dronc that is essential for DIAP1 binding to Dronc, and for targeting Dronc for ubiquitination. Three proteins, Reaper, Hid and Grim, (RHG proteins) promote apoptosis in *Drosophilia melangaster* in part by binding to the BIR2 of DIAP1 through their conserved N-terminal sequences in a manner similar to that observed for the Smac and XIAP complex.[192]

Five very similar BIR repeats are observed in the melanoma inhibitor of apoptosis (ML-IAP).[193] The zinc sites in these domains lie in a trapezoid-like geometry (pdb# 1OXN) with the distances between zinc in domains A and D and B and C being 13.5 Å while all other distances between neighboring zinc sites varies between 26 and 35 Å (Figure 15). Peptides based on the processed N-terminus of Smac/DIABLO can negate the ability of overexpressed ML-IAP or XIAP to suppress drug-induced apoptosis.[193] These peptides have been demonstrated to bind to a single BIR of ML-IAP (protomer E) and the BIR3 of XIAP with similar high affinities (~0.5 μM).[193] Protomers A-D form a tetramer with the N-terminus peptide of a neighboring domain binding to the Smac binding site.

A somewhat similar zinc site is seen in one of the ADP ribosylation factors (ARFs), which are members of the Ras superfamily of GTP-binding proteins. Sequences of ARF-GAP domains show no recognizable similarity to those of

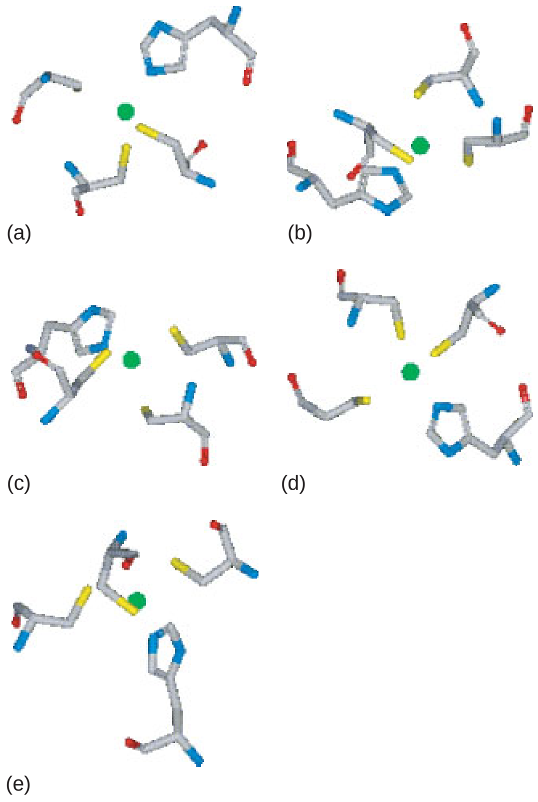

Figure 15 The zinc sites in the five BIR domains of the melanoma inhibitor of apoptosis are arranged in a trapezoid-like geometry (pdb# 1OXN). Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

other GAPs, and contain a characteristic $Cx_2Cx_{16-17}Cx_2C$ motif[194] similar to that found for the zinc sites in inhibitor of apoptosis proteins (Table 6). The crystal structure of the ARF-GAP domain comprises a central three-stranded β-sheet flanked by five α-helices, with a zinc ion coordinated by four cysteines with spacing and secondary structure similar to that found in the zinc sites of the BIR-containing proteins (Table 6).

7.3 CH1 Domain

Three zinc ions bound in a triangular relationship are found in the transcriptional coactivators CBP and p300.[195] Adaptation to hypoxia is mediated by transactivation of hypoxia-responsive genes by hypoxia-inducible factor-1 (HIF-1) in complex with the CBP and p300. The domain the zinc ions bind to is referred to as a Cys/His region, CH1. The three zinc ions bind to Cys and His ligands covering 66 amino acids, with no overlaps in the sequence (Table 6). Each binding site contains three Cys and one His ligand. The first two ligands are always a His and Cys with a spacer of 3 and supplied by α-helices. The spacing varies for the last two Cys ligands. The three zinc sites are at the vertices of a nearly perfect equilateral triangle with 21 to 22 Å distances between zinc ions on the sides of the triangle (pdb# 1P4Q). The zinc ions are critical to the structural stability of this domain since their removal by EDTA yields an NMR spectrum characteristic of an unfolded protein.[195] CH1 serves as a scaffold for folding of the HIF-1α C-terminal transactivation domain (TAD), which forms a vise-like clamp on the CH1 domain that is stabilized by extensive hydrophobic and polar interactions.

The protein CITED2, which binds p300/CBP, is thought to be a negative regulator of HIF-1 transactivation.[196] The CITED2-TAD binds a more extensive surface of CH1 than does the HIF-1α C-TAD. However, a conserved amino acid sequence motif, LPxL, in CITED2 and HIF-1α interacts with an overlapping binding site on CH1 likely accounting for the negative regulation effect.

7.4 Zinc Transporters

A number of bacterial metal transporters belong to the family of ATP-binding cassette (ABC) transporter system (*see* ***Metallochaperones & Metal Ion Homeostasis***).[197] These systems constitute one of the most abundant superfamilies of proteins. They are involved in the transport of a wide variety of substances and in many cellular processes. The zinc transporter ZnuA from *E. Coli* and *Synechocystis* sp. 6803, the proposed zinc transporter TroA from *Treponema pallidum,* and the proposed manganese transporter *Streptococcus pneumoniae* surface antigen, PsaA, are placed in cluster 9 of the ABC transporters.[198]

These zinc-binding sites mainly use His ligands and span a relatively great distance in the protein (Table 6). The periplasmic zinc-binding protein TroA from the human parasite *Treponema pallidum*[199] and pneumococcal surface antigen PsaA[200] are very similar. The bound zinc ion is coordinated by the NE2 nitrogens of His68, His133, His199 and both oxygens of Asp279 in TroA and His67 (NE2), His139 (NE2), and one oxygen of the carboxylates of Glu205 (OE1) and Asp280 (OD1) in PsaA. The latter two His residues of TroA are also further stabilized by H-bonding interactions with the carboxylates of Asp131 and Glu248 (pdb# 1TOA). In the case of PsaA only His139 is observed H-bonding the carboxylate of Asp137 (pdb# 1PsZ). The coordination geometries are described as tetrahedral for PsaA and distorted square pyramidal in TroA owing to the interaction of both oxygens of Asp279. The apex of the pyramid is occupied by the nitrogen of His199 while the other His ligands and the two oxygens of Asp279 make up the square plane.

A similar zinc-binding site is predicted by sequence alignment for Znu.[201] The bound zinc ion is coordinated by the NE2 nitrogens of His83, His179, His243 in a manner quite similar to TroaA (Table 6). The latter two His residues are also further stabilized by H-bonding interactions with the carboxylates of Asp177 and Glu261 (pdb# 1PQ4) as in TroA and PsaA. However, the proposed fourth Asp ligand does not bind and is replaced by a water molecule in a large hydrophobic cavity.[201]

The function of the proteins is presumed to be similar to that of members of the periplasmic ligand-binding protein (PLBP) family that function as ligand-binding receptors for active transport and chemotaxis. However, these proteins do not have the flexible interdomain β-strands of the PLBPs. An argument has been proposed for a more rigid hinge (in this case a backbone α-helix) if the purpose of these proteins is 'small' metal ion transport.[199] Thus, since the free energy difference of zinc in solution and bound to a protein is considered to be small,[202] the binding of zinc to a protein cannot incur the large entropy changes that would be associated with the ordering of a very mobile hinge region.

1 INTRODUCTION

1.1 Historical Background

Zinc is a relatively recent arrival among the common metals, having been produced commercially in Europe only since the middle of the eighteenth century – in fact in Bristol in 1738. However, its history begins in prehistoric times. The oldest known piece is a Dacian idol discovered in a ruined prehistoric settlement at Dordosch, Transylvania, consisting of zinc of 87% purity. Bracelets in the form of hollow silver rings filled with zinc were made by the early Greeks and were found at Cameiros on the island of Rhodes. In fact, zinc was known in the brasses, alloys of zinc and copper, long before its isolation in a pure state. Brasses were known at least a thousand years before the Christian era; the Romans smelted mixtures of calamine (zinc carbonate) with copper ores to obtain brass.

Knowledge of zinc smelting appears to have come originally from India (13th century) and spread to Sumatra and China, where it was produced commercially by the middle of the eighteenth century: such a sample dated 1745 contained 99% of zinc with tin and iron as impurities. There is evidence that zinc was being imported into Europe from these countries as early as 1611, but zinc smelting in Europe and America really started on a large scale in the nineteenth century in centers such as Liege, Bristol, and Swansea in Europe and at the Washington arsenal in America.

Zinc compounds were known to the alchemists; several have been in therapeutic use (calamine for skin problems, zinc sulphate for eye treatments) for over a thousand years.

1.2 Occurrence and Abundance

Estimates of the abundance of zinc in the sun, in meteorites, in the Earth's core and crust, and in the oceans are very difficult to make,[1] but its abundance in the Earth's crustal rocks and soils is of the order of 100 ppm, about 1000 times as abundant as its congeners cadmium and mercury. All three elements are *Chalcophiles* so that, in the reducing atmosphere that prevailed when the earth's crust solidified, they were deposited in the sulfide phase giving rise to the sulfide ores, their most important source. Later, as weathering took place, zinc became soluble only to be precipitated as the carbonate, silicate, or phosphate.

The main zinc ores are the sulfide ZnS, known as zinc blende in Europe and sphalerite in the United States, and the carbonate $ZnCO_3$ (calamine in Europe, smithsonite in the United States). Major deposits are found in Canada, Australia, Mexico, Peru, Russia, and the United States. Minor ores include the silicates willemite, Zn_2SiO_4 and hemimorphite, $Zn_4Si_2O_7(OH)_2{\cdot}H_2O$. Franklinite, $(Zn, Fe)O{\cdot}Fe_2O_3$, is mainly a zinc ferrite (see below), but is also important for its manganese content. Zinc also occurs in a number of other minerals, for example, goslarite, $ZnSO_4{\cdot}7H_2O$, wurtzite, ZnS, zincite, ZnO, and a number of secondary arsenate and phosphate minerals, such as hopeite, $Zn_3(PO_4)_2{\cdot}4H_2O$.[2]

Zinc occurs to the extent of between 5 and $10 \times 10^{-3}\,\mathrm{mg\,L^{-1}}$ in seawater, with a residence time of about 2×10^4 years; there are significant amounts of zinc in the manganese nodules on the ocean floor. In river waters, there is between $100\,\mathrm{mg\,L^{-1}}$ (in the Nile) and $900\,\mathrm{mg\,L^{-1}}$ (in the Garonne),[3] mainly in particulate form rather than dissolved. The principal species present in natural waters[4] are Zn^{2+}aq, $[ZnOH]^+$, $ZnCO_3$, and, in the oceans, $[ZnCl]^+$. Kinetic processes in natural waters have been reviewed,[5] as have methods for analysing for zinc in natural, potable, and effluent waters.[6]

1.3 Biological Importance

Zinc was demonstrated to be an essential trace element for eukaryotes in 1869; it has subsequently been shown to be essential for all life forms.[7–9] It generally plays either a catalytic or a structural role; in some metalloproteins that interact with DNA, zinc appears to play both roles. It is an essential constituent of many enzyme systems, as first demonstrated, for carbonic anhydrase, in 1940. Several hundred zinc metalloenzymes and metalloproteins have now been recognized, in a wide range of organisms. It generally functions at or near the active site, particularly in catalysis of

nucleophilic substitutions. In the early years of bioinorganic chemistry, analytical difficulties and spectroscopic restrictions hampered the investigation of zinc centers in biological systems, but increasingly powerful diffraction, spectroscopic, and other techniques have in recent decades enormously increased understanding of their structure and function. The development during the past decade of fluorescent probes for zinc has also helped in studying the nature and function of zinc-containing species in biological systems. Such probes generally contain an anthracene or fluorescein moiety substituted into a cyclic, acyclic, or tripodal polyamine that can bind firmly to the zinc. Photoinduced electron transfer (PET) sensors operate by the Zn^{2+} interrupting the PET of the ligand and restoring or enhancing its fluorescence.[10–12]

The long history and slow early development of the subject has been briefly reviewed (*see also* ***Zinc Enzymes*** and ***Zinc: DNA-binding Proteins***).[13,14] More recent general reviews of the biological role of zinc, including its regulatory role and the intriguing question of the localization of zinc in particular organs (e.g. parts of the male reproductive system of both plants and animals have high concentrations of zinc, as has the hippocampus in the brain), are available.[15,16] The manifold important zinc-containing biological systems have spawned a multitude of model complexes,[17] thereby greatly enriching knowledge of the coordination chemistry of zinc (see Sections 8 and 9). Types of model complexes include those with amino acid ligands to model zinc-peptide interactions, NNN-donor ligands to model the active site of carbonic anhydrase or carboxypeptidases, NO-donor Schiff bases to model Zn_2 sites, and μ-O^{2-} and μ-${CO_3}^{2-}$ polynuclear complexes to model Zn_3 and Zn_2Mg active sites. The biological inorganic chemistry, particularly the coordination chemistry of Zn^{2+} in biological systems, has been well covered in a number of books[18–20] and several aspects are mentioned elsewhere in this encyclopedia.

1.4 Zinc in the Human Body

There is a somewhat more than 2 g of zinc in the average adult; its plasma concentration is about 20 µM. There are believed to be some 200 zinc-requiring enzymes in the human body. Zinc is essential for healthy skin and proper wound healing, for a strong immune system, for bone metabolism, and for normal taste and smell. To maintain the required levels of zinc in the human body, a daily intake of several milligrams is required. Recommended Dietary Allowances (RDA; USA; 1989) are 12 and 15 mg per day for adult females and males respectively; Reference Nutrient Intakes (RNI; UK; 1991) are 9.5 and 7.0 mg per day.[21] Zinc contents of foods are 3 to 4 mg per serving for meat, 1 to 2 mg, for, for example, grains, nuts, cheese (there is very little zinc in fruit), giving a daily intake of the order of 20 mg.[22] But there can be problems of absorption, with the phytates present in many cereals significantly reducing zinc uptake by forming a stable complex that is very poorly absorbed from the gastrointestinal tract. A low-zinc diet, especially a plant-based diet with high phytate levels, results in slow growth, as first convincingly demonstrated in Iran in the late 1960s. Zinc deficiency reduces testosterone production in men, and delays puberty for male adolescents. Some 30 clinical disorders may be attributed to zinc deficiency; correcting this may be the key to delaying macular degeneration of vision, and to curing anorexia, acne, alcoholism, postnatal depression, and even the common cold.[23] There is a continuing controversy as to whether a large number of people suffer from a modest zinc deficiency in their daily diet; zinc supplements are popular. However, it is important not to exceed daily requirements, as a modest excess of zinc leads to reduced copper absorption and a large excess of zinc is toxic. One gram of zinc sulfate may induce nausea, vomiting, abdominal cramps, and diarrhea; higher doses have proved fatal. Rice polluted with zinc sulfide was implicated in an outbreak of severe skeleto-muscular disorders in Japan. Zinc inhalation can give rise to 'metal fume fever', whose symptoms are similar to those of influenza. The nutritional role[24,25] and the toxicity[26,27] of zinc have been considered in detail, its diverse function in the particular context of inorganic microbiology has been explored,[28] and the biological monitoring of zinc has been reviewed.[29]

A number of zinc compounds and complexes have been developed for therapeutic purposes.[30] Several zinc complexes of cyclam-based ligands have proved potent inhibitors of HIV, while hydroxypyridinone complexes are being assessed as insulin mimics for the treatment of diabetes. There is some evidence that the administration of certain zinc chelates may help to ward off strokes, while a suberoylanilide hydroxamate complex has been in clinical trials as an anticancer agent since 2000.

1.5 Zinc in Supramolecular Chemistry

A wide range of zinc-based coordination polymers[31] has been developed in recent years, ranging from simple chains to layers, clusters, and a variety of three-dimensional frameworks. Molecular architectures generated include helicates, rotaxanes, catenanes, knots,[32] grids, cylinders, capsules, and various structures containing tailored holes and channels. Such supramolecular assemblies can be valuable in molecular recognition, in catalysis, in separation, and in modeling of biological systems, for example, the 'biological motors' that operate flagella and muscles – where zinc is almost certainly involved in association with adenosine phosphates.

Supramolecular entities are prepared either by designed or self-assembly, or by the breakdown of larger species – the so-called 'bottom-up' and 'top-down' approaches respectively. Most supramolecular zinc compounds have been obtained by self-assembly methods, often operating in a rather hit-and-miss way. However, controlled cleavage of coordination polymers should prove a useful route to predesigned supramolecular assemblies. An example of this approach is provided by the

generation of a supramolecular hexanuclear zinc species from the three-dimensional coordination polymer prepared from zinc acetate and di-2-pyridyl ketone.[33]

1.6 General

There are good overviews of zinc chemistry in several inorganic textbooks, especially those by Greenwood and Earnshaw[34] and by Cotton, Wilkinson, and their recent collaborators.[35] Much detailed information, especially on the preparation and properties of binary compounds and salts, can be found in the elderly multivolume treatises of Mellor[36] and Pascal,[37] while Sidgwick's more modest pair of volumes[38] also contains much useful information of this type. The organometallic chemistry of zinc is considered in detail elsewhere (*see* ***Zinc: Organometallic Chemistry***).

2 PRODUCTION OF THE ELEMENT

World production of zinc rose from about 300000 tons per annum towards the end of the nineteenth century to about 7 million tons in 1996. Zinc blende is the most important ore of zinc and is usually found in association with galena, PbS, and some mineral detritus from which it is separated by differential flotation. The concentrate is then heated in air to give SO_2, which is used in sulfuric acid manufacture, and zinc oxide. The latter is then used in either an electrolytic isolation step or in a smelting process. In the former, extensively used in North America and in Tasmania, the oxide is leached out with dilute sulfuric acid and the solution electrolyzed with aluminum cathodes and, usually, lead anodes, the deposited zinc (99.95% pure) being stripped off the cathodes from time to time. Various smelting processes, based on the reduction of ZnO with coke, rely on the low boiling point of zinc (907 °C). Early batchwise procedures using horizontal retorts were superseded by continuous processes using vertical retorts made of silicon carbide. The zinc produced by such procedures was fairly pure but required to be further purified, by fractional distillation or electrolytic refining, to 99.99% for use in die-casting alloys and in high quality brass. The retort processes do not have the thermal efficiency of a blast furnace in which the combustion of the fuel for heating takes place in the same space as the reduction of the oxide. Early attempts at adapting the blast furnace for zinc smelting were unsuccessful, for which there are sound thermodynamic reasons.[39] There are two main difficulties: firstly, ZnO reduction by carbon is not spontaneous below the boiling point of zinc and, secondly, the zinc vapor is a good reducing agent for CO_2 so that, during subsequent cooling of the vapor to condense it, the zinc is liable to be reoxidized to ZnO, with concomitant formation of CO. A solution to the problem is found in the Imperial Smelting Process in which hot Zn and CO from the blast furnace are passed through a chamber drenched by a spray of molten lead at 550 °C. Zinc dissolves appreciably in lead at this temperature so that it is collected in the lead droplets and passes down with them, too quickly to be oxidized, into a molten lead bath below. The solution of zinc in lead passes to a separate cooler chamber at 440 °C, when the lower solubility of zinc at this temperature causes it to separate from the lead. The molten zinc is run off and the lead returned to the spray chamber. The process can be operated continuously and mixed zinc and lead ores may be used so that both metals can be produced simultaneously.

For small deposits, the ZnS may be converted into $ZnCl_2$ and thence into the metal. Zinc can also be solubilized from sphalerite by bacterial oxidation.[40]

Technical aspects of the production and of the uses (cf. following section) of the element have been detailed at length.[41]

3 USES

The most important of the many uses of zinc is as an anticorrosion agent for iron and steel,[42] in the form of a coating that may be applied by immersion in molten zinc ('hot-dip galvanizing'), electrolytic deposition, spraying with liquid metal, or heating with powdered zinc ('sherardizing' after its inventor Sherard Cowper-Coles). Zinc is also used to prevent corrosion in the form of sacrificial anodes (*see Sacrificial Anode*), particularly in marine applications. Zinc sheeting is used in roof cladding, zinc plates are used in lithography (zinc has a low contact angle with respect to printing inks), and zinc dust is used as a reductant.

A major use is in the manufacture of brasses, alloys of copper and zinc containing about 20–50% zinc, the ductility and tensile strength of which are controlled by the zinc content. The *Phase Rule* diagram of the zinc-copper system is complex: of the six solid solutions that may be formed as the zinc concentration increases over the whole composition range, the practically useful alloys are confined mainly to two, the α and β (the latter being much harder than the former) and their mixtures. The topic is interesting both from a practical and structural point of view and has been dealt with in detail elsewhere.[43] Small percentages of aluminum, iron, manganese, tin, and nickel are frequently added to 60–40 copper–zinc alloy to increase tensile strength without markedly affecting ductility: these are referred to as 'high tensile brasses' (*see* ***Alloys***).

As a casting metal for pressure die casting into permanent, steel casting dies, zinc is one of the cheapest metals and is widely used to produce small parts of complex shape such as automobile parts (door handles, locks, carburettors, petrol (gasoline) pumps) and is readily chromium plated. The zinc used for such castings must be highly pure to avoid corrosion and disintegration along impurity grain boundaries.

It is alloyed with about 4% Al and 0.02% Mg. The aluminum strengthens the zinc and also prevents the molten alloy from attacking the steel pressure casting dies. Zinc readily reacts with mercury or will displace mercury from a mercury(II) salt to form an amalgam that is useful for reductions, as in the preparation of compounds of the lower oxidation states of transition metals and lanthanides (e.g. Cr^{II}, V^{II}, Eu^{II}, dimeric Mo^{III}) and in analytical chemistry (e.g. in the Jones reductor; *see* ***Analytical Chemistry of the Transition Elements***).

The long-familiar Daniell cell used a zinc electrode; zinc sheeting is still much used in battery manufacture. Useful background material for this aspect of zinc chemistry is to be found in the article ***Electrochemistry: Applications in Inorganic Chemistry***, further details elsewhere.[44,45] The original Leclanché battery (1866), based on the cell

$$Zn(s)|ZnCl_2(aq), NH_4Cl(aq)|MnO_2(s), C(s)$$

was a wet cell. Some two decades later, Geissner patented the idea of manufacturing the zinc anode in the form of a cup that would act as a container for the electrolyte, which was immobilized with plaster of Paris. This development was combined with the use of the manganese dioxide/carbon cathode and an electrolyte immobilized using a cereal paste to form the basis of modern dry cell technology. The discharge mechanism of the Leclanché cell is not as simple as it is sometimes represented. In outline, oxidation of zinc to Zn^{2+}aq occurs at the anode, while at the cathode reduction of Mn^{IV} to Mn^{III}, either as MnO(OH) (s) or $Mn_2O_3{\cdot}H_2O$, takes place. The initial products of the electrode reactions then undergo further reactions in solution, mainly forming $[Zn(NH_3)_2]^{2+}$, then slightly soluble $Zn(NH_3)_2Cl_2$. For light discharges, an alternative reaction between Zn^{2+}(aq) and a Mn^{III} hydroxyoxide can give $ZnO{\cdot}Mn_2O_3$. At lower NH_4^+ concentrations, chloride and hydroxide or hydroxide alone are preferred ligands to NH_3, and a variety of solid complexes are formed, such as $ZnCl_2{\cdot}4Zn(OH)_2$ or simply $Zn(OH)_2$. The main cell reactions can be summarized as

$$Zn\ (s) + 2MnO_2\ (s) + 2NH_4^+\ (aq) + 2Cl^-\ (aq) \longrightarrow 2MnO{\cdot}OH\ (s) + Zn(NH_3)_2Cl_2\ (s) \quad (1)$$

and

$$Zn\ (s) + 2MnO_2\ (s) \longrightarrow ZnO{\cdot}Mn_2O_3\ (s) \quad (2)$$

However, if the initial ammonium chloride concentration is depleted, the reaction, as indicated above, becomes more complex and formation of hydroxochloro complexes plays an increasingly important role. The zinc alloy sheet used for the anode manufacture contains small quantities of lead and cadmium, and various corrosion inhibitors, such as a soluble mercury salt, are added to improve shelf life.

A variation of the Leclanché cell is the zinc chloride cell in which the ammonium chloride is completely replaced with zinc chloride. Such cells have a better service capacity at high current drain, at low temperatures, and on continuous discharge.

A further variation of the Leclanché cell is the so-called alkaline manganese cell. The negative pole is a hollow cylinder of powdered amalgamated zinc set in carboxymethylcellulose gel. The current collector is usually made of brass and the interior space is filled with immobilized KOH electrolyte solution. The positive pole consists of a mixture of electrolytic MnO_2 and graphite in a ratio of 4–5:1 wetted with electrolyte solution. The cell reaction is given approximately by the equation

$$2Zn\ (s) + 2MnO_2\ (s) + H_2O\ (l) \longrightarrow 2MnO{\cdot}OH\ (s) + 2ZnO\ (s) \quad (3)$$

but in practice is considerably more complicated. The main advantage of alkaline manganese cells over Leclanché cells is their relatively constant capacity over a wide range of current drainage conditions. An interesting feature of these cells is that provided the discharge is limited when the cell voltage reaches about 0.9 V, the cell reaction can be reversed and the system can function as a secondary cell.

The Ruben-Mallory zinc–mercury(II) oxide battery, which revolutionized the battery industry, uses the cell

$$Zn(s)|ZnO(s)|KOH(aq)|HgO(s),C(s)$$

The anode reaction is

$$Zn\ (s) + 2OH^-\ (aq) \longrightarrow ZnO\ (s) + H_2O\ (l) + 2e^- \quad (4)$$

and the cathode reaction may be represented as

$$HgO\ (s) + H_2O\ (l) + 2e^- \longrightarrow Hg\ (l) + 2OH^-\ (aq) \quad (5)$$

The overall cell reaction is then

$$Zn\ (s) + HgO\ (s) \longrightarrow ZnO\ (s) + Hg\ (l) \quad (6)$$

Important features here are (i) the invariance of the electrolyte solution and (ii) the constancy of the chemical potentials of the reactants and products as the cell is discharged. The former fact means that only a very small quantity of electrolyte is required, giving the cell an almost constant internal resistance and therefore a flat discharge curve; the latter means that, during discharge, the open circuit voltage remains constant, both desirable features in a battery. (The standard free energies of formation of Hg(s) and Zn(s) are respectively $-58.4\ kJ\ mol^{-1}$ and $-318.2\ kJ\ mol^{-1}$, giving a free energy change for the cell reaction of $-259.8\ kJ\ mol^{-1}$ and a cell emf of 1.347 V, close to the open circuit voltage of 1.357 V of commercially produced cells.)

The zinc–silver oxide cell, widely used in miniature applications and larger ones in military applications, is closely

related to the zinc–mercury(II) oxide system and has the configuration

$$Zn(s)|ZnO(s)|KOH(aq)|Ag_2O(s), C(s)$$

The main features of the zinc–silver oxide cell are similar to those of the zinc–mercury(II) oxide system. The principal difference apart from cost is the higher open circuit voltage: the emf calculated from the standard free energies of formation of ZnO and Ag_2O is 1.593 V, in close agreement with the open circuit voltage of commercial cells of 1.60 V.

Zinc has found application in several other types of battery, including industrially important zinc-air cells in which the oxygen of the air is used as the cathodic reactant in a cell such as

$$Zn(s)|NaOH(aq)|C(s), O_2(g)$$

The zinc-air cell has marginally the highest theoretical voltage (1.65 V) of all these zinc-based cells.

All the zinc-based cells, except for the alkaline manganese cell under certain conditions, are primary cells. Secondary (rechargeable) cells are generally based on cadmium rather than zinc, especially in the form of nickel–cadmium cells.

4 PROPERTIES OF THE ELEMENT

4.1 Physical Properties

Some physical properties of zinc are shown in Table 1. The naturally occurring isotopes, with their abundances, are ^{64}Zn(48.89%), ^{66}Zn(27.81%), ^{67}Zn(4.11%), ^{68}Zn(18.57%), and ^{70}Zn(0.62%). Man-made isotopes include ^{63}Zn ($\tau_{1/2} =$ 38.1 min; $E_{\beta^+} = 2.32$ MeV), ^{65}Zn ($\tau_{1/2} = 243.6$ days; $E_{\beta^+} =$ 1.353 MeV, EC, γ), and ^{69m}Zn ($\tau_{1/2} = 13.9$ h; $E_{IT} =$ 0.4389 MeV, γ). All three have been used for tracer studies, for example, of zinc absorption; ^{65}Zn has been used to monitor the performance of diesel engines and to trace the movement of underwater silts and sediments (^{65}Zn is incorporated into powdered glass mixed with natural sand); ^{63}Zn can be used for PET (Positron Emission Tomography); ^{67}Zn is suitable for Mössbauer and nuclear magnetic resonance (NMR) spectroscopy (see below).

The electron configuration of zinc, [Ar]3d^{10}4s^2, might have been expected to lead to a structure based on close packing of spheres (see Figure 1); such is not the case and the experimental hexagonal close-packed structure is markedly distorted, the axial ratio being nearly 1.9 instead of 1.63 as in perfect hexagonal closest packing. Each Zn atom has six nearest neighbors in its own plane at a distance of 2.659 Å; the other six, three above and three below, in the adjacent planes, are at a greater distance, 2.906 Å. It is not satisfactory simply to regard the atoms in this structure as packing like prolate spheroids, for in the close-packed ε-phase of the Cu–Zn system the axial ratio is less than 1.63 and one would then have to assume that the atoms are behaving at some compositions as prolate and at others as oblate spheroids. It has been suggested that there is some tendency to form covalent bonds, with dp^2 hybrids playing a part in the basal planes, leading to a smaller interatomic distance in the close-packed planes.

Table 1 Selected physical properties of zinc

Atomic number	30
Relative atomic mass	65.38
Electron configuration	[Ar]3d^{10}4s^2
Ionization energies (kJ mol^{-1})	906.1 (1st); 173.3 (2nd); 3831 (3rd)
Density (g cm^{-3})	7.14 (at 298 K)
Mp (°C)	419.5
Bp (°C)	907
Lattice type	Hexagonal close-packed
ΔH°_{fus} (kJ mol^{-1})	7.28
ΔH°_{vap} (kJ mol^{-1})	114.2
S° (J K^{-1} mol^{-1})	41.6
C°_p (J K^{-1} mol^{-1})	25.1
Electrical conductivity (S m^{-1})	0.167 (at 298 K)

4.1.1 *Zinc Mössbauer Spectroscopy*

Zinc is one of the few elements with an isotope useful for Mössbauer spectroscopy.[46,47] ^{67}Zn has a long-lived isomer state, which leads to potentially narrow line widths (as narrow as 3.2×10^{-4} mm s^{-1}) in the Mössbauer spectrum. Disadvantages are a smaller cross section than, for example, ^{57}Fe and a much higher recoil energy, decreasing the rate of recoil-free events. The ^{67}Zn isomer may be produced using a ^{67}Ga source.

4.1.2 *NMR Spectroscopy in Zinc Systems*

The only NMR-active isotope of zinc is ^{67}Zn, whose resonance is at 6.254 MHz at 2.344 T. Sensitivity with respect to ^{1}H is only 2.85×10^{-3}, and the natural abundance of ^{67}Zn is only 4.1%. The nucleus ($I = 5/2$) has a quadrupole moment and because of line broadening this causes difficulties in the study of binding with large ligands, especially in metalloproteins (*see* ***Zinc Enzymes***). Given the low abundance of ^{67}Zn, Fourier Transform NMR methods are used. For example, in such an NMR study[48] of zinc halide solutions the dependence of the chemical shift on concentration is strongly nonlinear, higher frequencies being observed with increasing concentration, an effect partly ascribed to the change of stereochemistry from octahedral to tetrahedral on passing along the series from $[Zn(H_2O)_6]^{2+}$ to $[ZnX_4]^{2-}$ (cf. Section 9.2). In contrast, no shifts were observed for perchlorate, nitrate, or sulfate salts, where presumably the zinc-containing species is $[Zn(H_2O)_6]^{2+}$ throughout.

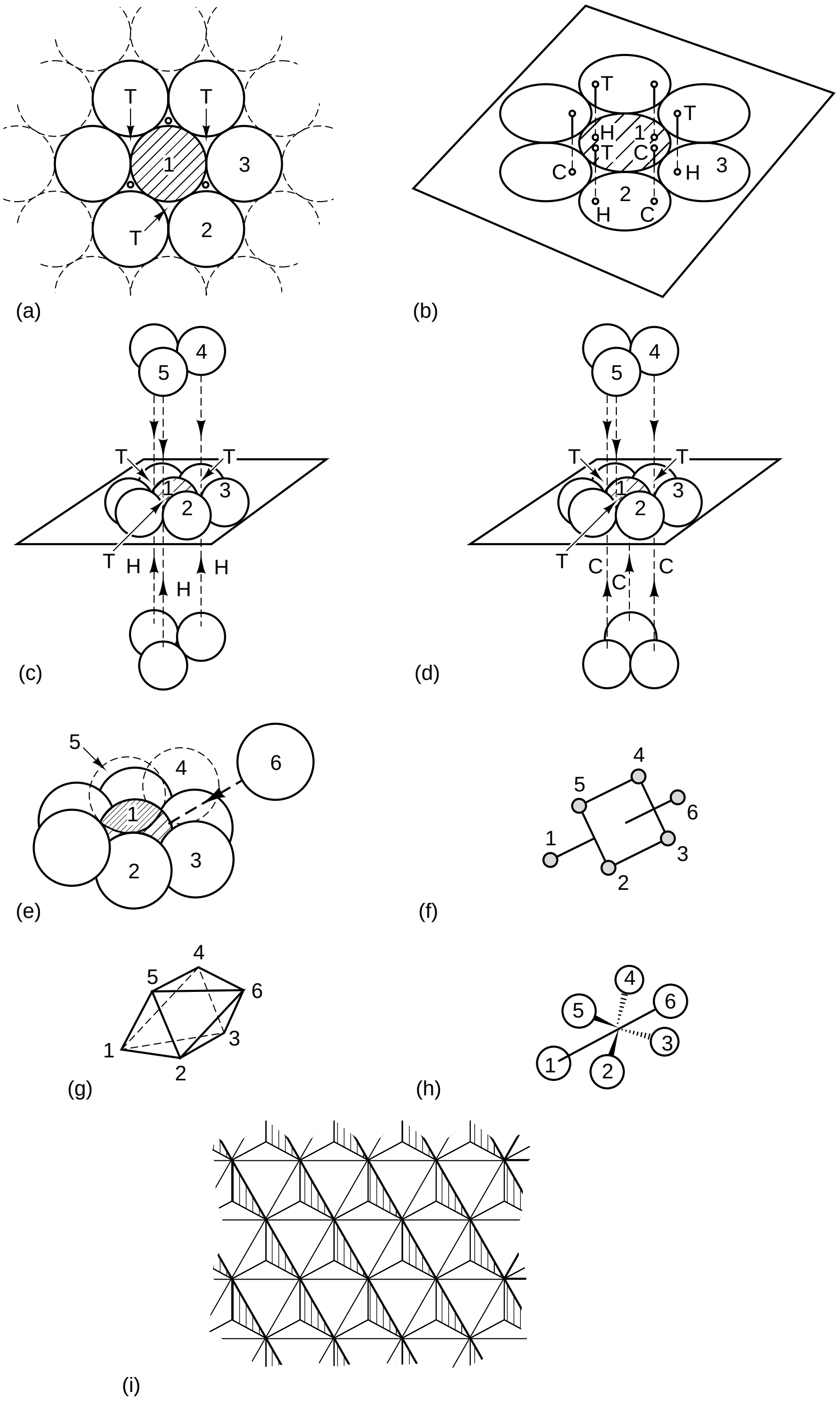

Figure 1 The relation of close packing to the structural chemistry of zinc and its compounds. (a) Close-packed identical spheres in a plane surrounding a central sphere (shaded, 1). (b) An equatorial plane through the spheres in (a) showing the location of the centers of holes above and below the equatorial plane. Only three spheres from above the plane may be placed in the positions corresponding to alternate holes, such as those marked T, so as to achieve close packing; the centers of these spheres lie directly over the hole centers. An atom at the center of the T holes is coordinated to the four contact spheres in regular tetrahedral coordination. (c), (d) The two ways of adding three spheres from below the equatorial plane to achieve close packing; in (c) the centers of the upper and lower spheres lie above each other so that the lower ones are located at H in (b). This is hexagonal close packing and is found in the structure of metallic zinc (albeit distorted, see text). In (d) the three lower spheres alternate with respect to the upper ones (i.e. three upper spheres at T, three lower spheres at C, in b). This is cubic close packing and is the foundation of the structures of many zinc compounds (e.g. ZnS, ZnO, see text). (e) Two of the three spheres, 4 and 5, added above the plane form an octahedral hole when sphere 6 is added. Spheres 1–6 surround this hole in an octahedral arrangement that may be represented as shown in (f), (g), or (h). If a zinc atom lies at the center of the octahedral holes and the spheres are, for instance, halogen atoms linked in layers of MX_6 octahedra sharing edges, this is the so-called cadmium iodide structure adopted by the zinc halides as in (i)

Ligand nuclei have been the subject of many studies; for example, ^{35}Cl NMR has been used to examine the environment of chelated zinc(II). Molar relaxivity can be used to characterize the zinc environment in terms of the quadrupolar relaxation of ^{35}Cl that it can produce in 0.5 M NaCl. Bidentate chelation (as with glycinate, glutamate, succinate) increases its effectiveness in producing ^{35}Cl relaxation. Terdentate chelation (iminodiacetate, aspartate) can either increase or decrease the amount of relaxation caused by zinc; the least relaxation is produced when the ligand atoms have a formal negative charge and a large acidity constant. In some cases, zinc chelated by four ligand atoms (nitrilotriacetate) is effective for ^{35}Cl relaxation, a good indication that such chelation does not constitute a coordinatively saturated environment. This point is significant in connection with the function of zinc in the active site of zinc metalloenzymes (*see* ***Zinc Enzymes***). Molar relaxivities for 1:1 and 2:1 chelates usually differ and it is possible to derive formation constants that are consistent with literature values determined by other methods. Carbon-13 NMR studies have been widely used to investigate complexing of a variety of organic ligands with zinc. A more exotic example of the use of ligand nuclei to evaluate the properties of zinc-containing species is afforded by the ^{119}Sn NMR study of a zinc complex derived from a tripodal triamidostannate(II) ligand, viz. $Zn[Sn\{SiMe_2N(p\text{-tolyl})\}_3SiMe]_2$. The NMR results establish the metal–metal bond polarity, X-ray diffraction having shown the Sn–Zn–Sn unit to be linear.[49]

4.2 Chemical Properties

Freshly cut zinc is a shiny metal with a bluish lustre but it tarnishes rapidly in moist air, to give a protective coating of ZnO, $Zn(OH)_2$, and $ZnCO_3$. It combines readily with oxygen, sulfur, phosphorus, or the halogens on heating. Nonoxidizing acids dissolve zinc with evolution of hydrogen to give zinc(II) salts that, in aqueous acids, contain the hydrated Zn^{2+} ion and often a range of its complexes with the acid anion. With oxidizing acids, the reactions are more complicated: nitric acid, for example, gives a variety of nitrogen oxides (and frequently some of their reduction products) depending on the concentration and temperature. Zinc is the only element of the Zn, Cd, Hg triad to dissolve in aqueous alkali to give ions such as aquated $[Zn(OH)]_4{}^{2-}$, the zincate ion. Such solutions are technically important in the electrolytic deposition of zinc on aluminum.

Since zinc has a filled d shell, few characteristic transition metal properties are shown and zinc(II) compounds are colorless and diamagnetic. Indeed, zinc shows similarities to magnesium, many of their compounds being isomorphous and, like magnesium, it displays class a (hard) behavior in complexing readily with O-donor ligands (*see Class A & Class B Behavior*). In contrast to magnesium, however, zinc has a much greater tendency to form covalent compounds (e.g. ZnO has a tetrahedral wurtzite structure whereas MgO has the normal NaCl structure). Zinc does share one feature in common with transition elements and that is its tendency to form a large number of stable complexes not only with O-donor ligands but also with N- and S-donor ligands and with halides, pseudohalides, and cyanide (Section 8). Its versatile complexing behavior places zinc on the class a/b (hard/soft) borderline (*see Class A & Class B Behavior*) and this feature of zinc chemistry is doubtless important in the catalytically active and structural sites of zinc enzymes in which complexation with O-, N-, and S-containing groups from amino acid side chains readily occurs (*see also* ***Zinc Enzymes*** and ***Zinc: DNA-binding Proteins***). In a more specific resemblance to a transition metal, zinc(II) complexes resemble those of high-spin cobalt(II) in terms of *Kinetic Lability* and *Stereochemistry*; for each element in the +II state it is generally true that four-, five-, and six-coordinated complexes readily interconvert. This is reasonable since, in terms of electron density, high-spin $3d^5 4s^2$ would be expected to behave similarly to $3d^{10} 4s^2$, and the ionic radii are almost identical. Use is made of this in the substitution of cobalt for zinc in zinc metalloenzymes, with minimal structural perturbation, thereby providing a spectroscopically active probe for the active site environment of the metal ion.

5 OXIDATION STATE AND STEREOCHEMISTRY

5.1 Oxidation State

The Raman spectrum of the glassy solid obtained from a melt of Zn in $ZnCl_2$ indicates the presence of the $(Zn–Zn)^{2+}$ ion, but the chemistry of zinc is dominated by the +II state and, except possibly in the *Pulse Radiolysis* of complexes of Zn^{2+}, for example, those of cyclic ligands (L) such [14]ane-1,4,8,11-N_4 where species of the type LZn^+ have been detected, and the radical ligand complex of the same stoichiometry where L = the radical anion of glyoxal bis(N-t-butylamine) generated in the cavity of an electron spin resonance (ESR) spectrometer, the role of zinc(I), real or apparent, is minimal so far as the general chemistry of zinc is concerned. It is interesting, however, that the Zn^+ ion is formed, albeit slowly ($k < 10^5\,M^{-1}\,s^{-1}$), by the reaction of the *Hydrated Electron* with Zn^{2+}. The Zn^+ species is a powerful reductant and from the *Marcus Treatment* of the reduction of $[Ru(NH_3)_6]^{3+}$ it is estimated that $E°(Zn^{2+/+})$ is approximately -1.0 V; other estimates are even more negative.

5.2 Coordination Numbers and Stereochemistry

The key one-volume source of information on inorganic structures remains the overview by Wells,[50] the source of most unattributed structural information in this article. It is necessary to trace specific zinc compounds through

Table 2 Stereochemistry of Some Zinc(II) Compounds

Coordination number	Stereochemistry	Example
2	Linear	$ZnCl_2$ (g), $ZnEt_2$
3	Planar	$[ZnMe(NPh_3)]_2$, bis(ethylxanthato) (py)Zn
4	Tetrahedral	$[ZnCl_4]^{2-}$, $[Zn(NH_3)_4]^{2+}$
	Planar	$[Zn(TPP)]^{2+}$
5	Trigonal bipyramidal	$[Zn(tren)NCS]^+$
	'Square' pyramidal	$[Zn(S_2CNEt_2)_2]_2$, $[Zn(acac)_2OH_2]$
6	Octahedral	$[Zn(en)_3]^{2+}$
7	Pentagonal bipyramidal	$[Zn(H_2dapp)(H_2O)_2]^{2+}$
8	Distorted dodecahedral	$[Zn(NO_3)_4]^{2-}$

Wells's formula index as well as consulting his general discussion of zinc compounds. Coordination numbers of Zn^{2+} in its compounds and complexes range from 2 to 8 (Table 2). The filled d shell confers no crystal field stabilization on Zn^{2+} (*see Crystal Field Stabilization Energy*) and coordination number and stereochemistry are determined by the size of the Zn^{2+} cation and the *Steric requirements* of the ligands. Both tetrahedral and octahedral geometry are commonly found in complexes, though essentially all Zn^{2+} ions in biological systems are in tetrahedral coordination. Several zinc complexes are mentioned in a recent review of seven-coordinate complexes.[51] Where ligands bind by chelation (*see Chelating Ligands*), and quite often even where ligands are monodentate, distortions from regular geometries are widespread.

Six-coordinate complexes may be octahedral or trigonal prismatic. The synthesis of a number of six- and five-coordinate complexes with amino acids and pyrazole throws light on the factors involved both in the determination of the geometry of six coordination and on possible mechanisms of interconversion through a five-coordinate intermediate or transition state.[52] Zn^{2+} can exhibit two coordination numbers in the same compound – indeed the unit cell of the maltol complex $[Zn(malt)_2]\cdot 1.5H_2O$ contains both five- and six-coordinate Zn^{2+} ions.[53] Both five- and six-coordinate cations have been found in a binuclear complex of an unsymmetrical compartmental ligand,[54] in a tetrazinc metallacrown species,[55] and in the bis-Zn^{2+} complex of a ligand containing both a bipy and a terpy unit. Zn^{2+} occupies both octahedral and trigonal bipyramidal sites in $Zn_3V_4(PO_4)_6$, and square pyramidal sites in $Zn_2(VO)(PO_4)_2$,[56] while Zn is found in trigonal planar, tetrahedral, and trigonal bipyramidal sites in $[Zn_4(thf)_4(MeZn)_4(O_3SiR)_4]$, where $R = -N(SiMe_3)(2,6\text{-}^iPr_2C_6H_3)$.[57] Such metallasiloxanes can act as models for zinc-containing zeolite catalysts, which have recently been reported to facilitate a range of organic reactions.

6 BINARY COMPOUNDS

6.1 Zinc Hydride, Carbide, and Related Compounds

Zinc hydride, a moderately stable solid slowly decomposed by water, may be prepared by the reaction of LiH, NaH, or $LiAlH_4$ on a zinc halide such as the bromide or iodide. If organometallic derivatives of zinc of the type Li_nZnR_{n+2} are treated with $LiAlH_4$, complex hydrides such as $LiZnH_3$, Li_2ZnH_4, and Li_3ZnH_5 may be prepared.

The carbide ZnC_2 may be regarded as an acetylide containing the $C_2{}^{2-}$ ion. A zinc carbene, $ZnCH_2$, can be prepared by the *Matrix Isolation* technique; it undergoes a carbene-carbyne change to HZnCH on UV irradiation. The carbene may possibly be regarded as a radical ion pair formed by transfer of an electron from Zn to CH_2 to give an anionic carbene.[58,59]

Zinc alkyls and aryls are reactive to air and water and their reactions are similar to, but less vigorous than, those of Grignard reagents, from which they differ in the important respect that they do not react with CO_2 and are usually prepared in an atmosphere of this gas. Zinc may be used to generate, in effect, the nucleophile $^-CH_2CO_2R$ from α-halo esters that can then react with carbonyl compounds as in the well-known Reformatsky reaction:

$$\text{RCOR}' + \text{BrCH}_2\text{CO}_2\text{Et} \longrightarrow \text{RR}'\text{C(OH)CH}_2\text{CO}_2\text{Et} \qquad (7)$$

Metal–hydrogen and metal–carbon bond strengths, including some values for zinc, have been reviewed.[60]

6.2 Compounds with Group 15 Elements

Zinc nitride, Zn_3N_2, may be prepared by heating zinc amide, $Zn(NH_2)_2$, to 330 °C or by heating zinc dust to 600 °C in a stream of ammonia. It is regarded as an ionic nitride containing the N^{3-} ions in an α-Mn_2O_3 structure in which the zinc ions have four tetrahedral neighbors and N has two types of distorted octahedral coordination groups. The radius of the nitride ion in this and similar nitrides is close to 1.5 Å, larger than that of most metal ions.

Zinc phosphides, which include Zn_3P_2, Zn_7P_{10}, ZnP_2 (α- and β-forms), and ZnP_4, may be prepared from the elements. The structure of Zn_3P_2 is closely related to that of Zn_3N_2: the zinc atoms are surrounded tetrahedrally by four P but each P is surrounded by six Zn at six of the vertices of a distorted cube. The compound is used as a lubrication additive and as a pesticide and rodenticide. It works as a poison by releasing phosphine in the rat's stomach. Phosphidozincates $M[ZnP]_2$ are known for M = Ca, Sr, Ba, Cd; the Sr^{2+} salt has been shown to have the calcium aluminum silicide structure, consisting of layers of edge-shared ZnP_4 tetrahedra alternating with Sr^{2+} layers.[61]

Zinc antimonides (Zn_3Sb_2, Zn_4Sb_3, and ZnSb) are semiconductors.

6.3 Compounds with Group 16 Elements

Tetrahedral coordination is again a dominant theme. All the monochalcogenides adopt either a wurtzite or zinc blende structure, described below, in which the metal is tetrahedrally coordinated. Various aspects of close packing in relation to the structures of ZnO, ZnS, and other zinc compounds are depicted in Figure 1.

6.3.1 Zinc Oxide, Zinc Hydroxide, and Zincates

ZnO is the most important manufactured zinc compound; it was known long before the metal itself. The technical product is made by burning in air the zinc vapor obtained on smelting the ore but this can contain a few tenths of a per cent of lead as an impurity. A purer product is made from the vapor of refined zinc. It is a finely divided white solid with the wurtzite structure (cf. Figure 1 and zinc sulfide below). On heating, it changes to a yellow colored solid: this is associated with the evaporation of oxygen from the lattice to give a nonstoichiometric phase ZnO_{1-x} ($x \leq 70$ ppm).[62] The excess zinc atoms produce lattice defects that can be excited by absorption of visible light, and by 'doping' zinc oxide with an excess of 0.02–0.03% zinc metal a range of colors – yellow, green, brown, or red – can be obtained. The photophysics of zinc oxide and its functioning as an archetypal binary compound semiconductor have been reviewed,[63] and the self-assembly of zinc oxide into nanorods reported.[64]

The major use of zinc oxide is in rubber production, where it lowers the vulcanization temperature and shortens vulcanization time. It is also used as a pigment in paints, 'zinc white' in oils and 'chinese white' in water colors, having the twin advantages compared with 'white lead' (the 'flake white' or Cremnitz white of the artist), a basic lead carbonate, that it is nontoxic. Also, since zinc sulfide is white, it is not discolored by sulfur compounds. It has the disadvantages compared with TiO_2 (*see* ***Titanium: Inorganic & Coordination Chemistry***) of a lower refractive index and therefore a lower covering power, sometimes used to advantage by the artist. In some paint vehicles, it is inclined to give a brittle paint film and consequent durability problems. However, it improves the chemical durability of glass and for this reason is used in the production of special glasses, both opaque and transparent, and in enamels and glazes. It is used as the starting material for a range of other zinc chemicals such as zinc soaps (zinc salts of the longer chain fatty acids) that are used as paint driers, fungicides, and stabilizers in plastics. It is used in the production of zinc silicate, Zn_2SiO_4, for television screen manufacture. A minor but important use is in the manufacture of 'zinc ferrites' (*see Ferrite*). These are *Spinels*, $Zn^{II}_xM^{II}_{1-x}Fe^{III}_2O_4$, having the second metal, M, in oxidation state two (M is frequently Mn or Ni). When $x = 0$ the structure is that of an inverse spinel (i.e. half the Fe^{III} ions occupy tetrahedral sites in the close-packed array of oxide ions, the other half of the Fe^{III} ions occupying octahedral sites), and when $x = 1$ it is that of a normal spinel in which all the Fe^{III} ions occupy octahedral sites because Zn^{II} displaces Fe^{III} at the tetrahedral sites. Lowering the fraction of Fe^{III} ions in the tetrahedral sites lowers the *Curie Temperature*. The magnetic properties of the ferrite are therefore controllable by adjustment of the zinc content. Thin films of zinc oxide have excellent piezoelectric properties and high transmittance and are used in transducers, gas sensors, surface acoustic wave devices, solar cell windows, and transparent conducting films;[65] spectra of transparent colloidal suspensions of very small zinc oxide particles have been reported.[66] Zinc oxide is also used for desulphurization of, inter alios, carbon dioxide, and feedstocks for catalytic processes, and in ZnO/Cr_2O_3 catalysts for high-pressure synthesis of methanol.[67] There are also a number of medicinal and cosmetic uses for zinc oxide – it is used in various dermatological treatments, alone or mixed with Bi_2O_3 or bismuth subgallate in the treatment of hemorrhoids, in dental cements, in sun screens, and to give 'body' to cosmetic formulations.

ZnO is amphoteric, dissolving in acids to form salts containing the hydrated zinc(II) cation (cf. Section 9.1), which may be more or less complexed with the acid anion depending upon its affinity for zinc and on concentration. Zinc oxide dissolves in alkalis to form zincates such as $[Zn(OH)_3]^-$ and $[Zn(OH)_4]^{2-}$. Various salts of these hydroxy-ions have been structurally characterized. Zinc also forms zincates of the type $M^{II}ZnO_2$, where M = Sr or Ba, and $M^IM^{I'}ZnO$, where M^I, $M^{I'}$ = Li, Na, K variously. These are prepared from the respective component oxides. In $SrZnO_2$, layers of ZnO_4 tetrahedra, sharing all vertices, provide sites for Sr^{2+} ions in seven coordination between the layers, whereas in $BaZnO_2$ the ZnO_4 tetrahedra form a quartz-like framework containing Ba^{2+} ions in positions of irregular eight coordination.

An important structure in the chemistry of hydroxy (and carbonate) derivatives of zinc is the so-called CdI_2 (or brucite, $Mg(OH)_2$) structure. This structure may be represented in various ways – Figure 1(a) shows one representation. From this close-packed description, it follows that because different layer sequences are possible there is a very large number of closely related structures (more than 80 such structures have been characterized). Zinc hydroxide, for example, exists in a number of forms based on this structure but with differing layer sequences; one of them has the simple CdI_2 structure, others have more complex layer sequences and one, the γ-form, has an entirely different structure consisting of rings of three tetrahedral $Zn(OH)_4$ units that are linked through their remaining vertices into infinite columns (Figure 2). The upper vertices (x) of the tetrahedra of one ring are the lower vertices (y) of the ring above, thus sharing all the vertices within the column and giving the composition $Zn(OH)_2$. Each column is linked to neighboring ones by hydrogen bonds.

A number of zinc hydroxy compounds are based on the CdI_2 layer structure but with zinc ions attached to the outside of the layer. Since the I atoms are close packed in a CdI_2 layer, there are two kinds of site on either side of such a layer for

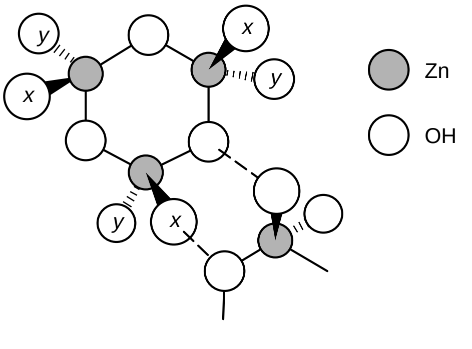

Figure 2 The coordination of zinc in γ-Zn(OH)$_2$

additional metal ions: above an occupied octahedral interstice or above an empty tetrahedral site. On electrostatic grounds, neither type of site is suitable for a straightforward addition of the metal ion to the layer because of the proximity to either one or three cations of the layer. This difficulty is overcome in the first case by removing the metal ion from within the layer (Figure 3). The mineral chalcophanite, $ZnMn_3O_7 \cdot 3H_2O$, has layers of the simplest cadmium iodide type (cf. Figure 1) derived from Mn^{4+} and O^{2-} ions from which one-seventh of the metal ions have been removed, giving the composition Mn_3O_7 instead of MnO_2. Bound to each side of this layer directly above and below the unoccupied Mn^{4+} positions are Zn^{2+} ions and between the uncharged layers are layers of water molecules, three of which complete the octahedral coordination of the Zn^{2+}.

In the hydroxy chloride $Zn_5(OH)_8Cl_2 \cdot H_2O$, the structure is based on charged layers with chloride ions and water molecules in between. One-quarter of the zinc ions are missing from a $Zn(OH)_2$ layer, and for each absent Zn^{2+} two such ions are added beyond the surfaces of the layer so that the composition is $Zn_5(OH)_8{}^{2+}$. The charge is balanced by the chloride ions between the layers. The Zn^{2+} ions are tetrahedrally coordinated on the outer surfaces of the layers, in contrast to octahedrally coordinated Zn^{2+} within the layers. A similar structure is found in the hydroxy nitrate, $Zn_5(OH)_8(NO_3)_2 \cdot 2H_2O$. Closely related to these structures is one in which the layers are linked by bonds to the Zn^{2+} ions on the surface: the compound in question is hydrozincite, $Zn_5(OH)_6(CO_3)_2$, formed during the corrosion of zinc and in the weathering of zinc ores. Again one-quarter of the Zn^{2+} are absent from a $Zn(OH)_2$ layer and replaced by twice their number of zincs, equally distributed on either side of the layer. In addition, there is replacement of one-quarter of the OH^- ions in the layer by O atoms of $CO_3{}^{2-}$ ions, giving the composition $Zn_2[Zn_3(OH)_6](CO_3)_2$ instead of $Zn_4(OH)_8$ of the parent compound. A second O atom of each $CO_3{}^{2-}$ is bonded to the surface Zn atoms, which are tetrahedrally coordinated as in the hydroxy chloride (see Figure 3). Since there is bonding between the Zn and O throughout the structure in its entirety, this is not a layer structure although its relation to one is clear. The close-packed layers of O atoms around octahedrally coordinated Zn atoms are again a prominent feature of the structure. All these structures illustrate the ease with which zinc is able to enter into tetrahedral and octahedral coordination.

In addition to the normal oxide, ZnO, a peroxide MO_2 is also known. This decomposes slowly at ambient temperature, but nonetheless has been used as an astringent, a deodorant, and a vulcanizing agent.

6.3.2 *Zinc Sulfide*

ZnS, zinc blende or sphalerite, is the most common ore of zinc, but it is also found in a rarer mineral, wurtzite, which is the more stable at high temperatures. These minerals are important archetypal structures found in many other AB compounds that are essentially nonionic and these structures bear the names of the respective minerals. In both, each Zn is tetrahedrally coordinated by four S and each S is coordinated tetrahedrally by four Zn. The structures differ only in the type

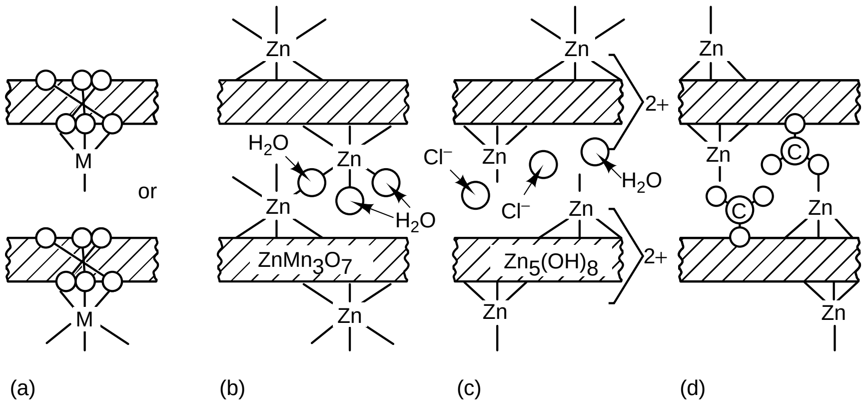

Figure 3 Removal of a metal ion from a close-packed CdI$_2$-type layer to the surface: diagrammatic representation of its occurrence in the structures of some zinc compounds

of close packing: it is cubic in zinc blende and hexagonal in wurtzite (see Figure 1).

When pure, ZnS is white and is used as a pigment that, when coprecipitated with barium sulphate, gives the white pigment ‘lithopone’. Various grades are produced containing 26–60% ZnS; it is more opaque than zinc white and when suspended in water or oil has thixotropic properties. Its commercial importance has greatly decreased, however, since the introduction of titanium pigments. Zinc sulfide when freshly precipitated dissolves easily in mineral acids with evolution of H_2S, but roasting renders it far less reactive and it is then used as a harmless nontoxic pigment.

Zinc sulfide turns gray on exposure to UV light, probably due to some dissociation into the elements, a process that is inhibited by trace addition of cobalt salts. X-rays, radioactivity, and cathode rays produce fluorescence or luminescence in a variety of colors (e.g. traces of copper give a greenish phosphorescence after exposure to light or in the presence of a trace of a radioactive compound). The range of colors can be extended by changing the trace metal added or by the replacement of zinc by Cd and of S by Se. It is widely used in the manufacture of cathode-ray tubes and of luminous dials. Zinc sulfide is a semiconductor; Mn-doped zinc sulfide nanoparticles have promising optical properties.[68]

6.3.3 Zinc Selenide and Telluride

Zinc selenide (yellow) and telluride (brown) have similar structures to those of the sulfide, both existing in both wurtzite and zinc blende modifications. The selenide is used with zinc sulfide as a phosphor. It has the interesting property that it can act as a blue–green solid state laser: blue–green laser action in solids is rare (most solid-state lasers function towards the red end, 635 nm or more, of the spectrum). At room temperature, laser action with the selenide at a wavelength of 525 nm (green) is observed and at −196 °C at 495 nm (blue). Unfortunately the laser is relatively short-lived. Zinc telluride is a wide band gap semiconductor whose electron transport properties in the form of thin films of stoichiometric and nonstoichiometric forms have been much studied.[69,70] Its applications in optoelectronics, for example, as an optical recording material, have been reviewed.[71]

6.4 Zinc Halides and Pseudohalides

All four halides are known. In the gas phase, they consist of linear X–Zn–X molecules with internuclear distances (in Å) as a function of X as follows: F, 1.81; Cl, 2.05; Br, 2.21; I, 2.38. The difluoride has the highest melting point (872 °C), the melting points rising thereafter from chloride to bromide to iodide (275, 394, and 446 °C, respectively). ZnF_2 may be prepared by the action of HF on the metal or by the action of heat on the tetrafluoroborate $Zn(BF_4)_2$. It has the typically ionic 6:3 rutile structure in which zinc is six coordinated by F^- ions. This stereochemistry persists in the complex fluoride $KZnF_3$, which has the ideal perovskite structure. Although its solubility is low, ZnF_2 may be crystallized as a tetrahydrate from aqueous solutions. The nearly anhydrous compound has been used in the fluorination of organic compounds and has been used in the manufacture of phosphors for fluorescent lights, glazes, and enamels for porcelain, for preserving wood, and in electroplating.

$ZnCl_2$, $ZnBr_2$, and ZnI_2 are hygroscopic with extremely high solubilities in water, which is able to dissolve about four times its mass of ZnX_2. Aqueous methods of preparation give hydrates, of which a number are known. The halides are best prepared anhydrous by the usual dry methods such as treating the heated metals with HCl, Br_2, or I_2, as required. Water-free solutions of ZnX_2 may also be prepared by treating a suspension of finely divided zinc in an inert solvent with the appropriate halogen.

The chloride, bromide, and iodide show properties characteristic of covalent compounds such as solubility in ethanol, acetone, methyl cyanide, and other organic solvents. They also have comparatively low-melting points, and crystal structures based on a two-dimensional array that may be regarded as derived from a close-packed lattice of halide ions in which the zinc ions occupy the tetrahedral sites. The crystal chemistry of $ZnCl_2$ is more complex than at first appeared. Three polymorphs were originally described that, although they can be regarded as having approximately close-packed chloride ions, had different layer sequences. It has been found, however, that the structure is extremely sensitive to the presence of water and if crystallization is carried out with rigorous exclusion of water, an orthorhombic hexagonal close-packed structure is formed that changes into one of the other structures on exposure to the atmosphere. The presence of OH^- ions formed on exposure to moisture may facilitate the rearrangement of the layers. The hcp structure is the only stable one for $ZnCl_2$. All four structures consist of tetrahedral $ZnCl_4$ groups, each sharing vertices with four others. The bromide is also based on tetrahedral MX_4 units. The iodide has a unique structure: one-quarter of the tetrahedral interstices in a ccp array of I atoms are occupied in groups of four to form supertetrahedral Zn_4I_{10} groups, which are joined by sharing four vertices to form a three-dimensional structure. The structures of all three halides contrast strikingly with those of the typically ionic MX_2 halides. Molten $ZnCl_2$ has a remarkably high viscosity at its melting point and an X-ray diffraction study indicates that the liquid consists of Zn^{2+} and $[ZnCl_4]^{2-}$ ions, rather than molecular $ZnCl_2$. On the other hand, the temperature dependence of the viscosity and the electrical conductance of the liquid has been interpreted in terms of polymeric species $[ZnCl_2]_x$ and free Zn^{2+} and Cl^- ions arising from dissociation of the salt.

Zinc chloride has a large number of uses. It has been used as a deodorant, disinfecting, and embalming material; alone or with phenols or other fungicides in the preservation of railway sleepers (ties); for fireproofing timber; with ammonium

chloride as a flux for soldering (it readily dissolves other oxides); for etching metals; in the manufacture of parchment paper, artificial silk, dyes, activated carbon, cold-water glues, and vulcanized fiber; for browning steel, galvanizing iron, copper plating iron; in magnesia cements, and with zinc oxide in dental cements; in petroleum oil refining; in cements for metals and for facing stone; as a mordant in printing and dyeing textiles; for carbonizing woollen goods; in producing crepe and crimping fabrics; for mercerizing cotton, sizing and weighting fabrics, and vulcanizing rubber; as a solvent for cellulose; for preserving anatomical specimens; in microscopy for separating silk, wool, and plant fibers; as a dehydrating agent and catalyst in some organic syntheses. Its astringent properties make it useful in dentistry as a dentine desensitizer and in veterinary practice in the treatment of ulcers and similar conditions.

Zinc bromide is used in making silver bromide collodion emulsions for photography and in the shielding of viewing windows for nuclear reactions.

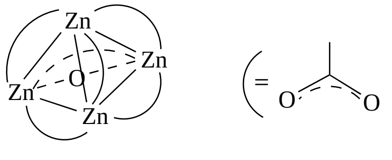
Zinc cyanide has a three-dimensional structure with tetrahedral zinc and coordination to both C and N of the cyanide, the latter lying along the line joining the zincs in the tetrahedral array of zincs in its anticuprite structure. $Zn[C(CN)_3]_2$ has a rutile-related infinite framework in which trigonal carbon centers are linked via –C≡N– units to half as many octahedral zinc(II) centers; the structure resembles knitting and exhibits a twofold penetration.[72] Zinc thiocyanate in the solid consists of thiocyanate-bridged tetrahedral ZnN_4 and ZnS_4 centers; it decomposes on heating to give ZnS.

7 SALTS

7.1 Oxoanion Salts: Preparation, Properties, and Structures

The salts are prepared by the usual neutralization methods. They are generally isomorphous with the corresponding salts of magnesium but are not thermally as stable. The nitrate, sulfate, and carbonate all decompose ultimately to the oxide on heating. Many of the salts, such as the nitrate, perchlorate, and sulfate, are very soluble in water and often form more than one hydrate; octahedral $Zn(H_2O)_6{}^{2+}$ units are usually present when there is sufficient water of crystallization. Attempts to prepare anhydrous salts by heating give hydroxy salts. The volatile anhydrous nitrate may be prepared by the action of N_2O_4 in ethyl acetate or methyl cyanide on the metal. The zinc phosphates provide a range of structures–α-$Zn_3(PO_4)_2$ contains ribbons of ZnO_4 tetrahedra, β-$Zn_3(PO_4)_2$ contains ZnO_4 and ZnO_5 polyhedra, while $Zn(HPO_4)\cdot H_2O$ consists of H-bonded sheets of linked ZnO_3 and ZnO_6 polyhedra. Templated hydrothermal syntheses in the presence of organic bases, for example, triethylenetetramine or piperazine (whose protonated forms provide the necessary cations), gives a variety of zincophosphate (and zincoarsenate[73]) anions,[74] all of which contain zinc in ZnO_4 tetrahedra. Such compounds generally have infinite structures, such as 3D frameworks ($[Zn_2P_2O_8]^{2-}$ and $[Zn_3(PO_4)_2(HPO_4)]^{2-}$ consist of ZnO_4 and PO_4 tetrahedra, the latter ion with 1D channels), 2D layers (e.g. $[Zn_2(HPO_4)_3]^{2-}$ and $[Zn_4P_4O_{16}]^{2-}$), and 1D ladders (e.g. $[Zn(HPO_4)_2]^{2-}$).[75] The use of creatinine as template permitted the synthesis of the first uncharged cluster, $C_4H_7N_3O\cdot Zn(H_2O)(HPO_4)$.[76] It is fairly easy to transform low dimensional structures, such as 1D ladders, into 2D and 3D structures. Zinc phosphonates appear in intercalated layer, pillared, and porous forms;[77] the complex prepared hydrothermally from *N*-methyliminobis(methylenephosphonic acid) is monoclinic, comprising a 3D network of phosphonate-bridged ZnO_4 tetrahedra.[78] Zinc 2-aminoethylphosphate has a phosphate-bridged infinite chain structure; it provides a useful model for metal–phosphate interactions.[79]

Anhydrous zinc acetate may be prepared from zinc nitrate and acetic anhydride; the dihydrate may be crystallized from dilute acetic acid. The zinc in the dihydrate is in an octahedral environment with *trans* diaxial water ligands and bidentate chelating (*see Chelating Ligands*) acetate groups. In the anhydrous salt, the zinc is in a distorted tetrahedral environment with bridging acetate groups. Distillation of zinc acetate gives a crystalline basic acetate $[Zn_4O(OCOMe)_6]$, the structure of which (**1**) is analogous to that of basic beryllium acetate. The two compounds are isomorphous; in each the metal is coordinated by four oxygens, three from bridging acetate groups and the fourth lying at the center of the tetrahedron of zinc ions. The two compounds differ in that the zinc complex is hydrolyzed rapidly in water. Absorption and emission spectra of $[Zn_4O(OCOMe)_6]$ have been investigated[80] as well as the X-ray PES (Photoelectron Spectroscopy), and a theoretical treatment shows how well this complex throws light on the electronic structure of zinc oxide itself.[81] The complex is photoluminescent and has a *Ligand-to-Metal Charge Transfer* band, a feature not shown by simple $[ZnX_4]^{2-}$ complexes. Other basic carboxylates $[Zn_4O(RCO_2)_6]$ with R = for example, Et, or *n*-Pr, or NEt_2 are known.



(**1**)

The crystal structures of a wide range of carboxylates have been described, the main features being that octahedral and tetrahedral coordination, sometimes distorted, are commonly observed and polymeric structures, especially with polyfunctional ligands, are frequently found.

7.2 Oxoanion Salts: Uses

Zinc sulfate has been used in rayon manufacture, as a mordant in calico printing, for preserving wood and skins, for clarifying glue, in electrodeposition processes, and in the manufacture of other zinc salts. Thus, for example, zinc nitrite cannot be prepared from aqueous solutions because of rapid hydrolysis but it can be prepared by treating sodium nitrite with zinc sulfate in alcohol. Zinc sulfate also has medicinal uses, in eye lotions and drops, in postoperative tissue healing, and as an emetic. It is also used as a zinc supplement, as also are zinc gluconate, zinc citrate, and zinc picolinate. Zinc phosphate is used in dental cements and temporary fillings. Zinc carbonate and basic zinc carbonate have, alongside zinc oxide, been used since the time of Ancient Egypt to treat a variety of skin conditions (Calamine Lotion, and a variety of ointments and dusting powders).

Several zinc salts act as, or can be doped to give, pigments.[82] Zinc germanate doped with V^{4+} (cf. zircon purple, V^{4+} doped into $ZrGeO_4$) and Fe^{3+} doped into $ZnGa_2O_4$ give brown pigments; the brown color of the latter can be varied by varying the Fe^{3+} content. Zinc chromate(VI) is a useful yellow pigment widely used in metal priming paints. Zinc in a silicate matrix is used as a gray pigment in primers; a zincosilicate has been synthesized that acts as a molecular sieve containing three-membered rings.[83]

Zinc acetate is used in wood preservation, as a mordant in dyeing, and in the manufacture of glazes for painting on porcelain. Zinc citrate is used in toothpastes and mouthwashes – it inhibits plaque growth.[84] The sulfanilate and several carboxylates, for example, propionate, caprylate, and undecenoate, find use in skin dusting powders and as fungicides. Zinc *p*-phenolsulfonate has been used in insecticide formulations and in veterinary practice for the treatment of ulcers. Polymerization of metal-containing monomers in the matrix of a different polymer or compound can lead to dramatic modification of properties; for example, of the tensile strength of materials such as polyethylene, where zinc acrylates and acrylamide complexes are useful in this context in giving rise to cross-linking that is controllable by adjusting the concentration of the zinc compound.

7.3 Other Salts

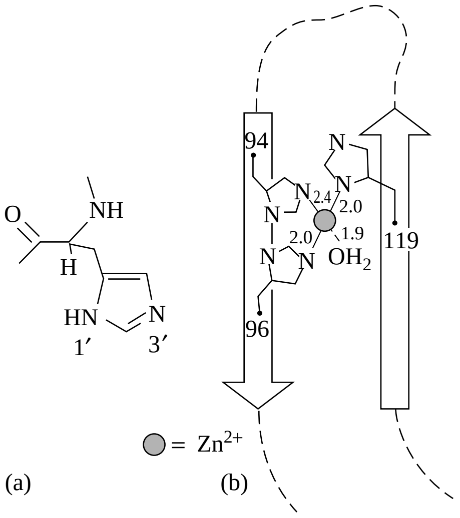
Zinc thiocyanate forms colorless deliquescent crystals, but zinc cyanide is insoluble in water. The salts $Zn_3[Co(CN)_6]_2$ and $Zn_3[Fe(CN)_5(NO)]_2$ can act as molecular sieves. The former can separate hexane isomers, thanks to the large holes arising from anion vacancies.[85] The latter has no large holes, but can separate methane from carbon dioxide. $Zn[Au(CN)_2]_2$ has a quartz-like structure with –NCAuCN– units bridging tetrahedral zinc centers.[86] Zinc cyanamide, $ZnCN_2$, a nonpolluting white pigment, has a structure in which ZnN_4 tetrahedra form Zn_4N_4 rings that in turn form twisted chains.[87] Zinc also forms a number of stable fluoroanion salts, such as $Zn(BF_4)_2$ (see Section 6.4) and water-soluble $ZnSiF_6{\cdot}H_2O$.

8 COORDINATION CHEMISTRY

Zinc has an extensive coordination chemistry, though less extensive than that of some of the preceding 3d elements. Tetrahedral complexes are particularly readily formed with halides and with a variety of O-donors. Numerous stable complexes are formed with N-donors such as NH_3, amines, and azaheterocycles, but complexing to phosphines is limited. Complexes with S-donors are common; several have unusual structural features. Zinc complexes have in recent years assumed considerable importance in the generation and self-assembly of a great range of 1-, 2-, and 3-D infinite structures and frameworks, of which a few examples are cited below. Zn^{2+} has also recently proved useful as a templating cation for the preparation of a variety of macrocycles, rotaxanes, catenanes, and molecular knots, though it must be admitted that its importance in this area, though increasing, is much less than that of Cu^{+}.[88]

Zinc(II) complexes of amino acid, peptide, nucleotide, and nucleoside ligands are of obvious biological significance. We mention them here as they illustrate well the variety of coordination modes exhibited by tetrahedral Zn^{2+}. Individual amino acids can bind through one or more N, O, or S-donor atoms. In metalloenzymes (*see* ***Zinc Enzymes*** and ***Zinc: DNA-binding Proteins***) and metalloenzyme models, the overall coordination environment of the Zn^{2+} is usually NNN, NNO, or NNS, with water in the fourth position. The most common ligating residues are histidine, glutamate, aspartate, and cysteine – the Zn^{2+} is, for example, bonded to cysteine and histidine in zinc finger proteins. The area is well covered in the introductory chapters of several standard bioinorganic chemistry textbooks; the amino acid moieties bonded to the zinc in 21 zinc enzymes have been detailed.[89] Many zinc metalloproteins contain Zn^{2+} bound to one or more imidazole ligands of the amino acid residue histidine (**2a**). Purely in terms of mode of coordination of the ligand, it is interesting to note that, where more than one histidine coordinates to the metal ion, coordination is not always through the same N atom of the imidazole ring. Thus, in carbonic anhydrase, in which the zinc is bound to three histidines and a water molecule, two of the histidines, which are on the same strand of β-pleated sheet separated by one amino acid residue, bind through the N(3′) atom of the imidazole ring whereas the imidazole of the third histidine, lying in an adjacent strand of β-pleated sheet, binds through the N(1′) atom (**2b**). A distorted tetrahedral coordination results that has some unusual features: one of the N(3′)-zinc distances is the same as the N(1′)-zinc distances. Furthermore, the two N(3′) atoms are not bound equivalently: one of them is 0.4 Å further from the zinc atom than the other one and the imidazole bearing it is also the most exposed. The

latter may well be concerned with the hydration mechanism of the enzyme[90,91] (*see also* ***Zinc Enzymes***). The role of the coordination chemistry of Zn^{2+} in the mechanisms of action of carbonic anhydrase, carboxypeptidase, and alcohol dehydrogenase has been reviewed.[92]



(**2**)

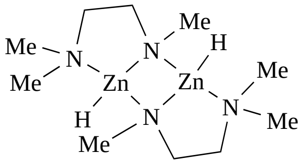
Very thorough and comprehensively referenced surveys of the coordination chemistry of zinc are available. In each of these multivolume compendia, there is an article devoted to zinc complexes,[93] but there are also numerous mentions of zinc complexes in the introductory volumes and in the volumes on applications and uses.[94] Thermodynamic data (ΔH_f°, ΔS_f°, ΔG_f°; also some ΔX° values for e.g. $ZnX_2 + 2L$) are available for about 100 zinc complexes.[95] In this present encyclopedia, we are only able to mention a very small selection of the more important and interesting complexes. Preparations, structures, properties, and uses are dealt with in this section, the solution chemistry of zinc complexes in later sections (Sections 9.2 and 9.3).

8.1 N-Donors

In salts of $[Zn(NCS)_4]^{2-}$, the thiocyanate ligand is N-bonded, whereas it is S-bonded to cadmium in $[Cd(SCN)_4]^{2-}$ salts, reflecting the respective hard and soft characters of the respective metal ions. Zinc complexes with the azide ion are well known; crystallographic determinations of the structures of the compounds $M_2Zn(N_3)_4$ ($M = K$ or Cs) show the presence of discrete $[Zn(N_3)_4]^{2-}$ tetrahedra with linear azide groups. Some of the complexes in this category, such as those with hydrazine and azide, for example $[Zn(N_2H_4)_2(N_3)_2]$, are of interest as primary explosives and care is needed in their manipulation. The 2,2′-dipyridylamine-azide complexes $[Zn(dpa)(N_3)_2]$ and $[Zn(dpa)(N_3)(NO_3)]$, which have infinite 2D and 3D structures respectively, display fluorescence and phosphorescence.[96]

The complexes $[M(NH_3)_4]^{2+}$ and $[M(NH_3)_6]^{2+}$ ($M = Zn$ or Cd) have long been known. They have tetrahedral and octahedral coordination, respectively. Interestingly, the Zn–N distance in the tetrammine complex is shorter than that in the analogous N_4 bis-1,2-ethanediamine chelate, $[Zn(en)_2]^{2+}$. Raman and IR studies, including ^{15}N labelling, have been used in the calculation of the force constants for the M–N bond in these complexes. The force constant increases with decreasing coordination number and also decreases from zinc to cadmium. Zinc ammine complexes can function as host lattices. For example, the compounds $[M(NH_3)_2Ni(CN)_4]$, where $M = Zn$ (or Cd), which consist of two-dimensional polymeric sheets of tetracyanonickelate ions bridged by coordinating diamminezinc(II) cations, function as host lattices for the clathration (*see Clathrate*) of small aromatic molecules such as thiophen, furan, pyrrole, or pyridine; IR studies indicate hydrogen-bonding between the host lattice ammonia ligands and the aromatic guest molecules.

Less work has been done on the complexes of amines, RNH_2, than on those with polyfunctional amines such as 1,2-diaminoethane, and to a lesser extent its *N*-alkylated derivatives, for which a large body of data exists. Tetrahedral and octahedral coordination again feature prominently in the structures of these compounds, though with some interesting variations. For example, the hydrido complex $[ZnH(MeNCH_2CH_2NMe_2)]$ (**3**) is dimeric; each zinc atom has a terminal hydride bonded to it and is also bonded to three nitrogen atoms to give a distorted tetrahedral N_3H environment.



(**3**)

In relation to polyfunctional amines, it is interesting to observe the way in which the chelating properties of a ligand (*see Chelating Ligands*) vary with the metal: in studies on the chelating behavior of the triamine $H_2N(CH_2)_2NH(CH_2)_4NH_2$ (L) towards copper, nickel, and zinc, the five complexes ML^{2+}, $ML_2{}^{2+}$, MHL^{3+}, $M(HL)_2{}^{4+}$, and $MHL_2{}^{3+}$ are common to all three metals. In addition, Cu^{2+} and Zn^{2+} form the hydroxo complexes $[Cu(OH)L]^+$, $[Zn(OH)L]^+$, and $[Zn(OH)_2L]$. With regard to the complex ML^{2+}, the amine acts as a *Bidentate Ligand* towards Ni^{2+} and Zn^{2+} and in a terdentate manner towards Cu^{2+}, the latter containing both five- and seven-membered rings. On the other hand, the $ML_2{}^{2+}$ complexes contain only five-membered rings, with both amine ligands acting in a bidentate manner.

The catalytic properties of polyazamacrocyclic complexes of the transition metals and zinc[97] represent an active

area of investigation that began on a large scale in the 1960s. Macrocyclic ligands that can bind two different metal ions (Zn,Co; Zn,Mn) in six- and four-coordination sites within the same ligand are interesting both from the catalytic and the structural point of view.[98] The cation of $[Zn_3(triscyclam)](NO_3)_6$ is trinuclear, with a Zn^{2+} in each of the macrocyclic rings of the triscyclam ligand, which consists of three cyclam units linked by a pair of $–CH_2–p–C_6H_4–CH_2–$ bridges.[99]

Complexes of pyridine, substituted pyridines, and ligands containing fused pyridine rings (bipyridyls and 1,10-phenanthrolines) have been widely studied. Many of these complexes have interesting photophysical properties (*see* ***Photochemistry of Transition Metal Complexes***). The suberate ($^-O_2C(CH_2)_6CO_2{}^-$) hydrate of $[Zn(phen)_3]^{2+}$ has a three-dimensional hydrogen-bonded network with the cations in tunnels in the structure; suberate, glutarate, and succinate can all bridge pairs of $[Zn(phen)_2]$ units to give binuclear complexes.[100] Early studies of bipyridyl complexes concentrated on the 2,2′-isomer,[101] but in recent years there has been increasing interest in the 4,4′-isomer, arising from the numerous structural possibilities inherent in its bridging properties. The compound $Zn(4,4'\text{-bipy})SiF_6{\cdot}2H_2O$ has a structure consisting of interpenetrating perpendicular square grid sheets, each sheet stretching to infinity. Each zinc is octahedrally coordinated to four pyridine nitrogens with two water molecules in *trans* positions; the four pyridine rings about each zinc are arranged in propeller fashion and the 4,4′-ligand bridges the zinc centers.[102] 4,4′-Bipyridyl, and analogs containing units such as –C≡C– linking the pyridine rings, can be used to build a range of coordination frameworks consisting of penetrating and noninterpenetrating ladders.[103] In fact, ligands containing the 2,2′-diimine chelating group of 2,2′-bipyridyl can also be used to generate clusters and supramolecular species, though to achieve this it is necessary to have two such units in the potential linking ligand, as, for example, in Schiff bases of the type $RN{=}CHCH{=}N(p\text{-}C_6H_4)_2N{=}CH\text{–}CH{=}NR$. Three-coordinate zinc complexes of the extremely sterically demanding diazabutadiene ligand RN=CMe–CMe=NR with $R = 2,6\text{-}{}^iPr_2C_6H_3$ (the third ligand is alkyl or $N(SiMe_3)_2$) are catalysts for ring-opening polymerization of propene oxide and ε-caprolactone, thanks to the relatively high Lewis acidity of the zinc and its accessibility in this low-coordination number environment.[104] Both Zn^{2+} ions are five coordinate in a dimeric rotaxane containing phen and terpy units in each monomeric component. Addition of an excess of Cu^+ to this doubly threaded molecular assembly displaces the zinc, and decreases the length of the molecule from 83 to 65 Å as the threads slide along each other so that the Cu^+ ions are both coordinated by two phen moieties.[105]

Pyrazine, piperazine, and pyrazole[106] are, like 4,4′-bipyridyl, suitable ligands for bridging pairs of Zn^{2+} ions to give a variety of polynuclear species, while multifunctional (bi)pyridine-pyrazine ligands give scope for the assembly of various supramolecular assemblies. Using pyrazine with two 2,2′-bipyridinyl substituents as bridging ligands leads to chiral molecular squares, which can be considered to be circular helicates,[107] while diffusion of a methanolic solution of zinc iodide into a nitrobenzene/methanol solution of 2,4,6-tris(4-pyridyl)triazine, tptz, gives a complex with a doubly interpenetrated 3D network structure. This latter species crystallizes with guest nitrobenzene molecules, whose reversible release from the complex gives rise to contraction and expansion without disturbing the overall structure – behavior described as ‘springlike’ by its discoverers.[108]

Pyrazole rings are also important as constituents of the tripodal ligands colloquially known as scorpionates (polypyrazolylborates and polypyrazolylmethane), which family includes ligands with NNN-, NNO-, and NNS-donor sets.[109,110] Zinc complexes of hydrotris(pyrazolyl)borate ligands have been used to elucidate drug-metalloprotein interactions[111] and to model carbonic anhydrase and several hydrolysis enzymes.[112] Imidazole can also act as a component of similar tripodal ligands. Thus, reaction of zinc acetate with the ligand consisting of three imidazol-1-ylmethyl groups attached at the 2,4,6-positions benzene gives a complex whose structure is described as one-dimensional tubelike.[113]

Porphyrin and phthalocyanine complexes show many interesting features, including their photochemical and photophysical properties. Zinc phthalocyanine complexes have good photosensitizing properties for photodynamic therapy, PDT. In a polymetallic system containing a zinc porphyrin and silver, a photoinduced charge separation occurs giving rise to a long-lived ($\tau = 1.4$ ms) charge-separated state of the complex.[114] The limit of charge separation is redox reaction, which in the case of zinc complexes generally involves redox at the ligand. Both porphyrins and phthalocyanines can act as π-electron acceptors or donors, to give radical ligands bonded to Zn^{2+}.[115] Much effort has been devoted to varying the electronic properties of ligand substituents to tune redox potentials.[116] There is currently considerable interest in assembly and self-assembly of zinc porphyrins,[117] for example the generation of a nonameric porphyrin array.[118] A phosphine-substituted porphyrin zinc complex has been found to be a useful building block for supramolecular assemblies thanks to the high affinity of phosphines for ruthenium(II) centers.[119] Several groups have demonstrated that porphyrin dimers have a high affinity for [60]fullerene; a high affinity for [60]fullerene has now been found for a dendritic hexa-zinc-porphyrin receptor.[120]

8.2 O-Donors

Water is a good O-donor ligand, both in the solid state, where many crystal hydrates, for example, of the sulphate, bromate, and perchlorate, contain octahedral $[Zn(H_2O_6)]^{2+}$, with Zn–O 2.08–2.14 Å, and in solution (Zn^{2+}aq is discussed in Section 9.1 below).

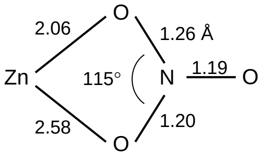


Figure 4 Bond distances in the coordination of nitrate ligands in the $[Zn(NO_3)_4]^{2-}$ ion

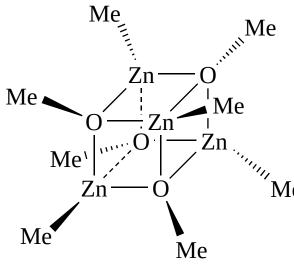
$[Zn(NO_3)_4]^{2-}$, which can be isolated as its tetraphenylarsonium salt, has a distorted dodecahedral structure,[121] each nitrate functioning as a bidentate chelating ligand (*see Bidentate Ligand* and *Chelating Ligands*) through two oxygen atoms to give eight-coordinated zinc. The nitrate coordination is not symmetrical (Figure 4), the longer bond to zinc corresponding to the shorter N–O bond and vice versa, the asymmetry tending towards tetrahedral coordination for the zinc.

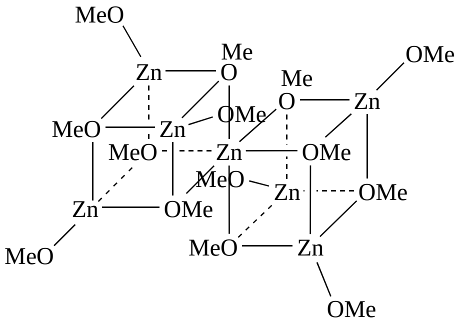
Monodentate perchlorate complexes of zinc have been identified.[122] The NO_2^- ion can, like NO_3^-, function either as a monodentate or as a chelating ligand[123] depending upon the steric requirements of other ligands present in the complex. Interestingly, nitrobenzene can also function as a mono-O- or bidentate O,O′-donor, which it does in ternary complexes also containing the $–OTeF_5^-$ ligand.[124] Carbonate can act as a monodentate or bidentate ligand – in the binuclear complex $[(bipy)_2(H_2O)Zn(\mu\text{-}CO_3)Zn(bipy)_2]^{2+}$, isolated as its nitrate heptahydrate, the bridging carbonate acts in both capacities.[125] Indeed, tetrahedral, trigonal bipyramidal, and octahedral sites have been identified in various carbonate-bridged polynuclear zinc complexes;[126] carbonate is able to act in a μ_1, μ_2, μ_3, or even μ_4 fashion in this type of complex. Zinc complexes of benzoates and related carboxylates have long been studied as catalysts for the coupling of epoxides with carbon dioxide to afford polycarbonates. Dissolution of the 2,6-difluoro- or 2,6-dichloro-benzoates – the former complex is heptanuclear with μ-benzoate and μ_4-oxo ligands – in pyridine gives mononuclear ternary complexes.[127] Dicarboxylates as bridging ligands for $[Zn(phen)_2]$ moieties are mentioned in Section 8.1.

Phosphate and vanadate complexes of zinc show a diversity of coordination behavior. Zn^{2+} accelerates polyphosphate hydrolysis (Section 9.3); appropriate zinc-organic phosphate complexes provide models for ATP transport and biological phosphate transfer, and are of possible relevance to DNA and RNA polymerases (*see* ***Zinc: DNA-binding Proteins***).

As with oxoanion salts, a number of interesting structures are found with simple organic species as ligands, for example, a crystal-structure determination of the tetrameric methylzinc(II) methoxide, $\{MeZn(OMe)\}_4$, reveals the structure (**4**) in which zinc and oxygen are each tetrahedrally coordinated. Closely related to this structure is that of the polymerization catalyst $Zn(OMe)_2(EtZnOMe)_6$ (**5**). The complex is centrosymmetric and consists of two enantiomorphic cubes sharing a corner at which a zinc atom is situated; the zincs occupy the corners of a tetrahedron and the oxygens the corners of an interpenetrating, but smaller, tetrahedron. The structure illustrates the occurrence of both four- and six-coordinated zinc in the same structure. It is interesting that mass spectroscopic investigations of the complexes MeZnOR (R = Me, Et, or *t*-Bu) show that all form oligomers in the gaseous state having either six or seven monomer units. So far as solution reactions are concerned, depending on the molar ratio of reactants, the reaction of NaOMe with $ZnCl_2$ in MeOH produces the complex ions: $[Zn(OMe)_4]^{2-}$, $[Zn(OMe)_3(MeOH)]^-$, $[ZnCl(OMe)_2]^-$, and $[Zn_2Cl_4(OMe)]_2{}^{2-}$. The last complex is postulated to have methoxide bridges rather than bridging chlorides; analogous reactions occur with sodium isopropoxide. The synthesis, properties, structures, and uses (e.g. as precursors for ceramics) of alkoxides have been reviewed.[128]



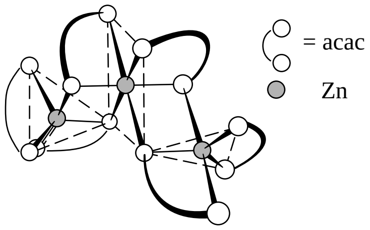
(**4**)



(**5**)

Complexes of Zn^{2+} with carbohydrates such as D-fructose and D-galactose have been isolated. Complexes with ethers, simple or crown, are rare, though it is possible to prepare zinc salts of several crown ethers from ethylene oxide and zinc fluoroanions in the presence of BF_3. An interesting template synthesis of ether-containing ligands with metal-ether bonds has been described in which zinc (and cadmium) are used to template the condensation; this contrasts with their usual inactivity in analogous aza systems.[129] Complexes with aldehydes and simple carbonyl compounds coordinated through oxygen in η^1 mode are also rare but bonding of an aromatic aldehyde, as well as acetone, in this way to zinc

in the compounds $[Zn(EC_6H_4\text{-}t\text{-}Bu_3)_2(p\text{-}O{=}CHOCHOMe)]_2$ (E = S, Se) has been reported.[130] On the other hand, β-diketones have long been studied as ligands for zinc. With acetylacetone, zinc achieves both five and six coordination in the trimer $[Zn(acac)_2]_3$ (**6**). The complex $[Zn(acac)_2(H_2O)]$ has a distorted bipyramidal structure. Complexes of the β-diketone itself, as opposed to those of the β-diketonate anion, are rare but such complexes have been described in the cases of $[Zn(acacH)_3][InCl_4]$ and $[Zn(MeCOCH_2CO_2Et)_3][InCl_4]$. Five coordination at zinc is also found in $[ZnL_2][ClO_4]_2$ [L = *o*-phenylenebis(dimethylarsine oxide)], which consists of dimeric cations, $[ZnL_2]_2{}^{4+}$, with approximately trigonal bipyramidal coordination about each zinc.



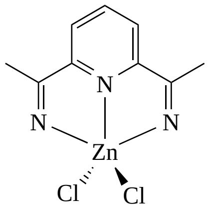
(**6**)

Zinc complexes with hydroxypyranones, for example, maltol or kojic acid, have been known for many years.[131,132] These, and analogous complexes with hydroxypyridinones, have been assessed as zinc supplements in cases of severe zinc deficiency, and more recently as potential insulin mimics.

8.3 N/O Donors

There are several series of important complexes in which zinc is coordinated by O,N-donor ligands, in particular, amino acid and aminocarboxylate anions. Both types of ligand frequently chelate metal ions through $>NCH_2CH_2CO_2{}^{-}$– units. The aminocarboxylate group contains not only such familiar ligands as ethylenediaminetetraacetate (EDTA) and nitrilotriacetate (nta), but also a number of polyazamacrocyclic ligands bearing pendant methylene carboxylate groups. Complexes of such high-denticity ligands are stabilized by both the chelate effect and the macrocyclic effect (*see* ***Macrocyclic Ligands***), and can be extremely inert to substitution, that is, dissociate extremely slowly. Zn^{2+} forms complexes with a variety of cryptands, for example, $N[(CH_2)_nNHCH_2\text{–}o\text{-}C_6H_4O(CH_2)_2]_3N$, with $n = 1, 2$, or 3. Anthracene derivatives of these ligands can act as fluorescent Zn^{2+} sensors (cf. Section 1.3 above).[133] Cryptands incorporating longer chains, for example $N[(CH_2)_2\,NH(CH_2)_2O(CH_2)_2NH(CH_2)_2]_3N$, can form stable binuclear complexes, in which the two Zn^{2+} ions are 4 to 5 Å apart. There is little metal–metal interaction at such separations, indeed it is possible to bridge the two metal centers by adding an appropriate small anion or molecule. A chiral hexaazatriphenolic macrocycle has been synthesized in efforts to model the active site of P1 nuclease. This macrocycle forms Zn_3 and Zn_2Cu trinuclear complexes. The Zn^{2+} ions in the Zn_3 complex have N_2O_2 and N_2O_3 coordination shells; the two N_2O_3 coordinated ions are bridged by acetate in the active site model.[134] Zinc complexes of calixarene-imidazole ligands mimic the active sites of other zinc enzymes.

NO-Donor Schiff bases (*see Schiff Base*), particularly multidentate ones, are powerful ligands and many examples of their zinc complexes are known. Zinc(II) often promotes formation of such Schiff bases, for example, those from salicaldehyde and 1,2-diaminoethane or 1,3-diaminopropane.[135] An interesting feature here is that these ligands readily exert a stereochemical control over the complex and thereby provide many examples of unusual geometry about the central ion, illustrating once more the coordination flexibility of zinc. An example is provided by the complex (**7**), $[ZnLCl_2]\cdot H_2O$ (L = 2, 6-diacetylpyridine dioxime), in which the metal is in a distorted trigonal bipyramidal environment. Schiff bases incorporating aliphatic or phenolic hydroxy groups as well as tertiary or pyridine nitrogens can give binuclear (Zn_2 or e.g. ZnCu) complexes. Such Schiff bases may be linear, tri- or tetrapodal,[136] or macrocyclic.[137]

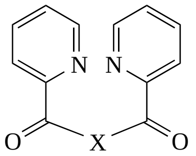


(**7**)

Zinc will dissolve in a solution of oxine (8-hydroxyquinoline). The anhydrous complex $Zn(oxinate)_2$ is a linear tetramer with bridging oxygens; the two central zinc atoms are six-coordinated octahedral and the two terminal zincs are five-coordinated trigonal bipyramidal units (Zn–O between 1.97 and 2.18 Å). This structure is reminiscent of that of the $Zn(acac)_2$ trimer.[138] Zinc complexes of oxines with a $p\text{-}NC_6H_4NMe_2$ group linked to the 5-position are luminescent, and potentially of interest in relation to OELDs (Organic Light Emitting Devices).[139]

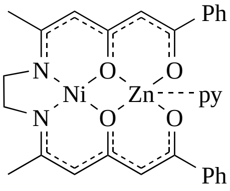
In hydroxylamine complexes of the type ZnX_2L_2 (X = Cl, Br, or $0.5SO_4$), coordination to zinc can be through either N or O depending on the method of preparation (with Cd, coordination is exclusively to N). In the corresponding *O*-methyl derivative, $ZnCl_2(MeONH_2)_2$, bonding is through nitrogen. A substantial number of hydrazide complexes using $RCONHNH_2$ as a ligand are known and the ligand usually binds through the carbonyl oxygen and the NH_2 nitrogen atom when R is unbranched, but through N only when R is branched, for example, when $R = {}^{i}Pr$. Much of the interest in amides as ligands has been directed towards the factors that control the alternative O- or N-binding modes adopted in these compounds. With simple

amides, L, such as acetamide or N,N-dimethylacetamide, in complexes of the type L_2ZnX_2 (X = halide or SCN), the coordination is tetrahedral to oxygen. On the other hand, binding of Zn^{II} enhances amide deprotonation of N,N-bis(2′-pyridinecarboxamide)-1,2-benzene (**8**), LH_2, to give planar $[ZnL{\cdot}H_2O]$, having maximum electron delocalization; here coordination of the amide oxygens is hindered by the resulting decrease in the chelating ability of the ligand.



(**8**) X = –NH(o-C_6H_4)NH–

An interesting case in which the stereochemistry of zinc coordination is controlled by the local environment is provided by the heteronuclear chelate complex (**9**) in which planar Ni^{II} selects the N_2O_2 sites and the Zn^{II} the O_2O_2 sites. Coordinated pyridine completes five coordination for the zinc. The Zn–O distances average 1.95 Å to the terminal oxygens and 2.09 Å to the bridging oxygens. The zinc is displaced from the basal plane by 0.32 Å towards the pyridine.[140]



(**9**)

8.4 S, S/N, and S/O Donors

Complexes of dithiolene anions, such as maleonitriledithiolate and toluene dithiolate, where the delocalized S–C–C–S unit chelates the metal ion (*see Chelating Ligands*), are interesting from several points of view.[141] These include the frequent occurrence of square-planar and trigonal prismatic coordination geometries, the often extensive charge transfer, which can lead to unusual formal oxidation states (spectra of $[Zn^{II}(mnt)_2]^{2-}$ in dichloromethane, suggest a Zn^{III} complex containing an mnt^{3-} radical ligand), and their potentially valuable conductivity, optical, and magnetic properties. The recently reported first molecular magnetic semiconductors are based on 1,3-dithiol-2-thione-4,5-dithiolate ligands. Zn^{2+}-dithiolene centers occur in several essential enzymes.

Sulfur- and selenium-donor ligands stabilize several polynuclear zinc complexes, for example, the $[E_4Zn_4(SPh)_{16}]^{4-}$ (E = S or Se) anions, prepared as their Me_4N^+ salts.[142] The complex $[Zn_4(SPh)_{10}]^{2-}$ forms a ground-state charge transfer complex with methyl viologen.[143] These zinc–sulfur anions, and also $[Zn_4(SPh)_4]^{2-}$, all contain tetrahedral ZnS_4 units. They may be regarded as fragments of the cubic ZnS lattice. The benzylthiolate complex $[Zn_4(SBz)_{10}]^{2-}$ has an adamantane framework; $[Zn_8(S)(SBz)_{16}]^{2-}$ incorporates a cuboctahedral framework.[144] Self-assembly of a zinc-cyclen complex with thiocyanuric acid gives a Zn_{12} supramolecular capsule consisting of a cuboctahedral framework enclosing a tetrahedral cavity in which lipophilic organic molecules of appropriate size, for example, adamantane or 2,4-dinitrophenol, can be accommodated as guests.[145] $[Zn_8(SPh)_{16}Cl]^-$ consists of a tetracapped tetrahedron of zincs with the Cl^- at the center; 12 thiolate ligands act as bridging edge groups, four are terminal. The thiophosphate $Zn_3(PS_4)_2$ contains ZnS_4 and PS_4 tetrahedra; the former form corner-shared two-dimensional layers.[146] Reaction of zinc perchlorate with bis(2-aminoethanethiolato)zinc in aqueous acetonitrile gives polynuclear complexes with Zn_3S_3 and Zn_4S_4 cores; all zincs also bear N-donor ligands.[147] Zinc diethyldithiocarbamate is a rubber preservative; zinc halide thiosemicarbazone complexes show promising second-order nonlinear optical properties.

Complexes with the thio-oxamate ligands $NH_2(CO)CSO^-$ and $NH_2(CS)CO_2{}^-$, which bind through O and S, exhibit trigonal bipyramidal geometry around the zinc.[148] The zinc complex of the O,S-donor ligand 2-pyridinethiolate 1-oxide, known as zinc pyrithione, is a fungicide and bacteriocide much used in hair shampoos.

Thiolate-thioether complexes with $S_2S'_2N$ donor sets provide useful models for such bioinorganic systems as alcohol dehydrogenase and zinc fingers[149] (cf. start of this Section). The affinity of Zn^{2+} for nitrogen/sulfur donor ligands means that there are a few zinc complexes of thioazacryptands, as well as complexes of standard (aza)cryptands. Nitrogen- and sulfur-containing macrocyclic ligands are important in the modeling of enzymes and transmembrane metal ion carriers.[150]

8.5 Halide, Cyanide, and Thiocyanate Complexes

Complex anions $[ZnX_4]^{2-}$ are readily obtained for X = Cl, Br, or I, though not for X = F. They may be isolated as solids using the standard technique of precipitation using a large cation such as $[Ph_4As]^+$ or $[Co(NH_3)_6]^{3+}$. Zinc chloride readily accepts chloride ions to form tetrahedral $[ZnCl_4]^{2-}$ complexes, and a large number of structural studies on these and related complexes have been carried out. For example, the crystal structure of Cs_2ZnCl_4 contains this ion with very little distortion from tetrahedral,[151] but it is interesting that in the complex $[Co(NH_3)_6][ZnCl_4][Cl]$ the same anion shows marked distortion (Zn–Cl = 2.22 to 2.36 Å; ∠Cl–Zn–Cl = 101.6 to 115.4°). Calculations indicate that the major cause of the bond length distortion is anisotropy in the applied electrostatic crystal forces.[152] Other cases of deviation from tetrahedral geometry caused by packing forces are known, for example, the $[ZnI_4]^{2-}$ ion in its salt with the 2,4-dimethyl-1H-1,5-benzodiazepinium cation has

strict C_2 symmetry. These findings suggest that care should be exercised in other cases when seeking explanations for stereochemical distortions in a complex in the solid state in terms of electronic and bonding effects within the complex itself. The $[Zn(NCS)_4]^{2-}$ anion is tetrahedral; Zn–NCS–Zn bridging has been demonstrated in molten KNCS at 200 °C.

9 AQUEOUS SOLUTION CHEMISTRY

9.1 The Zn^{2+} Aqua Cation

The Zn^{2+} cation appears to be six coordinate in water, from NMR (^{1}H peak areas), EXAFS (Extended X-ray Absorption Fine Structure), and Raman evidence, and six in methanol. X-ray and neutron diffraction studies indicate a Zn–O distance between 2.08 and 2.17 Å (cf. 2.08–2.14 Å in crystal hydrates). There is EXAFS evidence for a secondary hydration shell, containing about 12 water molecules at an average Zn–O distance of 4.1 Å.[153] Hydration numbers determined by methods other than NMR peak areas indicate values substantially larger than six, generally because both primary and secondary hydration shells are being monitored. The single-ion hydration enthalpy, ΔH_{hydr}, of Zn^{2+} is $-2044\,kJ\,mol^{-1}$ (relative to $\Delta H_{hydr}(H^+) = -1091\,kJ\,mol^{-1}$). Full discussions of hydration of metal ions are available.[154–157] The Zn^{2+}aq ion is labile to water exchange ($k > 5 \times 10^7\,s^{-1}$ at 298 K). There is some evidence that Zn^{2+} is only five coordinated in some mixed aqua ligand complexes.

Zn^{2+}aq has very weak acidic properties – the most favored value for its pK_a is 8.96, though values ranging from 8 to over 10 have been reported from determinations by various physical techniques in a variety of media of different ionic strengths and containing different counterions. $ZnOH^+$aq is, like all hydroxo-metal ions, prone to polymerize; species such as $[Zn_2(OH)]^{3+}$, $[Zn_2(OH)_6]^{2-}$, and $[Zn_4(OH)_4]^{4+}$ (cf. the well-established $[Pb_4(OH)_4]^{4+}$ and $[Ni_4(OH)_4]^{4+}$) have been postulated.

9.2 Stoichiometry, Structure, and Stability of Complexes in Solution

Table 3 collects together a number of stability constants (*see* ***Stability Constants & their Determination***) for formation of monoligand complexes of Zn^{2+} in aqueous solution ($\log_{10}K_1$), culled from several sources. Stability constants for no fewer than 81 bis-ligand complexes ($\log_{10}\beta_2$) were conveniently collected together as long ago as 1959.[158] Much additional information on zinc complexes with ligands of biological importance is available.[159] Figures mapping the predominant species in solution over a range of pHs are available for 21 Zn^{2+}-ligand systems.[160]

Table 3 Stability constants ($\log_{10}K_1$) for formation of a range of Zn^{2+} complexes, in aqueous solution at 298.2 K

Group 15		*Group 16*	
Azide	0.8	Acetate	1.6
Thiocyanate	0.9	Thiosulphate	2.3
Pyridine	1.0	Phosphate	2.4
Ammonia	2.3	Oxalate	4.3
Imidazole	2.6	Citrate	5.0
2,2′-bipyridyl	5.1	Acetylacetonate	5.1
Ethanediamine	5.9	ATP	5.2
1,10-phenanthroline	6.4	Maltolate	5.6
Group 15/16		*Group 17*	
Glycine	5.0	Fluoride	1.1
Cysteine	9.2	Chloride	0.5
Penicillamine	9.5	Bromide	−0.6
nta	10.7	Iodide	−1.5
EDTA	16.4		

Stability constant comparisons should be made with some caution, since the accuracies of some values may be no better than ±1, and experimental conditions (ionic strengths and the salts used to maintain them) are not identical for all systems. Nonetheless, the Table 3 values give some idea of relative stabilities for a range of ligands. The order of $\log_{10}K_1$ values for the halide ions should be noted, for comparison of this set of values for Zn^{2+} with analogous values for Cd^{2+} and Hg^{2+} (Table 4) positions these cations according to the ***Hard & Soft Acids and Bases*** principle, with Zn^{2+} just on the hard side, Cd^{2+} just on the soft side, of the hard/soft border, and Hg^{2+} definitely soft.

Zn^{2+} forms stable complexes with the group 14 donor ligand cyanide (mean $\log_{10}K_1 = 5.1$). The cyanide ion is a good σ-donor (e.g. the pK_a of HCN is 9.4) and this may be the main factor in complex stabilization here. Interestingly, the Zn^{2+} ion does not form π-complexes (*see* ***Coordination & Organometallic Chemistry: Principles***) with CO, NO, or alkenes although it is isoelectronic with Ni^0, archetypal in forming such species; possibly the 2+ charge on the Zn^{2+} ion is able to contract the d orbitals on the metal and reduce back donation (*see Back Bonding*) to the π-orbitals of the ligand.

Comparison of the stability constants for Zn^{2+} complexes with those for the preceding transition metal M^{2+} cations shows conformance to the Irving-Williams stability order (*see Irving–Williams Series*) ($Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} \gg Zn^{2+}$) for essentially all ligands. As an example,

Table 4 Comparison of stability constants ($\log_{10}K_1$) for complex formation between Zn^{2+}, Cd^{2+} and Hg^{2+} and halide ligands

	Zn^{2+}	Cd^{2+}	Hg^{2+}
Fluoride	1.1	0.5	1.6
Chloride	0.5	1.8	6.7
Bromide	−0.6	1.9	9.4
Iodide	−1.5	2.0	12.9

Table 5 Stepwise stability constants ($\log_{10} K_n$) for formation of a selection of Zn^{2+} complexes, in aqueous solution at 298.2 K

	Monodentate ligands					Bidentate ligands			
	Imidazole	Ammonia	Thiocyanate	Azide		Oxalate	Glycinate	Kojate	ethanediamine
$\log_{10} K_1$	2.6	2.3	0.9	0.8					
$\log_{10} K_2$	2.4	2.5	0.7	0.5	$\log_{10} K_1$	4.3	5.0	5.0	5.9
$\log_{10} K_3$	2.2	2.3	0.6	1.0					
$\log_{10} K_4$	2.0	2.2	0.3	0.6	$\log_{10} K_2$	2.5	4.2	4.2	5.2
					$\log_{10} K_3$	1.0	2.5	2.6	1.9

the values of $\log_{10} K_1$ for 1,2-ethanediamine complexes are 2.7, 4.3, 5.9, 7.6, 10.7, and 5.9 respectively. Differences between stability constants for Zn^{2+} complexes and of their respective Mg^{2+} analogs are much larger for N-donor than for O-donor ligands. Indeed, a formula relating to the difference and the number of N- and O-donor sites on various ligands has been developed and used to determine the nature of the coordination sphere of the Zn^{2+} in cases where this is not clear-cut.[161,162]

Stability constants for Zn^{2+} complexes of the homologous dicarboxylate ligand series $^{-}O_2C(CH_2)_nCO_2^{-}$ provide a good illustration of the decrease in stability as chelate ring size increases. $\text{Log}_{10} K_1$ values for the oxalate ($n = 0$), malonate ($n = 1$), succinate ($n = 2$), and glutarate ($n = 3$) complexes are 5.0, 3.7, 2.5, and 2.0, quantifying the decrease in stability as the chelate ring increases in size from a five-membered to an eight-membered ring. The ligand series NH_3 to en to dien to tren gives rise to modest chelate effects – $\log_{10}\beta_2$ for $[Zn(NH_3)_2]^{2+}$ is 4.8, $\log_{10} K_1$ for $[Zn(en)_2]^{2+}$5.9, while $\log_{10}\beta_3$ for $[Zn(NH_3)_3]^{2+}$ is 7.1, $\log_{10} K_1$ for $[Zn(dien)]^{2+}$8.9,[163] and $\log_{10}\beta_4$ for $[Zn(NH_3)_4]^{2+}$ is 9.3, $\log_{10} K_1$ for $[Zn(tren)]^{2+}$14.5.

Zn^{2+} forms stable complexes with the standard tetraaza-macrocyclic ligands, though the variation of stability constants with ring size is unusually small – $\log_{10} K_1$ values decrease from 16.2 for the 12-membered ring through 15.6 and 15.5 to 15.0 for the 15-membered ring ligand.[164] Studies on the complexing of zinc with 1,3,5-*cis,cis*-triaminocyclohexane (L) show that the $[ZnL]^{2+}$ complex formed is less stable than that formed with analogous linear triamines such as 3,3′-diaminodipropylamine (in the presence of excess of ligand only the hydroxo-ion $[ZnL(OH)]^{+}$ is formed in both cases). However, a significant macrocyclic effect is evident in the large stability constant observed for the $[ZnL]^{2+}$ complex of the cyclic triamine 1,4,7-triazacyclononane. Chelate and macrocyclic effects (K, ΔH, and ΔS), effects of ligand N-alkylation, and stability comparisons with selected M^{2+} ions, have been conveniently documented, for edta and for some tetra-aza macrocyclic ligands.[165] A comprehensive survey of thermodynamic, and kinetic, data for macrocyclic ligand interaction with cations, including extensive data on zinc, is available[166] (*see also* ***Macrocyclic Ligands***). Macrocyclic complexes sometimes have unexpected properties; for example, zinc complexes with the tetraazacycloalkanes [14]aneN_4 and [15]aneN_4 reversibly take up CO_2 in basic alcoholic solutions to form monoalkyl carbonates.[167]

Trends in stepwise stability constants (successive formation constants); (*see* ***Stability Constants & their Determination***) for Zn^{2+} complexes (Table 5) are often irregular, differing markedly from the normal trend of K_n decreasing as n increases. This has been known for at least sixty years – Jannik Bjerrum, in his seminal study of metal-ammine complexes carried out in about 1940, documented an irregular variation of K_n with n for this classic series. Table 5 documents this behavior for the ammines, and shows irregular behavior also for azide and for 1,2-ethanediamine. Only the imidazole, thiocyanate, and oxalate data in Table 5 show normal trends. Irregularities are all ascribed to changes between octahedral and tetrahedral geometries, as for example, for the unexpectedly large drop from K_2 to K_3 for 1,2-ethanediamine, and calculations have been made of the proportions of tetrahedral and octahedral species in several systems.[168] For penicillamine, $K_2 > K_1$, which unusual behavior has been ascribed to a change from tridentate to bidentate coordination.

In order to probe the immediate coordination sphere of the metal in zinc complexes in solution, especially to attempt to solve the tetrahedral versus octahedral uncertainties outlined above, it is possible to have recourse to a number of physical techniques, including Raman spectroscopy, NMR, X-ray and neutron diffraction,[169] and X-ray scattering (EXAFS). However, the complex equilibria present in electrolytically produced supersaturated solutions of zinc(II) in aqueous KOH show how different techniques can lead to different results in identifying the species present in what appears at first sight to be a simple system. Light scattering and NMR techniques[170] indicate the excess of zinc to be present as a solute, rather than a colloid, and the predominant species appears to be $[Zn(OH)_4]^{2-}$. However, Raman and potentiometric studies[171] indicate that initially quasicolloidal particles, based on $Zn(OH)_2$ and hydrating water molecules, are present. These undergo a first-order decay to yield a solution containing the species $[Zn(OH)_2(H_2O)_2]$, $[Zn(OH)_3(H_2O)]^{-}$, and $[Zn(OH)_4]^{2-}$, the actual composition depending on the concentration. The noncolloidal species in this system appear to be tetrahedral rather than octahedral.

X-ray scattering measurements, Raman, and IR spectroscopy on aqueous solutions containing Zn^{2+} and Br^{-} ions show that the highest complex formed is tetrahedral

$[ZnBr_4]^{2-}$; pyramidal $[ZnBr_3]^-$ is also formed but there is no evidence of Zn–Br–Zn bridges.[172] Studies of Zn^{2+}/Cl^- solutions have provided conflicting results, with X-ray studies indicating $[ZnCl_4]^{2-}$, other techniques indicating octahedral geometry, that is, $[ZnCl_4(H_2O)_2]^{2-}$. The apparent disagreement is almost certainly due to the different concentration ranges pertaining to the techniques used – the X-ray methods require concentrated solutions, the other techniques less concentrated media. Indeed neutron diffraction suggests $[ZnCl_4(H_2O)_2]^{2-}$ in 1 or 2 M $ZnCl_2$, $[ZnCl_4]^{2-}$ in more concentrated solutions. Diffraction results are consistent with tetrahedral $[Zn(NH_3)_4]^{2+}$ (Zn–N = 2.03 Å) and with both tetrahedral $[Zn(en)_2]^{2+}$ (Zn–N = 2.13 Å) and octahedral $[Zn(en)_3]^{2+}$ (Zn–N = 2.28 Å), depending on conditions.[173]

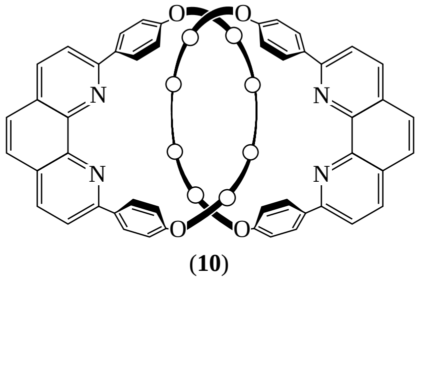
Complexes of the Group 12 metal cations with thiocyanate provide data on the relative affinities of these ions for N- or S-donors. X-ray scattering studies indicate the existence in solution of $[Zn(NCS)_4]^{2-}$, $[Cd(NCS)_2(SCN)_2]^{2-}$, and $[Hg(SCN)_4]^{2-}$, all tetrahedral, consistent with the 'hard' to 'soft' trend of the respective M^{2+} cations. A Raman study of zinc(II) coordination in aqueous thiocyanate solutions[174] showed that bonding to the zinc is totally in the Zn–NCS mode and the results were consistent with the presence of all four $[Zn(NCS)_{1-4}]^{n\pm}$ species. The two lower species are probably octahedrally coordinated, the remaining coordination sites being occupied by water molecules; higher species are probably tetrahedrally coordinated. No bridging thiocyanate is observed. This contrasts with evidence from the Raman spectrum of coordinated zinc in KSCN at 200 °C, which shows the presence of tetrahedral $[Zn(NCS)_4]^{2-}$ species, somewhat distorted by polymerization, and bands owing to Zn–NCS–Zn bridges are also observed. *Linkage Isomerism* is also present owing to both Zn–NCS and Zn–SCN bonding modes.

Sometimes coordination can affect the behavior of another ligand in the coordination shell of the metal and this is well illustrated by acidities of ternary aqua-ligand-Zn^{2+} complexes. Quadridentate 1,5-diazocyclooctane-N,N'-diacetic acid, H_2L, forms $[Zn(L)(H_2O)]$, the pK_a of whose coordinated H_2O (8.6) is slightly lower than that of Zn^{2+}aq (9.0), and considerably lower than that of the coordinated H_2O (10.5) in the octahedral complex formed by ethylenediaminediacetate. Increased acidity of coordinated H_2O with decreasing coordination number has also been observed in other complexes such as $[Zn(Me_6tren)(H_2O)]^{2+}$, $[Zn([12]aneN_3)(H_2O)]^{2+}$ (pK_a = 7.3) and $[Zn(cyclen)(H_2O)]$ (pK_a = 7.9).[175] This has been attributed, at least in part, to the hydrophobic environment provided by the methyl and methylene groups. This finding has some implications for the role of the Zn–OH_2/OH species in the zinc metalloenzyme carbonic anhydrase (*see* ***Zinc Enzymes***), where this unit is contained in a site of low-coordination number and a small movement can place it in an environment of decreased polarity. Such marked increase in the acidity of coordinated water has important implications, especially for biological systems: essentially the metal ion-hydroxy complex provides an efficient nucleophile at neutral pH[176] (*see also* ***Zinc Enzymes***). Model studies with metal ions, mainly zinc(II), as Lewis acid catalysts have been reviewed.[177]

Binding constants determined for ternary complex formation between capped and uncapped zinc porphyrins and small molecules such as imidazole and (substituted) pyridine[178] contribute to the understanding of capped zinc porphyrins in molecular recognition,[179] to which topic ternary zinc-cyclen complexes are also relevant.[180]

9.3 Kinetics and Mechanisms

Complex formation between Zn^{2+} and most monodentate and simple chelating ligands is rapid, with $k_f \sim 10^7\ M^{-1}\ s^{-1}$ at 298 K.[181] However, there are exceptions where the steric requirements of the ligand are particularly stringent. Reactions of Zn^{2+}aq with tetraazamacrocycles are slow – rate laws are complicated, but half-lives are of the order of a second. Formation of the Zn^{2+} complex of the *Quadridentate Ligand* 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (L), which is a five-coordinated species $[ZnL(H_2O)]^{2+}$, is probably slow owing to the requirement for conformational change on complexation. Dissociation of this complex is acid catalyzed (*see Acid Catalyzed Reaction*), with this five-coordinate species more labile than four- or six-coordinated complexes, a feature that could be relevant to the biological function of zinc.[182] Other cases of slow complex formation are provided by several porphyrins and by the catenand ligand (**10**). Half-lives for incorporation of zinc into porphyrins are typically of the order of a second. Reaction with the catenand is biphasic (*see Biphasic Process*); the first step (overall second order) probably represents binding of the ligand to one of the chelating subunits of (**10**). The second step, which is first order, is very slow ($k \ll 1\ s^{-1}$) and could well correspond to the sliding motion of one ring within the other while the second phenanthroline unit attempts to seek out and bind the zinc center.[183] Metal-for-metal replacement in porphyrin complexes can, however, be quite rapid, as in the case of Zn^{2+} with Hg(tpp) in pyridine, where no less than seven isosbestic points are observed.[184] There is rapid equilibration between Zn^{2+} and Pb^{2+} at the metal-binding site of zinc fingers despite steric constraints;[185] the rate constant for reaction of a typical *Zinc Finger* peptide with Zn^{2+}aq has been estimated as $2.8 \times 10^7\ M^{-1}\ s^{-1}$.[186]



(**10**)

There is a marked contrast between zinc and cadmium in the context of complexing of the 2+ ions with bipy, studied by high-pressure stopped-flow. There is a striking difference between the two elements, with Zn^{2+} reacting progressively more slowly with bipy as pressure increases, Cd^{2+} more rapidly. The *Activation Volume* ($\Delta V^{\ddagger}$) for the zinc reaction is $+7.1\,cm^3\ mol^{-1}$ whereas for cadmium the value is $-5.5\,cm^3\ mol^{-1}$. These values suggest that the substitutions are I_d and I_a in character respectively.[187] $\Delta V^{\ddagger}$ values for the reverse, dissociation, reaction and $\Delta S^{\ddagger}$ values for formation and for dissociation, are all consistent with this assignment of mechanism. Positive activation volumes for a few other substitution reactions at $Zn^{2+}aq$[188] also indicate I_d mechanisms, as proposed many years ago in discussions of ultrasonic data on complex formation from $Zn^{2+}aq$.

Metal ion promoted reactions are important – Zn^{2+}-catalyses of hydrolysis of a range of organic substrates, for example, phosphate and carboxylate esters and Schiff bases, have recently been reviewed,[189] as has their relevance to biological catalysis, particularly of reactions of phosphates.[190]

Kinetic patterns and parameters, and mechanisms, of these and other reactions involving zinc complexes have been detailed and reviewed.[191,192]

1 INTRODUCTION

The first organometallic compounds of zinc, namely, ethylzinc iodide (EtZnI) and diethylzinc (Et_2Zn), were prepared by Sir Edward Frankland in 1849[1–3] when he attempted the preparation of ‘ethyl radical’. Even if these two species were not the first organometallic derivatives to be prepared (cacodyl compounds and Zeise’s salt (*see Zeise’s Salt*) were discovered in 1760 and 1827, respectively), the work of Frankland is now recognized as the beginning of modern organometallic chemistry. He recognized very early the synthetic utility of EtZnI and Et_2Zn, and devoted his career to studying their properties and to preparing other organic compounds of tin, mercury, and arsenic. Owing to their low reactivity, a result of the high covalent character of the zinc−carbon bond and the low Lewis acidity (*see Lewis Acids & Bases*) of Zn^{II}, the organozinc reagents were replaced at the beginning of the twentieth century by the more reactive Grignard and organolithium reagents. For more than half a century, their application to organic synthesis was limited to specific reactions, mostly cyclopropanation and aldol reactions. However, in recent years it was found that the low reactivity of organozinc species makes them highly tolerant to a wide range of functional groups and allows good regio- and enantioselectivities in their transformations.

Furthermore, organozinc derivatives readily form complexes with electron-donating ligands as a result of the electron-deficient character of zinc. In spite of the early knowledge of this property, it was only after the 1960s that this subject became the source of extensive investigations and led to the development of an extremely rich coordination chemistry.

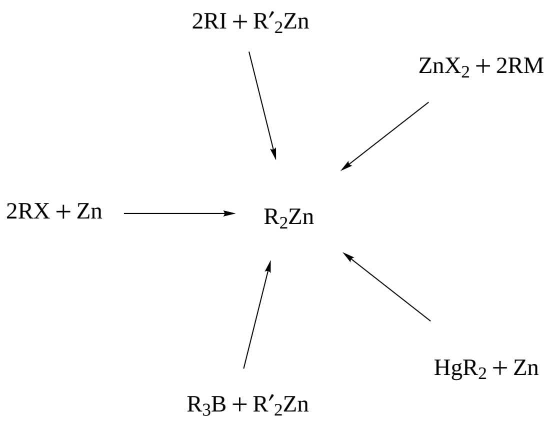
In the past few decades, these features have stimulated a growing interest for this area of organometallic chemistry and nowadays the organozinc compounds play a very important role in organic, organometallic, and inorganic chemistry. Their low toxicity, excellent functional group tolerance, chemoselectivity, and stereoselectivity make them ideal reagents for the building of complex molecules bearing polyfunctional groups.

Over the years, several reviews dealing with different aspects of the organometallic chemistry of zinc have been published.[4,5]

2 DIORGANOZINC COMPOUNDS

2.1 Preparation

The different routes for the preparation of organozinc compounds are summarized in Scheme 1. Detailed experimental protocols including important tips can be found in references 6 and 7. In the last decade, this subject was included in several reviews dealing with the applications of polyfunctional organozinc compounds in organic synthesis.[8–10]



Scheme 1

2.1.1 *Direct Reaction of Zn with Alkyl Halides*

This method was originally used by Frankland to prepare diethylzinc. It is described as an oxidative insertion (*see Insertion*) of zinc metal inside the carbon-halogen bond of an organic halide. The initial product of the reaction is an alkylzinc halide derivative (RZnX), from which the dialkylzinc compound (R_2Zn) is formed as the Schlenk-type equilibrium establishes (equations 1 and 2).

$$Zn + RX \longrightarrow RZnX \qquad (1)$$

$$2RZnX \rightleftharpoons ZnR_2 + ZnX_2 \qquad (2)$$

The ideal alkyl halide substrates are the alkyl iodides and usually the reaction requires the zinc to be activated by forming an alloy (*see* ***Alloys***) with a metal such as copper, sodium, or mercury. Finely divided forms of zinc (powder or dust), alone or previously treated with copper or sodium acetate, are also very effective.

Another procedure for the preparation of very active zinc uses the 'metal atom' approach in which zinc-metal vapor is coprecipitated with an ethereal solvent.[11] The unstable bis(trifluorosilyl)zinc and bis(trifluoromethyl)zinc have been prepared by cocondensing Zn atoms with $\cdot SiF_3$ radicals (*see Radicals*) and $\cdot CF_3$ radicals, respectively (generated by low-temperature radio-frequency glow discharge or plasma of hexafluoroethane or hexafluorodisilane).[12]

The Riecke zinc,[13] obtained by reduction of a zinc halide with sodium or potassium in THF, is commonly used for the preparation of simple or functionalized organozinc compounds and allows the use of less reactive alkyl halide reagents like alkyl bromides. The reaction of this very active form of zinc with organic bromides was shown to be strongly dependent on the structure of the organic moiety.[14] The results also support the presence of radicals (*see Radicals*) in the reaction and suggest a mechanism in which electron transfer (*see* ***Electron Transfer Reactions: Theory***) (ET) is the rate-determining step. In the reaction with alkyl bromides, the ET has an important component of inner sphere, whereas in the reaction with aryl halides there is a participation of aryl halide radical anions as intermediates. A classification of the organic bromides, depending on the nature of the organic group and attending to their relative reactivity, can be summarized by the diagram presented in Figure 1. The less reactive vinyl bromides are found in one extreme and the most reactive benzylic bromides in the other.

In the past years, numerous modifications for zinc activation have been developed, not only to increase the reaction efficiency, but also to allow the use of less reactive and inexpensive organic halides such as organic chlorides.

2.1.2 *Iodine–Zinc Exchange*

Diorganozinc reagents can be prepared efficiently by an iodine–zinc exchange reaction[15] between the appropriate alkyl halide and an excess of Et_2Zn or i-Pr_2Zn (equation 3). This method is suitable for primary and secondary alkyl iodides and requires catalytic amounts of a Cu^I salt. The reaction conditions with i-Pr_2Zn (25 °C, 1 h) are considerably milder than those used with Et_2Zn (50 °C) and allow the preparation of complex diorganozinc species in good yields. A possible mechanism for the catalyzed reaction with Cu^I is given in Scheme 2.[8]

$$2FG\text{–}RCH_2\text{–}I + ZnR'_2 \longrightarrow Zn(CH_2R\text{–}FG)_2 + 2R'I \qquad (3)$$

$$R' = Et, iPr \qquad FG = \text{Functional Group}$$

Other transition metals (*see Transition Metals*) such as $PdCl_2(dppf)$ and $Ni(acac)_2$[16,17] catalyze the reaction but lead to alkylzinc iodides instead of dialkylzinc compounds.

Recently, it was shown that the exchange reaction can be photochemically (*see Photochemistry*) induced by irradiating at $\lambda \geq 280$ nm the reaction mixture of an alkyl iodide and 0.5 equiv of R_2Zn (R = Et or i-Pr) (equation 4).[18]

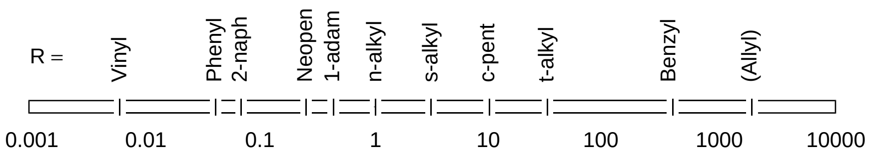


Figure 1 Relative dimensionless rates for RBr + Zn* → RZnBr

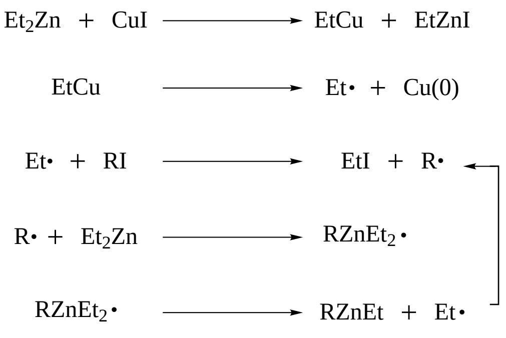


Scheme 2

In these conditions, excess of R_2Zn and the catalyst (transition metal) are not required. In addition, when a solution of an alkyl iodide is mixed with 1 equiv of R_2Zn the mixed diorganozinc compounds (R–Zn–R′) are obtained (equation 5). This reaction takes place only between dialkylzincs and alkyl iodides; however, in comparison with the few other methods described for the preparation of mixed diorganozincs, this procedure represents a fantastic enhancement for alkyl group exchange (R–Zn–R′).[19,20]

$$2RI + ZnR'_2 \xrightarrow[h\upsilon]{CD_2Cl_2} ZnR_2 + 2R'I \qquad (4)$$

$$RI + ZnR'_2 \xrightarrow[h\upsilon]{CD_2Cl_2} RZnR' + R'I \qquad (5)$$

2.1.3 *Alkylation of Zinc Salts*

This method, presented in equation (6), involves the alkylation of zinc salts, usually zinc halides or zinc acetate. The alkylating agents are typically Grignard reagents or organolithium (*see* ***Alkali Metals: Organometallic Chemistry***) reagents in an ethereal solvent, but trialkylaluminum or zirconocene reagents can also be used. For example the preparation of dimethyl- and diethylzinc is described by the reaction of trimethyl- and triethylaluminum with zinc acetate[21] (equation 7). This procedure is useful for the preparation of simple dialkylzinc but the high reactivity of organolithium or magnesium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***) reagents precludes the synthesis of zinc derivatives containing functional groups, although the use of low temperature can in some cases overcome this problem.[22]

$$2R[M] + ZnX_2 \longrightarrow ZnR_2 + 2[M]X \qquad (6)$$

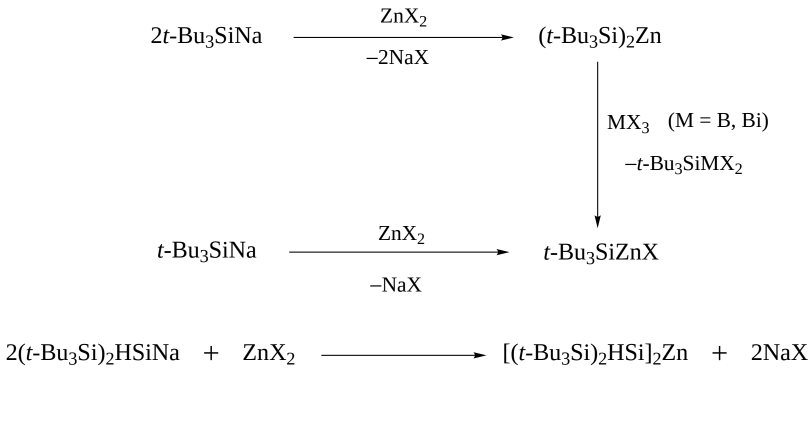
$$[M] = Li, MgX \qquad X = Cl, Br, I$$

$$2AlMe_3 + Zn(OAc)_2 \longrightarrow 2Me_2Al(OAc) + Me_2Zn \qquad (7)$$

It is worth mentioning here that disupersilylmetals $(t\text{-}Bu_3Si)_2M$, supersilylmetal halides $(t\text{-}Bu_3Si)MX$ and bis(disupersilyl)silylmetals $[(t\text{-}Bu_3Si)_2SiH]_2M$ (M = Zn, Cd, Hg; X = Cl, Br) have been recently prepared by reaction of the corresponding silyl-sodium salts with metal dihalides in 1:1 or 2:1 ratio, and could be fully characterized[23,24] (Scheme 3). The disupersilylzinc compound was found to react with $BiCl_3$ or BBr_3 to give the corresponding supersilylzinc halide $(t\text{-}Bu_3Si)ZnX$.

2.1.4 *Boron–Zinc Exchange*

The first boron–zinc exchange reported in the literature was the reaction of dimethylzinc with triethylborane to produce diethyl zinc[25] (equation 8). The driving force of the reaction is the formation of stable dialkylzinc compounds, and in some cases the formation of volatile organoboranes such as BMe_3 (bp = −22 °C). Primary dialkyl and benzylic organozinc compounds are successfully prepared when Me_2Zn or Et_2Zn are used as reagents,[26] but the B–Zn exchange is usually slow with hindered secondary alkylboranes. However, $i\text{-}Pr_2Zn$ has been found to undergo rapid exchange with both primary and secondary substrates, leading to the preparation of secondary dialkylzincs. An important feature of the exchange reaction is that retention of configuration was observed with several



Scheme 3

systems at low temperature[27] ($-10\,°C$).

$$3BEt_3 + 2ZnMe_2 \longrightarrow 3ZnEt_2 + 2BMe_3 \qquad (8)$$

The reaction conditions are significantly mild (0 °C) and allow the presence of a number of sensitive functional groups. Although this procedure presented limited applications when it was discovered, during the last years it became one of the most versatile preparations of polyfunctional diorganozinc species; a consequence of both its high tolerance towards functional groups and its high stereoselectivity.[8]

A recent theoretical study has shown that the B–Zn exchange proceeds with a low activation energy and could involve two intermediates (Figure 2), the particularly unusual bonding structures of which would be responsible for the retention of configuration.[28]

2.1.5 *Transmetallation with Mercury*

In 1864, Frankland discovered the transmetallation reaction between diorganomercurials and zinc metal[29] (equation 9). It is generally applicable when the organomercury compounds are available and when it is necessary to prepare absolute salt free diorganozinc compounds.

$$\text{Zn (excess)} + HgR_2 \longrightarrow ZnR_2 + Zn/Hg \qquad (9)$$

Usually the reaction requires an excess of zinc metal, a few hours in refluxing toluene, and can eventually be catalyzed with small amounts of zinc salts. A modification of this method, employing dimethyl zinc instead of zinc metal, has been used to prepare a stable complex of bis(trifluoromethyl)zinc with pyridine[30,31] (equation 10).

$$Hg(CF_3)_2 + ZnMe_2 \xrightarrow{\text{Pyridine}} Zn(CF_3)_2(\text{pyridine}) + HgMe_2 \qquad (10)$$

2.2 Properties of Diorganozinc Compounds

Depending on the nature of the alkyl group, simple dialkylzinc compounds can be mobile liquids or low-melting solids (Table 1). They are all colorless and completely miscible with common nonprotic solvents. With polar (*see Polar Compounds*) organic solvents containing electron-donating atoms, they form soluble complexes. However, in pure form or in hydrocarbon solvents, they exist as monomers, since association via alkyl bridges doesn't occur with zinc. Dialkylzinc compounds are all very susceptible to oxygen and moisture attack; in consequence all manipulations must be performed in an inert atmosphere. The derivatives of low-molecular weight are spontaneously flammable on contact with air, producing a fume of ZnO, while higher molecular weight derivatives are less sensitive. It is worth noting that both $[(Me_3Si)_3C]_2Zn$ and the closely related cyclic derivative $[–C(SiMe_3)_2SiMe_2CH_2CH_2Me_2Si(Me_3Si)_2C–]$ Zn are remarkably resistant towards water or electrophilic (*see Electrophile*) reagents.[32,33] The thermal stability of dialkylzinc compounds also varies with the nature of the alkyl group; it decreases with the increase of the chain length and the substitution degree on the α-carbon atom. Dimethylzinc is stable at room temperature, whereas di-*iso*-propyl- and di-*tert*-butylzinc decompose at 0 °C and should be stored at dry ice temperature. The mean Zn–C bond dissociation energies ($\bar{D}$) (*see Bond Dissociation Energy*) have been determined by calorimetric studies for some of the compounds listed in Table 1.[34] In the particular case of Me_2Zn, the first- and second-bond dissociation energies have also been calculated[35] ($D_1 = 266 \pm 6\,\text{kJ mol}^{-1}$; $D_2 = 102 \pm 17\,\text{kJ mol}^{-1}$).

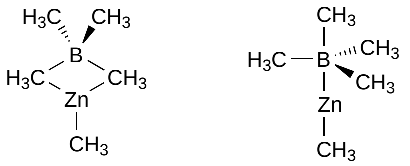


Figure 2 Calculated intermediates in the methyl exchange between BMe_3 and $ZnMe_2$

2.3 Structure of Diorganozinc Compounds

2.3.1 *Dialkylzinc Compounds*

Two-coordinate organozinc compounds, containing saturated alkyl or aryl groups (with the exception of Ph_2Zn), are invariably monomeric with linear geometries at the Zn atom. Therefore they are nonpolar, and most of those whose structures have been determined bear this out[36] (Table 2). Several studies of the vibrational spectrum of Me_2Zn showed unequivocally that the valence angle C–Zn–C is 180° and that the methyl groups undergo virtually free internal rotation. The

Table 2 C–Zn–C angle and C–Zn bond length of some dialkylzinc compounds

	C–Zn–C (°)	C–Zn (Å)
Me_2Zn^a	180	1.93
Et_2Zn^a	180	1.95
n-Pr_2Zn^a	180	1.95
$[2,4\text{-}(t\text{-}Bu)_2C_6H_3]_2Zn^b$	180	1.97
$[(MeOMe_2Si)(Me_3Si)_2C]_2Zn^b$	180	1.98
$(Me_3Si)_2CHZnC^*(SiMe_3)_3{}^b$	176.2	C^H–Zn 1.97/ C^* –Zn 1.95
$PhZnC^*(SiMe_3)_3{}^b$	177.6	C^{Ph}–Zn 1.92/ C^* –Zn 1.96

[a]Data determined by gas-phase electron diffraction.[38] [b]Data determined by X-ray crystallography.[36,39]

molecular structures of dimethyl-, diethyl- and dipropylzinc, determined by gas-phase electron diffraction,[37] display the Zn–C bond distances listed in Table 2.

This observation contrasts dramatically with the property of the pretransition metals, magnesium and beryllium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***), to adopt polymeric structures with bridging alkyl groups and four-coordinate metal centers. The low electronegativity (*see Electronegativity*) difference between zinc and carbon (χ Zn = 1.7; χ C = 2.5) leads to a low polarity (*see Polar Bonds*) of the Zn–C bond which associated with the large size of the zinc atom are thought to be responsible for the monomeric nature of diorganozinc compounds. However, an NMR study of methyl group exchange between dimethylzinc and dimethylcadmium shows that bridging alkyl groups between zinc and cadmium may be possible at least in transition states.[40,41]

The only exception to linear monomeric structure is diphenylzinc, which presents a dimeric structure in solid state by virtue of an interaction between the ipso carbon of one σ-bound phenyl group and the zinc center of another Ph_2Zn unit.[38] The bond lengths between zinc and the terminal phenyl groups are as expected [1.941(4) and 1.951(5) Å]. Nevertheless, the two phenyl groups bridge the two metal centers in an asymmetric fashion, with two short [2.006(5) and 2.016(3) Å] and two long [2.442(4) and 2.364(5) Å] Zn–C bonds (Figure 3). Thus, this interaction was best pictured as an electrophilic attack on the zinc phenyl group by an adjacent Lewis acidic (*see Lewis Acids & Bases*) center than as an association via three-center, two-electron (*see Three-center Bond*) alkyl bridges. The fact that diphenyl zinc is monomeric in hexane solution supports this suggestion.

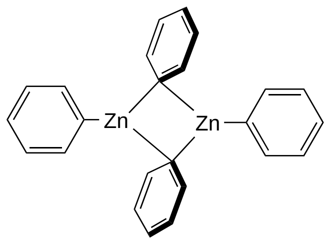

Figure 3 Structure of $PhZn(\mu\text{-}Ph)_2ZnPh$

In contrast to $(Ph_2Zn)_2$, both bis(pentafluorophenyl)zinc[42] and bis[2,4,6-tris(trifluoromethyl)phenyl]zinc[43] have a two-coordinate monomeric solid-state structure approaching linearity, which is certainly a result of electronic and steric (*see Steric Effect*) properties of the *ortho* substituents (Figure 4). In the crystal structure of both compounds, the aromatic rings are almost orthogonal to one another. This special situation alleviates intramolecular (*see Intramolecular*) steric interactions and allows intramolecular stacking interactions between rings on adjacent molecules.

It is worth mentioning that the molecular structures of different bis(disupersilyl)silylmetals $[(t\text{-}Bu_3Si)_2HSi]_2M$, determined by X-ray analysis,[24] show nonlinear frameworks Si–M–Si (M = Zn, Cd, Hg) (Figure 5). This feature, which is unprecedented for homoleptic (*see Homoleptic Compound*) dicoordinate zinc compounds, is believed to arise from van der Waals-attractions between methyl groups of the supersilyl substituents. In contrast, supersilylmetal derivatives of general formula $(t\text{-}Bu_3Si)_2M$ (M = Zn, Cd, Hg), present a common linear geometry at the metal center with a Si–M–Si angle of 180°.[23] The Si–Zn bond lengths vary from 2.384 Å in $(t\text{-}Bu_3Si)_2Zn$ to 2.449 Å in $[(t\text{-}Bu_3Si)_2HSi]_2Zn$.

2.3.2 *Unsaturated Dialkylzinc Compounds*

The situation is different when diorganozinc species bear unsaturated moieties. Although dialkenylzinc compounds such as divinylzinc are monomeric in benzene solution, they have higher melting and boiling points than their saturated analogues, indicating larger intermolecular interactions in

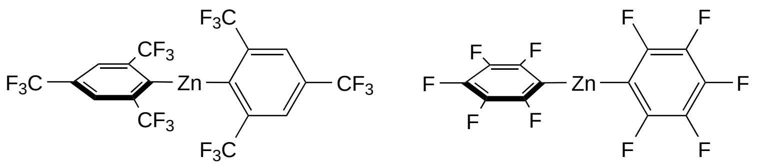

Figure 4 Structure of $[2,4,6\text{-}(CF_3)_3C_6H_2]_2Zn$ and $(C_6F_5)_2Zn$

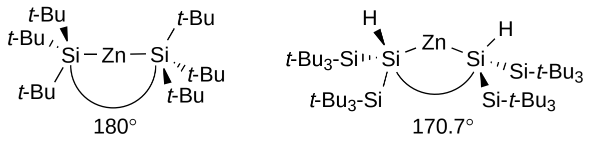

Figure 5 Structure of supersilylzinc $(t\text{-}Bu_3Si)_2Zn$ and bis(disupersilyl)silylzinc compounds $[(t\text{-}Bu_3Si)_2HSi]_2Zn$

solid and liquid phases. Directly bounded alkynyl groups are believed to be the only ones that can form stable bridges between zinc atoms (Figure 6). So far there is no structural determination of this type of compounds, but their associative nature is reflected by their high melting points and low solubility in nonpolar solvents.[44]

From ^1H NMR studies, it was shown that diallylzinc compounds undergo fluxional processes between all possible isomeric σ-bonded (*see σ-Bond*) allylic forms[45] (Scheme 4).

2.3.3 Cyclopentadienylzinc Compounds (See Cyclopentadienyl)

While dicyclopentadienyl compounds of transition metals (*see Transition Metals*) typically have a ferrocene-like (*see Ferrocene*) sandwich structure, the electron-deficient cyclopentadienides of the main group metals tend to form polymers with bridging cyclopentadienyl (Cp) groups.[46] Although exceptions are known, the tendency is rather consistent. The element zinc, owing to its borderline position between transition metals and main group metals, presents a variety of coordination (*see* ***Coordination Numbers & Geometries***) modes with the Cp anion.

The structure of $CpZnCH_3$ has been determined in both solid state and gas phase.[47,48] In the gas phase, the compound is monomeric with C_{5v} symmetry. The Cp ligand features η^5-coordination to zinc, thereby creating an 18-electron (*see Eighteen Electron Compounds*) shell for the zinc atom (Figure 7). However, in crystalline state, the compound exists as a polymer with Cp ligands bridging zinc centers. The hapticity (*see Hapticity*) of the Cp groups varies from two to three (Figure 8).

A related polymeric structure, somewhat more complex, occurs in the solid state of Cp_2Zn.[49] This structure consists of infinite chains of zinc atoms with bridging Cp groups and, in addition, each zinc atom carries a terminal Cp group (Figure 9). Neither the terminal nor the bridging Cp groups are bounded to zinc in a purely η^1-faschion; the bonding situation is best described as '$\eta^{2.5}$'. Owing to its low thermal stability, this compound could not be studied in the gas phase.

Zinconocenes possessing Cp ligands of different electronic and steric properties (*see Steric Effect*) have been synthesized and structurally characterized. Whereas Cp_2Zn is polymeric in the solid state, replacement of hydrogen atoms by methyl or isopropyl groups lead to compounds which exhibit a 'slipped-sandwich' (*see Slip Processes in Ligands*) motif with both η^1- and η^5-Cp ligands. For example, the structure of bis(pentamethylcyclopentadienyl)Zn (Cp^*_2Zn) determined in gas phase[50,51] and in crystalline state[52] is presented in Figure 10. The ^1H NMR spectra at room temperature of this derivative shows only one set of resonances, indicating a rapid haptotropic exchange, or 'ring-slippage', between η^1- and η^5-coordination (Figure 11). Comparable situations, showing different degree of 'ring-slippage', have been observed in gas phase for $(C_5H_4SiMe_3)_2Zn$, and by X-Ray diffraction

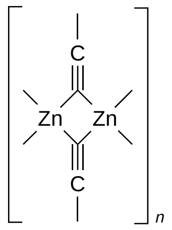

Figure 6 Bridging alkynyl groups between zinc atoms

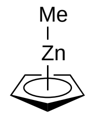

Figure 7 Structure of monomeric CpZnMe in the gas phase

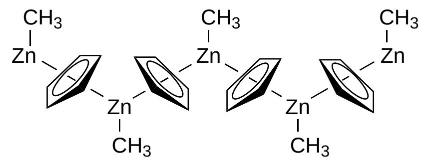

Figure 8 Part of the polymeric structure of CpZnMe in the solid state

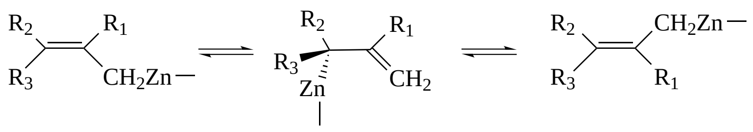

Scheme 4

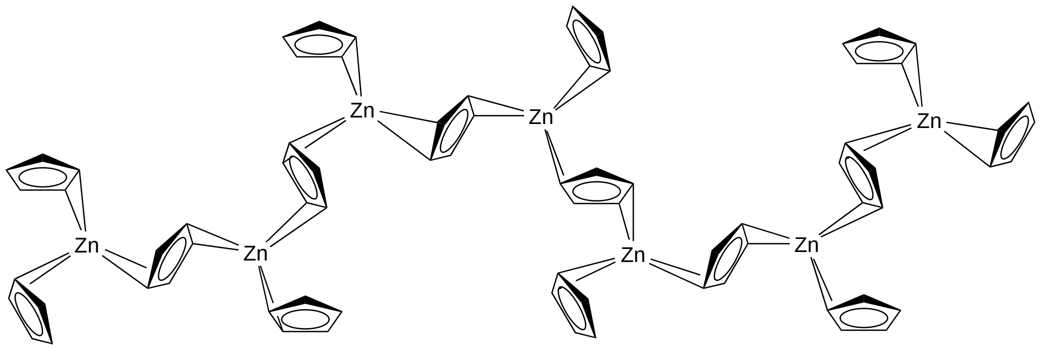

Figure 9 Schematic representation of the chain structure of Cp_2Zn

for $(C_5Me_4Ph)_2Zn$ and $(C_5H\text{-}i\text{-}Pr_4)_2Zn$.[52,53] Compared to the magnesium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***) derivatives η^5-Cp_2Mg or η^5-Cp^*_2Mg of regular sandwich (*see Sandwich Compound*) structures, zinc metallocenes are highly sensitive on contact with air. This sensitivity of slipped-sandwich compounds can be explained by a less effective encapsulation of the metal center.

A new bonding mode between the Cp ring and Zn has been observed for $[CpZn(\mu\text{-}Cp)\{\mu\text{-}N(TMS)_2\}ZnCp]$.[54] This compound is the first example of a Cp group that bridges between nonbonded metal atoms located on the same side of the ring plane (Figure 12).

The nature of the binding mode between zinc and three different (dialkylamino)ethylcyclopentadienyl ligands has been studied.[55] X-ray structural determinations of such derivatives show that the Cp rings are bound to the zinc centers in a η^1 fashion and via their amine groups, thus forming stable six-membered metallacycle (Figure 13). Similarly, the acyclic pentadienyl ligands in $(2,4\text{-}t\text{-}Bu_2C_5H_5)_2Zn$ and in the complex $(C_5H_7)ZnCl\cdot TMEDA$ only exhibit η^1 coordination.[56,57]

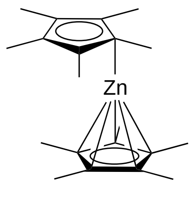

Figure 10 Molecular structure of $(Me_5C_5)_2Zn$ in the gas phase

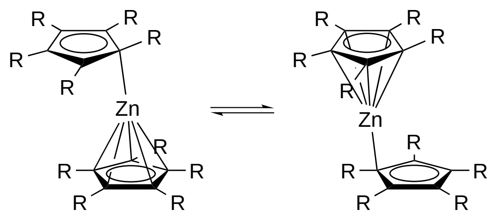

Figure 11 ''Ring-slippage'' in zinconocene compounds

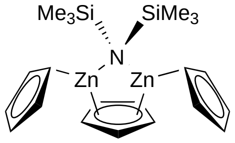

Figure 12 Structure of $Cp_3Zn_2N(SiMe_3)_2$

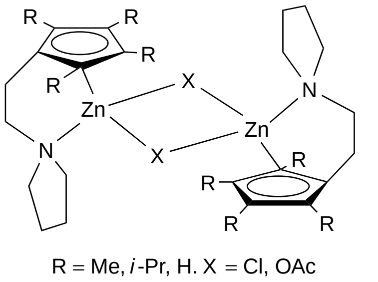

Figure 13 Structure of (dialkylamino)ethylcyclopentadienylzinc derivatives

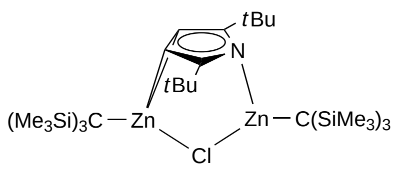

Figure 14 Structure of $[(Me_3Si)_3C\text{–}Zn]_2(\mu\text{-}Cl)(\mu\text{-}Pyr^*)$

Interestingly, the anion 2,5-di(*tert*-butyl)pyrrolide $[2,5\text{-}(t\text{-}Bu)_2C_4H_2N]^-$ (Pyr^*), which is isoelectronic (*see Isoelectronic*) with the Cp anion, reacts with tris-(trimethylsilyl)methylzinc chloride to give the very stable bis[tris(trimethylsilyl)methylzinc] chloride 2,5-di(*tert*-butyl)pyrrolide dimer (equation 11). The solid-state structure of the compound, shown in Figure 14, shows an unusual binding mode for Pyr^* with high steric shielding (*see Steric*

Effect) of the central Zn–Cl–Zn moiety. The Pyr* ligand and the chlorine atom bridge the zinc atoms that are found on the same side of the ligand. One zinc atom is bound to the N of the Pyr* ligand, while the other is bound in a η^2 fashion to the opposite C atoms.[58]

$$2(Me_3Si)_3C\text{–}ZnCl + Li\text{–}Pyr^* \longrightarrow [(Me_3Si)_3C\text{–}Zn]_2(\mu\text{-}Cl)(\mu\text{-}Pyr^*) + LiCl \quad (11)$$

In the different examples presented above, the coordination at zinc suggests that both σ- (*see σ-Bond*) and π-type interactions (*see π-Bond*) contribute to the cyclopentadiene-zinc bonding.

2.4 Coordination of Diorganozinc Compounds (*See Coordination Theory*)

In its ground state (*see Ground State*), the zinc atom has the electronic configuration [Ar] $3d^{10}4s^2$ (*see* ***Electronic Structure of Main-group Compounds***) and so, the low-lying 3*d* shell is completely filled. Therefore the coordination chemistry (*see* ***Coordination Numbers & Geometries***) of zinc is mainly determined by electrostatic factors with no ligand field effects. In terms of simple valence theory (*see Valence Bond Theory*), the zinc atom in diorganozinc compounds is *sp*-hybridized (*see Hybridization*) with a linear geometry and two low-energy orbitals remain available for coordination with electron-donating ligands. Additionally, this capacity to form complexes is enhanced by the low electronegativity (*see Electronegativity*) of zinc (χZn = 1.7), making it a rather electropositive element when bound to carbon (χC = 2.5).

If only one coordinate bond is formed between the diorganozinc and a ligand, the zinc atom becomes sp^2-hybridized (*see Hybridization*) with the typical trigonal planar geometry and it still has an unoccupied valence orbital (*see Valence Orbitals*). This case is quite rare and usually favored with sterically hindered ligands that can avoid the approach of a fourth ligand. When two-coordinate bonds are formed, the zinc atom becomes approximately sp^3-hybridized (*see Hybridization*) with the typical tetrahedral or pseudotetrahedral geometry. This is the most common situation, encountered in the majority of complexes with diorganozinc species. Despite five- and six-coordinated zinc atoms being common in inorganic zinc chemistry (*see* ***Zinc: Inorganic & Coordination Chemistry***), this situation is rare for organozinc compounds. Finally, intramolecular (*see Intramolecular*) coordination may occur when the alkyl groups of R_2Zn include donor atoms (*see Donor Atom*) or insaturations.[59]

2.4.1 Coordination with Oxygen-containing Ligands

When diorganozinc compounds dissolve in ethereal solvents, they readily form complexes with either one or two molecules of the solvent. Complexes with straight chain dialkyl ethers as Me_2O or Et_2O, have been known for a long time but they are generally not stable enough to be isolated.[60] Nevertheless, with cyclic ethers such as THF, and also with bifunctional ethers like 1,4-dioxane or 1,2-dimethoxyethane, the resulting complexes are more stable and some of them could be characterized. Several examples of ether complexes with diorganozinc compounds are presented in Table 3; all of them possess a tetracoordinated zinc center.[61]

The coordination of few diorganozinc species with crown ethers (*see Crown Ethers*) has been studied. The reaction of Ph_2Zn[64] or Et_2Zn[65] with 18-crown-6-ether leads to the formation of the corresponding rotoxane (Figure 15). The average Zn–C bond length found in the Et_2Zn rotoxane [1.957(5) Å] is almost identical with that found in gaseous Et_2Zn [1.950(2) Å], whereas it is somewhat longer in the Ph_2Zn rotoxane [1.984(3) Å]. The Zn–O distances are extremely long [average >2.8 Å] indicating only weak Zn–O bonding. Therefore these rotoxanes might be best regarded as clathrates (*see Clathrate*), having nearly linear R_2Zn encapsulated within the crown ether (*see Crown Ethers*) but only weakly bonded to its oxygens. The mechanism of formation of threaded Ar_2Zn·(18-crown-6) species has been studied.[66] The observations indicate that R_2Zn and 18-crown-6 rapidly form a 1:1 peripheral complex and more slowly form a rotoxane. The formation and dethreading of the rotoxane require free R_2Zn. Thus pure rotoxane is stable indefinitely in a benzene solution unless some R_2Zn compound is added.

A different coordination mode has been found with 1,3-xylyl 15-crown-4 and 1,3-xylyl 18-crown-5 ethers.[67] The crystal structure of three adducts with Ph_2Zn shows that bonding takes place only with two oxygens of the cryptand (*see*

Cryptands & Cryptates) (Figure 16), leading to a tetrahedrally surrounded zinc atom which remains outside the cavity of the crown ether (*see Crown Ethers*).

To date, the only five-coordinated Zn adduct structurally characterized is formed between Ph_2Zn and diglyme[62] (Figure 17) and has been shown to persist in solution.

Finally, an unusual planar-trigonal geometry of the zinc atom has been observed in the molecular structure of $(i\text{-PrOSiMe}_2\text{CH}_2)_2\text{Zn}$.[68] This situation results from intermolecular (*see Intermolecular*) coordination of one oxygen atom belonging to a neighboring molecule (Figure 18). Table 4 outlines important bond lengths and bond angles found in some adducts of dialkylzinc compounds with oxygen-containing ligands.

2.4.2 Coordination with Nitrogen-containing Ligands

The coordination chemistry of diorganozinc compounds with nitrogen-containing ligands has been known for many years, but until recently only little structural information was accessible. Zinc–nitrogen coordinate bonds are stronger than zinc–oxygen coordinate bonds because of the relatively soft character (*see* ***Hard & Soft Acids and Bases***) of zinc (*b*-type) in diorganozinc compounds. But, even though tertiary amines form very stable complexes, primary and secondary amine-complexes are usually unstable as a result of the protonolysis of the zinc–carbon bonds by the nitrogen-bound hydrogen(s) (equation 12). When bidentate ligands (*see Bidentate Ligand*) such as TMEDA are used, chelate complexes (*see Chelate Effect*) are formed[71] (Figure 19). This property has been successfully used to synthesize and isolate heteroleptic (*see Heteroleptic Compound*) diorganozinc compounds (RZnR′) which are otherwise unstable.[72,73] In fact, the occupation of the coordination sites at the zinc atom prevents dismutation to the homoleptic (*see Homoleptic Compound*) derivatives (R_2Zn and R'_2Zn). It is also worth mentioning that the complex between Me_2Zn and the chelate ligand (*S*,*S*)-*NN*′-ethylenebis(1-phenylethylamine) [(S,S)-ebpe] is the sole example of a complex between a dialkylzinc compound and a secondary amine to be isolated

$$R_2Zn + R'_2NH \rightleftharpoons R_2Zn{\cdot}HNR'_2 \rightleftharpoons RZnNR'_2 + RH \quad (12)$$

In the 1960s, Thiele[54,75,76] reported the preparation of complexes with both monodentate (e.g. triethylamine, pyridine) and bidentate ligands (*see Bidentate Ligand*) (e.g. 2,2-bipyridyl, 1,10-phenanthroline). While low-boiling liquid adducts were obtained with monodentate ligands, both in the 1:1 and 2:1 ligand to diorganozinc ratio, volatile solid adducts were obtained with bidentate ligands. As shown by cryoscopic molecular weight measurements in nonpolar solvents, extensive dissociation occurred for the 2:1 species giving equilibrium mixtures of the 1:1 adduct, the free amine and the 2:1 species. Eventually, on repeated distillation, these liquids of 2:1 stoichiometry reach a stable 1:1 stoichiometry. The adducts with N-heterocyclic ligands such as pyridine, 2,2′-bipyridine and 1,10-phenanthroline, are brightly colored owing to metal-to-ligand charge-transfer transitions.[77] A series of complexes between dialkylzinc compounds and bipyridine has been studied. The variation of the dissociation constants indicates that the metal-nitrogen bond strength increases with the size of the alkyl group; bigger alkyl groups provide more electron density, reducing the Lewis acidity (*see Lewis Acids & Bases*) of the metal but increasing back bonding (*see Back Bonding*) to the ligand.[4]

Recently there has been revived interest for adducts of dimethylzinc and diethylzinc with nitrogen-containing ligands owing to their useful application as precursors in metal organic chemical vapor deposition[78] (*see Metal–Organic Chemical Vapor Deposition*) (MOCVD) and in the purification of metal alkyls for subsequent use in MOCVD.[79] Less volatile adducts such as $[R_2Zn\{(C_5H_4N)(CH_2)_3(C_5H_4N)\}]_n$ have been used for the production of electronic grade R_2Zn by mild thermal dissociation.[80]

A number of relevant structures have been published. Table 5 summarizes some of the important bond lengths and bond angles found in complexes between diorganozinc compounds and amines. As a result of amine coordination, the geometry around the zinc center changes from linear to distorted tetrahedral (*see* ***Coordination Numbers & Geometries***).

It is noteworthy that the potentially tridentate triazine ligand coordinates only via one of its nitrogen atoms to form the $[Me_2Zn(CH_2NMe)_3]_2$.[81] In contrast, the reaction of Et_2Zn with 1,4-diazabiciclo[2,2,2]octane (DABCO) results in the formation of molecular chains in which the metal atom exhibits a distorted tetrahedral geometry through coordination to one nitrogen atom of two different DABCO molecules[82] (Figure 20).

The coordination of Me_2Zn with macrocyclic amines (*see* ***Macrocyclic Ligands***) such as 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (N_4-aza crown) and 1,4,7,10,13,16-hexamethyl-1,4,7,10,13,16-hexaazacyclooctadecane (N_6-aza crown) has been studied.[85] As shown by X-ray diffraction analysis, the structure of the complexes consists of molecular units with distorted tetrahedral coordination at zinc (Figure 21, Table 5). In $(Me_2Zn)_2[N_4$-aza crown], the

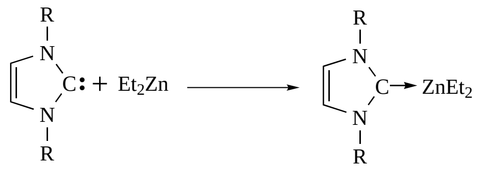
Me_2Zn forms two six-membered chelate rings, clearly favored over the more sterically strained five-membered configuration, whereas in $(Me_2Zn)_2[N_6$-aza crown], the Me_2Zn forms two five-membered chelate rings. While the N_4-aza crown adduct has the predictable Me_2Zn:ligand stoichiometry of 2:1, steric constraints (*see Steric Effect*) in the N_6-aza crown adduct limit the stoichiometry to 2:1. These adducts thermally dissociate at relatively low temperatures, making them suitable for Me_2Zn purification and its further use in MOCVD (*see Metal–Organic Chemical Vapor Deposition*).

The structures of some complexes with perfluoroalkylzinc derivatives have also been determined by X-ray diffraction. The first fully characterized compound of this type was the pyridine adduct $[(CF_3)_2Zn(C_5H_5N)_2]$, which presents the typical four-coordinated zinc center with a distorted tetrahedral geometry[86,87] (Table 5). The tetramethyltetrazene ligand forms a four-membered chelate ring via a 1,3-coordination with $(C_6F_5)_2Zn$[88] (Figure 22).

2.4.3 Coordination with other Ligands

The synthesis and characterization of Et_2Zn adducts with nucleophilic carbenes (*see* ***Carbene Complexes***) have been described.[89] They are directly available and in good yields from a smooth reaction between Et_2Zn and stable carbenes (*see* ***Carbene Complexes***) such as 1,3-dimesitylimidazol-2-ylidene or 1,3-di(1-adamantyl)imidazol-2-ylidene (equation 13). The solid-state structure of [Et_2Zn{1,3-di(1-adamantyl)imidazol-2-ylidene}] shows a zinc atom in a rather unusual trigonal planar arrangement, certainly due to a steric protection of the zinc center by the adamantyl substituents.



(13)

R = mesityl or 1-adamantyl

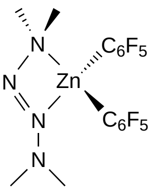


Figure 22 Coordination of tetramethyltetrazene to $(C_6F_5)_2Zn$

The recent preparation of $[Ph_2Zn\{S(CH_2)_n\}_2]$ ($n = 3$, 4) represent the first examples of complexes between a diorganozinc compound and a sulfur donor ligand.[90] The molecular structure of $[Ph_2Zn\{S(CH_2)_4\}_2]$, determined by X-ray crystallography, reveals a dimeric association with carbon-bridging groups (Figure 23).

2.4.4 Intramolecular Coordination

Diorganozinc compounds containing potential coordinating substituents beyond the α position generally exhibit intramolecular (*see Intramolecular*) coordinative interactions between the substituent groups and the central zinc atom.[52] This is the case for all the compounds containing carbon–carbon multiple bonds and those containing oxygen, nitrogen, sulfur, and phosphorus (Figure 24). In a study involving bis[3-(dimethylamino)propyl]zinc, both electron diffraction in gas phase and X-ray diffraction in solid state show a weak contact, around 0.23 nm, between the nitrogen and the zinc atom.[91] Analogous intramolecular coordination of the heterocyclic-*N* is found in the sterically hindered complex $[(2\text{-}C_5H_4N)(Me_3Si)_2C]_2Zn$[92] or with the amine-*N* in 2-[(dimethylamino)methyl]phenyl- and 2-(dimethylamino)benzyl derivatives.[93,94]

The monomeric zinc complex $[Zn(2\text{-}C_6H_4PPh_2NSiMe_3)_2]$, which was recently obtained by reaction of the *ortho*-metallated species $[Li(2\text{-}C_6H_4PPh_2NSiMe_3)]_2{\cdot}Et_2O$ with $ZnCl_2$ in THF, represents a good example of side-arm intramolecular coordination.[95] Its molecular structure determined by X-ray crystallography shows a tetrahedrally

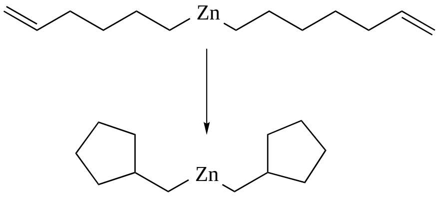
coordinated zinc atom with a Zn–C distance (2.008 Å) comparable to those found in diarylzinc compounds and a Zn–N distance (2.158 Å) typical for Zn–N dative bonds (Figure 25).

In compounds containing multiple carbon–carbon bonds, such as $[CH_2{=}CH(CH_2)_3]_2Zn$ and $[MeC{\equiv}C(CH_2)_3]_2Zn$, interactions between the multiple bond and the zinc center are also proposed on the basis of NMR spectra (^1H and ^{13}C) and Raman spectroscopy.[96,97] An electron diffraction study of the linear di-3-butenylzinc and the molecular structure of $(2,4\text{-}t\text{-}Bu_2C_5H_5)_2Zn$ determined by X-ray diffraction have been published.[52,98]

Interestingly, the intramolecular coordination of the carbon–carbon double bond in $[CH_2{=}CH(CH_2)_4]_2Zn$ is thought to be responsible for the formation of di(cyclopentylmethyl)zinc in 90% yield when the compound is kept several days at 120 °C (equation 14).[99]



(14)

3 ORGANOZINC COMPOUNDS OF THE TYPE RZnX

3.1 Organozinc Halides

3.1.1 Preparation

The procedures used for the preparation of diorganozinc compounds must be modified in order to obtain organozinc halide derivatives. The aim of these modifications is to avoid the Schlenk-type equilibrium which leads to diorganozinc derivatives (equations 1 and 2) although the positions of the equilibria are such that the R–Zn–X compounds are favored. In the last decade, this subject has been included in different reviews concerning the applications of polyfunctional organozinc compounds.[8–10]

Direct Reaction of Zn with Alkyl Halides. The direct insertion (*see Insertion*) reaction of Zn metal into alkyl halides – alkyl iodides being the ideal substrates – is a useful reaction to prepare simple or polyfunctional organozinc halide compounds (equation 1). With primary alkyl iodides, the reaction requires an excess of Zn dust (ca. 3 equiv), previously treated with few mol % of 1,2-dibromoethane and TMSCl, and a temperature of 40 °C in THF. In these conditions, secondary alkyl iodides react at room temperature and benzylic and allylic bromides at 0 °C. The insertion (*see Insertion*) into less activated C–X bonds may require more reactive forms of zinc (Riecke zinc), higher temperatures, or the use of polar (*see Polar Compounds*) solvent or cosolvent.

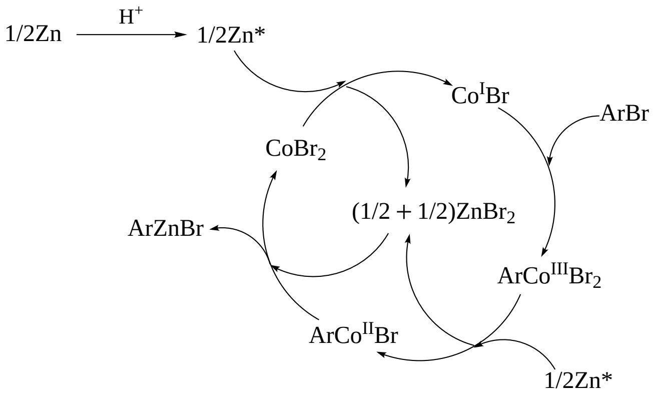
A novel and simple modification uses the catalysis with iodine in dimethylacetamide[100] (DMA) (equation 15). In these conditions, any form of metallic zinc can be used (dust, powder, granule, shot), a variety of functional groups is tolerated, and the use of less reactive alkyl chlorides is possible, although in this special case the reaction requires stoichiometric amounts of bromide salts. Electrochemical procedures, using a sacrificial zinc anode (*see Sacrificial Anode*), have been successfully employed to prepare organozinc halides from aryl bromides and chlorides in high yields, even those that are unreactive in the Riecke process.[101,102] Recently it was found that reducing agents can advantageously replace electricity and the group of Périchon developed a purely chemical reaction based on the activation of aryl bromides by low-valent cobalt species arising from the reduction of cobalt halide by zinc dust.[103] A possible catalytic cycle is shown in Scheme 5.

$$\text{R–X} + 1.5\text{Zn} \xrightarrow[\text{DMA } 80\,^\circ\text{C},\ 3-12\,\text{h}]{\text{I}_2(1-5\,\text{mol\%})} \text{R–Zn–X} \qquad (15)$$

$$\text{X} = \text{Cl, Br}$$

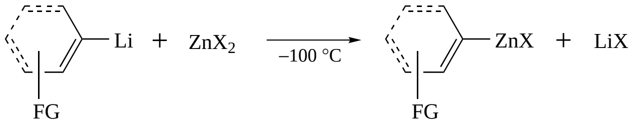
Numerous modifications of the direct zinc insertion procedure can be found in the literature. For example, simple dialkylzincs can be used as reagents instead of metallic Zn, but in this case the reaction is accelerated by catalytic quantities of zinc salts or transition metal (*see Transition Metals*) salts. Whereas the Cu^I-catalyzed iodine–zinc exchange reaction provides diorganozincs, the Pd^{II}, Mn^{II} and Ni^{II} catalyzed iodine- or bromine–zinc exchange leads to organozinc halides.

Lithium–Zinc Transmetallation. The transmetallation reaction of organolithium reagents with zinc salts is a more



Scheme 5

straightforward approach to organozinc halide derivatives, but the high reactivity and instability of these very polar (*see Polar Compounds*) reagents limit the applicability of this reaction. However, alkenyl- and aryllitiums are known to be less reactive than their alkyl counterparts. Thus, at low temperature (−100 °C), they tolerate a range of functional groups and readily undergo transmetallation reaction with zinc halides, leading to the corresponding organozinc halides**[21,104]** (equation 16).



X = Br, I. FG = functional group.

(16)

Other Preparations. A less general procedure involves the reaction of diorganomercurials with zinc dust in the presence of zinc bromide.

Allyliczinc halides reagents have been prepared from sterically hindered homoallylic alcohols, using a novel fragmentation reaction of the corresponding zinc alkoxide**[105]** (Scheme 6). The interest of this reaction resides in the absence of the Wurtz homocoupling product, usually present in high proportion when the direct reaction of zinc with allylic halides is used.

An *in situ* (*see In Situ Reaction*) generation of zinc acetylides has been performed in very mild conditions by the combination of a terminal alkyne with $Zn(OTf)_2$ and a tertiary amine base**[106]** (equation 17). The zinc acetylides were not isolated but they could be unequivocally identified by the large, characteristic shifts of the ^{13}C NMR corresponding to the *sp*-hybridized (*see Hybridization*) carbons.

$$\text{R–C}\equiv\text{C–H} + \text{Zn(OTf)}_2 \xrightarrow{\text{R}_3\text{N}} \text{R–C}\equiv\text{C–Zn(OTf)} + \text{R}_3\text{N·HOTf} \quad (17)$$

3.1.2 Structure of Organozinc Halides

As a result of the Schlenk-type equilibrium (equation 2), alkylzinc halide solutions are believed to contain some amounts of the corresponding dialkylzinc compound and zinc halide salt. The equilibrium usually lies on the left side in such a way that the alkylzinc halide compound is favored. Nevertheless, as already mentioned in Section 2, the equilibrium can be shifted to the right by distillation of the more volatile dialkylzinc derivative or by addition of complexing agents to remove the zinc dihalides from the solution.

Although organozinc halides have been extensively used in organic synthesis for many years, comparatively little information is available concerning their structure and coordination behavior. The crystalline ethylzinc iodide is a coordination polymer, with the iodine−zinc linkages giving rise to a layer structure as shown in the Figure 26. Each iodine atom forms one short (2.64 Å) and two long (2.91 Å) bonds to zinc.**[107]**

Ethylzinc chloride and ethylzinc bromide are tetrameric in benzene solutions and are believed to have the cubane-type structure**[108]** shown in Figure 27. In the Zn_4X_4 core, the zinc-halogen coordination is relatively weak; consequently when these compounds dissolve in coordinating solvents or when

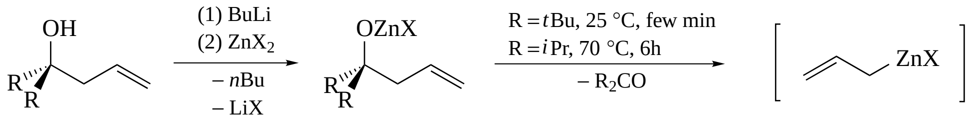

Scheme 6

they are reacted with ligands like TMEDA or bipyridine, they exist as monomeric complexes.[84] The highly sterically demanding $(PhMe_2Si)_3CZnCl$ exist as a dimer in solid state, with tricoordinate zinc atoms and bridging chlorine atoms.[109] As shown in Figure 27, the solid-state structure of the complex consists of a planar arrangement of zinc and chlorine atoms forming a parallelogram.

The reaction between lithiated bidentate ligands (*see Bidentate Ligand*), such as lithium (dialkylaminoethyl)cyclopentadienide or $[2\text{-}C_5H_4N(Me)_2Si(Me_3Si)_2C]Li$, with zinc dihalide ($ZnX_2$) also leads to dimeric derivatives containing bridging chlorine atoms but with tetracoordinate zinc centers as a result of intramolecular (*see Intramolecular*) coordination[55,110] (Figure 13 and 28 respectively). A cryoscopic study of $Et_2N(CH_2)_3ZnCl$ in benzene solution has shown a related dimeric structure with bridging chlorines independent of the concentration[111] (Figure 28). Selected bond lengths and bond angles for dimeric alkylzinc halide compounds characterized by X-ray crystallography are reported in Table 6.

A number of monomeric adducts between alkylzinc halide compounds and chelating ligands (*see Chelating Ligands*) have been isolated and structurally characterized (Table 7). For example, the reaction between the TMEDA adduct of lithium-phenyl(trimethylsilyl)methanide and $ZnCl_2$[63] directly led to the formation of the TMEDA

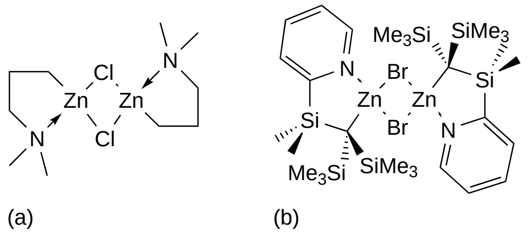

Figure 28 Dimeric structure of $Me_2NCH_2CH_2CH_2ZnCl$ (a) and $[(C_5H_4N)(Me)_2Si(Me_3Si)_2C]ZnBr$ (b)

complex of phenyl(trimethylsilyl)methanidezinc chloride. Its molecular structure determined by X-ray diffraction crystallography, and that of EtZnCl·TMEDA, are presented in Figure 29.

Even if alkylzinc halides in the absence of chelating ligands (*see Chelating Ligands*) or coordinating solvents generally form dimeric or polymeric species with bridging halogen atoms, a different situation has been found with the Reformatsky reagents derived from the ethyl- and *tert*-butyl esters of bromoacetic acid.[113] In the crystalline state, $(Br\text{–}Zn\text{–}CH_2COO^tBu)_2$ exists as a dimeric unit consisting of a nonplanar 8-membered $(ZnCCO)_2$ ring in which the THF coordination is preferred over the Zn–Br–Zn bridging (Figure 30). A rather short C–C bond length (1.41 Å)

associated to a quite long carbonyl C–O bond distance (1.31 Å) suggest that the Reformatsky reagent exists neither as a strictly C-metalated species nor as a strictly O-metalated form, but rather as a combination of the two. Association measurements and NMR spectroscopy studies show that the reagents are dimeric in all but the most polar (*see Polar Compounds*) solvents like dimethylsulfoxide.

Among the alkylzinc halide compounds, iodomethylzinc iodide deserves a special attention owing to its important applications in organic synthesis. This highly reactive reagent can be stabilized by chelation to ethers or even more efficiently to bipyridine.[114] In the later case, the resulting adducts are stable enough to be stored several months in the freezer with almost no decomposition. The complexes of ICH$_2$ZnI with 18-crown-6 and benzo-18-crown-6 ethers have been prepared and structurally characterized by X-ray diffraction crystallography.[115] The two structures are very similar; they reveal a coordination of three oxygen atoms from the crown ether (*see Crown Ethers*) to the zinc atom (Figure 31). Interestingly, this is one of the few crown ether-derived complex in which the metal atom is not centrosymmetric. Selected bond lengths and bond angles for alkylzinc halides coordinated to oxygen-containing ligands are found in Table 8.

3.2 Alkylzinc Compounds Containing a Zinc–Oxygen Bond

There are two principal classes of alkylzinc compounds containing a zinc–oxygen bond, that is, those derived from aliphatic and aromatic alcohols (commonly called alkylzinc

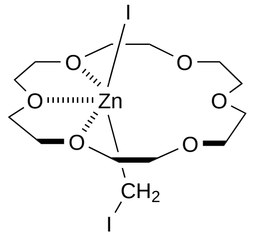

Figure 31 Structure of ICH$_2$ZnI·18-crown-6 complex

alkoxides and aryloxides) and those derived from other oxygen-containing compounds like water, carboxylic acids, silanol, boronic acids, and so on. Recently, Zn^{II} alkoxide or phenoxide derivatives have attracted much interest for their ability to catalyze numerous reactions, such as enantioselective (*see Enantioselectivity*) alkylation of aldehydes, asymmetric epoxidation of α,β unsaturated ketones, decarboxylation of carboxylic acids, copolymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***) of carbon dioxide with epoxides.

3.2.1 *Alkylzinc Alkoxides and Aryloxides*

Preparation. The synthesis of alkylzinc alkoxides and aryloxides is achieved by an alkane elimination process in the simple reaction of a dialkylzinc compound, R$_2$Zn, with one equivalent of an alcohol, R′OH (equation 18). This reaction proceeds either in hydrocarbon solvents or neat solution, to give essentially quantitative yields of the desired products. The volatility of the RH side product helps to drive the equilibrium to the right. The formation of relatively strong Zn–O and C–H bonds, at the expense of breaking the O–H and a relatively weak Zn–C bond also guarantee favorable reaction energetics.

$$\mathrm{R'EH + ZnR_2 \longrightarrow RZnER' + RH} \qquad (18)$$

$$\mathrm{R = Alkyl,\ Me_3SiCH_2 \cdot E = O,\ S,\ Se}$$

Structure. The presence of an oxygen atom directly bound to zinc increases both the electron deficiency of the zinc and the donor character of the oxygen atom. This condition will inevitably result in intermolecular (*see Intermolecular*) association increasing the coordinative saturation of zinc and leading to high thermal stability and low sensitivity towards oxygen and moisture. Organozinc alkoxides and aryloxides

Table 8 Selected bond lengths and bond angles for some alkylzinc halide complexes with oxygen-containing ligands

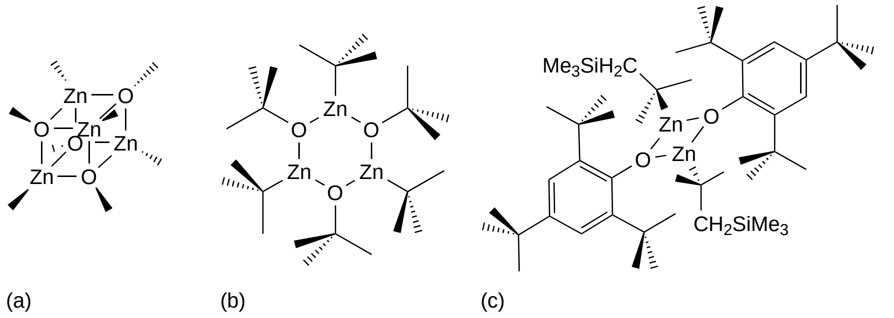

Figure 32 Tetrameric MeZn–OMe (a), trimeric *t*-BuZnO-*t*-Bu (b) and dimeric $Me_3Si(Me_2)CZn2,4,6$-*t*-$Bu_3C_6H_2$ (c)

are usually colorless or light-yellow solids. Depending on the nature of the alkyl and alkoxide groups and on the degree of association, they can be either highly soluble or virtually insoluble in both apolar and polar organic solvents.

The coordination chemistry (*see* ***Coordination Numbers & Geometries***) of organozinc alkoxides and aryloxides is very diverse but follow fairly well established patterns that can be rationalized mainly on the basis of steric considerations (*see Steric Effect*). As shown in Figure 32, the solid-state structure of methylzinc methoxide is tetrameric.[118] Although this tetrameric association with distorted cubic Zn_4O_4 core is observed as a common feature, the degree of association decreases with increasing bulk of the alkyl and alkoxide groups, resulting in trimeric[119] or dimeric species,[120] for example, [*t*-BuZn-(O-*t*-Bu)]$_3$ and [$(Me_3SiCH_2)(Me)_2CZnO$-2,4,6-*t*-$Bu_3C_6H_2$]$_2$ (Figure 32). The structure of these complexes also depends on the presence of potentially intramolecular coordinating donor atoms in either the organic or the alkoxide group. Such donor atoms are often involved in intramolecular coordination and may give rise to a very complex coordination behavior.

A number of alkylzinc complexes derived from phenoxide ligands, containing one or two potentially coordinating NMe_2 groups, have been studied by cryoscopic molecular weight determination.[121] When the potentially chelating groups (*see Chelating Ligands*) are in positions that result in the formation of six-membered chelate rings upon intramolecular coordination, the complexes are dimers or dimer–monomer equilibria, and when the potential chelate ring size is decreased from six- to five-membered, trimeric aggregation is observed (Figure 33). The introduction of bulky substituents in a potential five-membered chelate ring leads to further dissociation, and dimer formation becomes favorable. The dimer formation can also be favored when a strongly electron-withdrawing group is bound to the oxygen, leading to a weaker zinc–oxygen coordinate bond. Therefore, when ethylzinc phenoxide is a tetramer the related ethylzinc pentafluorophenoxide is a dimer.[119]

Multinuclear aggregates of alkylzinc derivatives have been prepared and structurally characterized by the reaction between tris(3,5-dialkyl-2-hydroxyphenyl)methanes with dimethyl- or diethylzinc.[122] Depending on both the steric

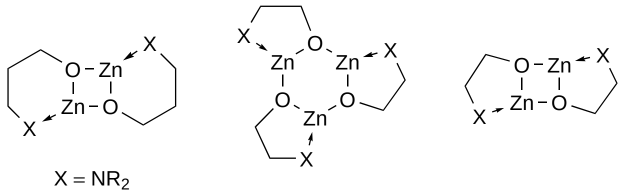

Figure 33 Intramolecular coordination in alkylzinc alkoxides

requirements (*see Steric Effect*) of the dialkylzinc reagent/trisphenol precursors and on the solvent used, hexa-, penta-, tetra-, and trinuclear aggregates are isolated. The reactions of polyalcoholic compounds (diphenol and triphenol derivatives) have also been studied, they lead to a variety of products depending on the conditions used.[123,124]

When the zinc atom is coordinatively unsaturated or when the oxygen atoms bound to zinc have a low electron density rising from mesomeric or inductive effects, the compounds can easily form complexes with coordinative reagents like pyridine and TMEDA.

In some cases, alkylzinc compounds containing oxygen are subject to redistribution equilibria.[125,126] This is shown in solution by the presence of different species. For example, compounds of general formula $R_6Zn_7(OMe)_8$ can be isolated from solutions of [RZn(OMe)]$_4$ (R = Et, Me). The structure of these aggregates, as shown in Figure 34, consists of two Zn_4O_4 cubic

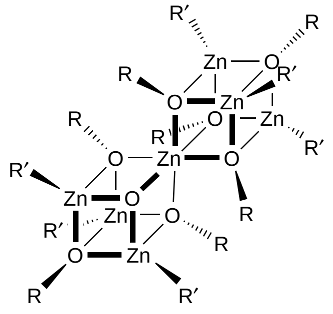

Figure 34 Structure of $(RO)_8Zn_7R'_6$

cores sharing a zinc atom. Interestingly, it has been found that the related compound $(ICH_2)_6Zn_7(MeO)_8$ is cleanly formed when a solution of ethylzinc methoxide and diiodomethane is photochemically (*see Photochemistry*) irradiated.[127]

In the last years, a large number of alkylzinc alkoxide or aryloxide derivatives have been prepared and structurally characterized. They have gained interest for their valuable catalytic activity for various reactions including enantioselective alkylation of aldehydes, asymmetric epoxidation of α,β-unsaturated ketones, and the copolymerization of carbon dioxide with epoxides (Section 6). Some selected averaged bond lengths found in organozinc compounds containing a zinc–oxygen bond are summarized in Table 9.

3.2.2 Other Organozinc Compounds Containing Oxygen

The dialkylzinc compounds are extremely moisture sensitive and even react explosively with bulk water. Nevertheless, cryoscopic studies carried out on the controlled hydrolysis of diethylzinc show the formation of organozinc hydroxide EtZnOH as intermediate.[130,131] This intermediate, which is thought to have the dimeric structure $(EtZnOH)_2$, is very unstable and reacts further to give polymers of the form $Et(ZnO)_n$ (equation 19). Some of these products exhibit a good catalytic activity for the polymerization of lactones and cyclic ethers.

$$nR_2Zn + nH_2O \longrightarrow [nRZnOH] \longrightarrow R(ZnO)_nH + (n-1)RH \quad (19)$$

The stabilization approach with bulky ligands allowed the isolation of the stable alkylzinc hydroxide dimer, that is, $[\{Zn(\mu\text{-}OH)C(SiMe_2Ph)_3\}_2]$ (Figure 35), obtained by reaction of $(Me_2PhSi)_3CZnCl$ with NaOH.[132] The hydroxy group is characterized by a sharp ν(OH) IR absorption at 3680 cm^{-1}.

Zinc siloxides derived from Si–OH species have received considerable attention in recent years, since they can be used as precursors for metal silicates and mixed-metal oxide systems as well as for models for heterogeneous silica-supported catalytic systems and complex zeolite systems.

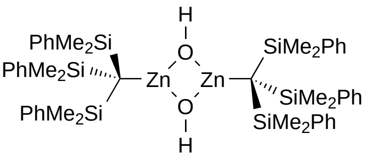

Figure 35 Structure of dimeric $[\{Zn(\mu\text{-}OH)C(SiMe_2Ph)_3\}_2]$

A polyhedral zinc siloxane compound, which was obtained in the reaction between dimethylzinc and trimethylsilanol, has been reported in 1965.[133] More recently, di-, tri-, and tetranuclear compounds of this kind have been prepared; the nature of the product being dependent on the molar ratio of the monosilanol to the alkylzinc compounds and on the steric demand (*see Steric Effect*) of the substituents at both the oxygen and zinc atoms.[134,135] The structures for the di- and tetranuclear species are similar to those found with alkoxide derivatives (Figure 32). In contrast, the trinuclear alkylzinc siloxides show a specific type of association, that is, two four-membered rings sharing a zinc atom (Figure 36). Recently, larger aggregates which remain soluble in organic solvents, have been prepared using the silanetriol $RSi(OH)_3$ [$R = 2,6\text{-}i\text{-}Pr_2C_6H_3N(SiMe_3)$]. Its reaction with an excess of Me_2Zn in THF/hexane at room temperature led to the neutral compound $[Zn_4(THF)_4(MeZn)_4(O_3SiR)_4]$,[136] while the ionic zinc siloxane $(LZnLiO_3SiR)_4$ was obtained when MeLi and N,N,N',N'-tetramethyl-1,-4-phenylenediamine (L) were present in the reaction mixture.[137] The molecular structure of the neutral aggregate exhibits a $Zn_8Si_4O_{12}$ core in which the zinc atoms are in a variety of geometries and coordination environments (Figure 36).

Recently, some interest in the chemistry of metal diorganoboryloxides $[M(OBR_2)]$ has emerged from their potential catalytic activity. Some alkylzinc diorganoboryloxides $[RZn(OBR'_2)]$ have been prepared with the expectation that the $p_\pi - p_\pi$ interaction between boron and oxygen may reduce π-donor properties of the latter, and consequently decrease the tendency for autoassociation to afford a coordinatively unsaturated boron atom.[138] Unfortunately, the diverse results obtained so far show no significant difference between diorganoboryloxides and typical alkoxides in their reactivity with dialkylzinc. Typical Zn_4O_4 heterocubane cores were obtained when $(9\text{-}BBN)_2O$ (9-BBN = 9-Borabicyclo-3,3,1-non-9-yl) or $(Et_2B)_2O$ was treated with Et_2Zn in toluene at room temperature (Figure 32). A less classic discrete dimer $[(Mes_2BO)ZnEt]_2$, comparable to the dimeric alkoxides $[(2,6\text{-}i\text{-}Pr_2C_6H_3O)\text{-}ZnCH_2SiMe_3]_2$ and $[(2,4,6\text{-}t\text{-}Bu_3C_6H_2O)ZnCH_2SiMe_3]_2$ (Figure 32), has been obtained in the reaction of dimesitylboronic acid (Mes_2BOH) with diethylzinc in toluene at 0 °C.[139]

The preparation and reactions of alkylzinc enolates have been studied. The main methods for their synthesis are metal exchange between lithium enolates and zinc chloride,[140] deprotonations of carbonyl compounds with

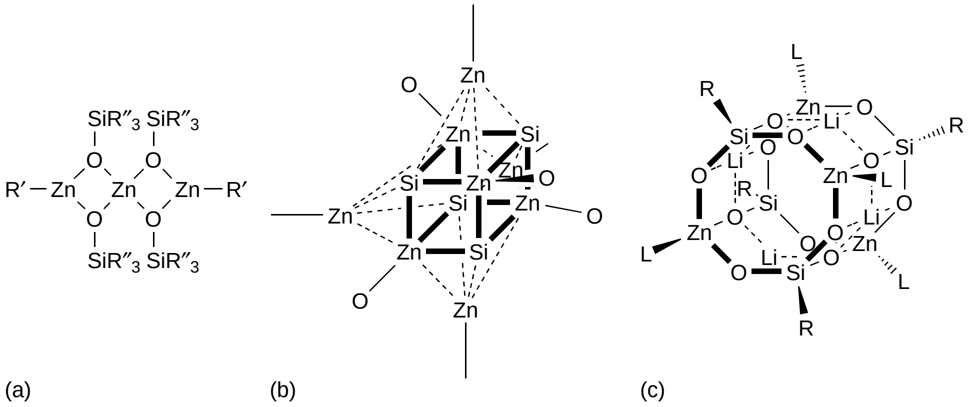

Figure 36 Structures of the trinuclear aggregate $[Zn(R'Zn)_2(OSiR''_3)_4]$ (a), the core of the neutral $[Zn_4(THF)_4(MeZn)_4(O_3SiR'')_4]$ (b) and the ionic $(LZnLiO_3SiR)_4$ (c) (R = 2,6-*i*-$Pr_2C_6H_3N(SiMe_3)$)

basic alkylzinc amides,[141] reduction of α-bromo carbonyl compounds[142] (Reformatsky reaction) and addition reactions of dialkylzincs to α,β-unsaturated carbonyl and heterocarbonyl compounds[143–145] (Scheme 7). Spectroscopic studies of the resulting alkylzinc ketone enolates suggest the presence of oxygen- rather than carbon-bound metal species. Oxygen-metalated compounds have also been found in *N*-protected α-amino-substituted zinc ester enolates.[146] In this case, the zinc atom is fixed via *N*,*O*-chelation, and intramolecular aggregates of various composition are formed. The same *N*, *O*-chelation occurs in ethyl zinc derivatives of β-carbonyl sulfoximines with formation of dimeric aggregates through dative Zn–O interactions in the case of β-ketosulfoximine, and through Zn–C interactions in the case of β-amidosulfoximine.[147]

Organozinc carboxylates formally derived from carboxylic acids are prepared *via* protonolysis of diorganozinc compounds by carboxylic acids (equation 20). Although dimeric carbamate complexes of the general formula $[RM(E_2CNR'_2)]_2$ (E = S or Se, R = Me or Et, R′ = alkyl, M = Zn or Cd) are readily formed by reaction of CE_2 with $RM(NR'_2)$[148,149] (equation 21), insertion (*see Insertion*) of CO_2 into methylzinc diethylamide leads to unusual species such as the tetramers $[Me_2Zn_4(O_2CNEt_2)_6]$ and $[Me_4Zn_4(O_2CNEt_2)_4]$[150,151] (Figure 37). Diorganozinc compounds are typically unreactive towards insertion of carbon dioxide into the zinc–carbon bond with one exception, that is, the specific activation of diethylzinc by *N*-methylimidazole.[152]

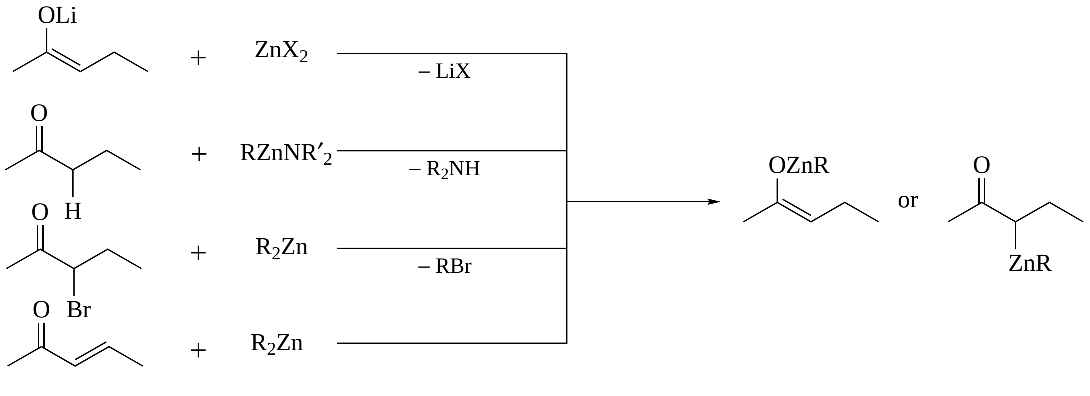
$$ZnR_2 + R'COOH \longrightarrow RZnO_2CR' + RH \qquad (20)$$

$$RZnNR'_2 + CE_2 \longrightarrow RZnE_2CNR'_2 \qquad (21)$$

$$E = O, S, Se$$

3.3 Alkylzinc Compounds Containing a Zinc–Sulfur or Zinc–Selenium Bond

Heteroleptic (*see Heteroleptic Compound*) alkylzinc thiolate and selenolate compounds present two major interests; they can be used as models for metalloenzyme activity[153] and as precursors for the formation of binary metal sulfides and selenides.[154] Furthermore, these compounds tend to



Scheme 7

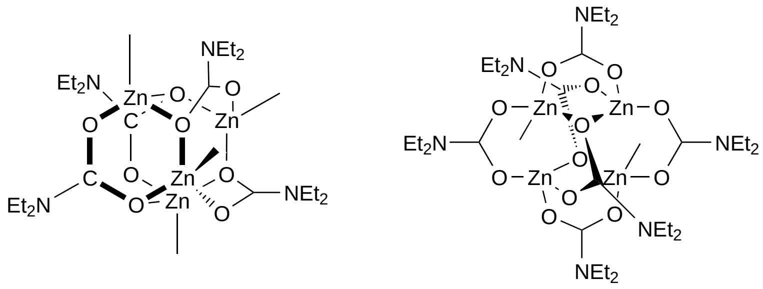


Figure 37 Structures of $[Me_4Zn_4(O_2CNEt_2)_4]$ and $[Me_2Zn_4(O_2CNEt_2)_6]$

oligomerize leading to a variety of inorganic rings (*see* ***Inorganic Ring Systems***) or larger aggregates with interesting optical and electronic properties.

3.3.1 Preparation

The title compounds are usually obtain in a straightforward manner and in almost quantitative yields by alkane elimination process between a dialkylzinc compound ZnR_2 and the desired thiol R′SH or selenol R′SeH species[155,156] (equation 18). This reaction works equally well in hydrocarbon solvent or neat solution. If thiocyanogen $(SCN)_2$ is used as the reagent, then alkylzinc thiocyanate derivatives (RZnSCN) are obtained.[157]

A different strategy, involving chlorotrimethylsilane elimination from the reaction of a Zn^{II} or Cu^{I} halide with (trimethylsilyl)arenethiolates $RSSiMe_3$, has been described for the preparation of zinc- and copper arenethiolates[158] (equation 22).

$$ArSSiMe_3 + RZn\text{–}Cl \longrightarrow ArS\text{–}Zn\text{–}R + ClSiMe_3 \quad (22)$$

Although insertion (*see Insertion*) of elemental sulfur into the zinc–carbon bond of dialkylzinc has not been studied extensively, it has been described in the special case of diethylzinc for the preparation of EtZn(SEt)[159] (equation 23).

$$Et_2Zn + \frac{1}{8}S_8 \longrightarrow EtS\text{–}Zn\text{–}Et \quad (23)$$

Mixed alkylzinc dithio- or diselenocarbamates of general formula $RZnE_2CNEt_2$ ($R = Me_3SiCH_2, Me_3C$; E = S, Se) are prepared by two different ways, namely, ligand redistribution between the corresponding dialkylzinc (R_2Zn) and bis(ditio- or bis(diseleno- carbamato)zinc compounds[160] (equation 24), and insertion of CE_2 into the zinc–nitrogen bond of a mixed alkylzinc amide $RZnNR'_2$ which was first reported by Noltes (Section 3.2.2 equation 21).[161]

$$(R'_2NCE_2)_2Zn + R_2Zn \longrightarrow 2R\text{–}ZnE_2CNR'_2 \quad (24)$$
$$E = O, S, Se$$

3.3.2 Structure

Alkylzinc thiolate compounds are insoluble or poorly soluble in hydrocarbon solvents, indicating their tendency to form aggregates. Indeed, all the compounds that have been structurally characterized obey the empirical formula $(RZnSR')_n$ with values of *n* varying from 2 to 10. As shown in Figure 38, these species reveal a remarkable structural chemistry.[158] The dimeric complex $(Me_3SiCH_2ZnSCPh_3)_2$ possesses a planar Zn_2S_2 array with trigonal planar zinc atoms and trigonal pyramidal sulfur centers. The core of the trimers $[Me_3SiCH_2ZnS\text{-}i\text{-}Pr_3C_6H_2]_3$ and $[Me_3SiCH_2ZnS\text{-}t\text{-}Bu_3C_6H_2]_3$ consists of an almost planar six-membered Zn_3S_3 ring, suggesting that the six nonbonded electron pairs of the sulfur atoms tend to delocalize (*see Delocalized Bonding*). More complicated arrays are found in the solid-state structure of the pentamer $[MeZn(S\text{-}t\text{-}Bu)]_5$[162] and the octamer $[MeZn(S\text{-}i\text{-}Pr)]_8$.[163] Interestingly, the octameric aggregation of the last compound is not retained in benzene solution where hexamers are observed. Finally, a wurtzite-like structure has been found for the decamer $[EtZn(SEt)]_{10}$.[159] The pentamer $[MeZn(S\text{-}t\text{-}Bu)]_5$ readily reacts with nitrogenous bases like pyridine and 1,3,5-trimethylhexahydro-1,3,5-triazine to form stable adducts of the dimeric species,[164] which, in contrast to the parent oligomers, present a good solubility in organic solvents. A selection of average bond lengths in organozinc compounds containing a zinc–sulfur bond can be found in Table 10.

Recently, some mononuclear alkylzinc complexes containing a zinc–sulfur bond could be prepared and structurally

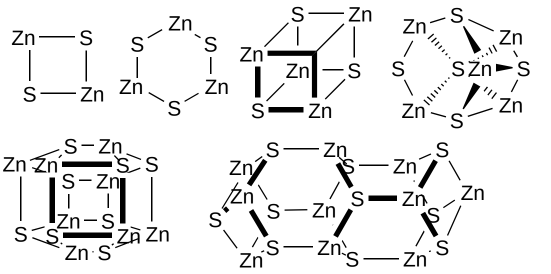

Figure 38 Structure of the $[RZn(SR')]_n$ cores that have been structurally characterized

Table 10 Average bond lengths for some structurally characterized organozinc compounds containing a zinc–sulfur bond

Compound	Zn–C (Å)	Zn–S (Å)	C–S (Å)

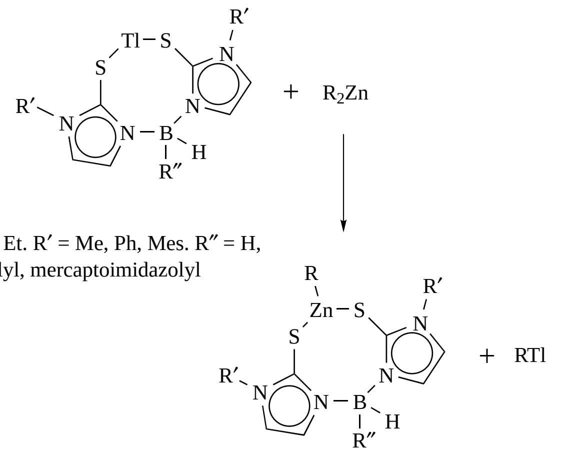
^{a}TImz = mercaptoimidazolyl; Imz = imidazolyl. Data taken from *The CSD System*[128] using *ConQuest*.[129]

characterized using the monoanionic bis- and tris (mercaptoimidazolyl)hydroborate ligands[165,166] (Figure 39). Their preparation follows the metathesis reaction between the corresponding thallium complexes and dimethylzinc (equation 25). The complexes with tridentate ligands show a classic pseudotetrahedral coordination geometry around the zinc atom, but an interesting feature is found in the solid-state structure of the bis(mercaptoimidazolyl)hydroborate derivative, that is, the presence of a 'boat like' eight-membered ring that allows for intramolecular (*see Intramolecular*) interaction between the zinc atom and one BH ligand (d Zn···B = 2.88 Å; d Zn···H = 1.77 Å). The compounds are strictly monomeric in the solid state but undergo redistribution reactions in solution to give the homoleptic (*see Homoleptic Compound*) species L_2Zn. In contrast, a monomeric solid-state structure which subsists in solution has been found for [MeZn(PATH)] (PATH = 2-methyl-1-[methyl-(2-pyridin-2-ylethyl)amino]propane-2-thiolate) (Figure 40). This complex is a valuable synthetic precursor to other complexes that are good models for the catalytic site of metalloenzymes.[153]



R = Me, Et. R′ = Me, Ph, Mes. R″ = H, Imidazolyl, mercaptoimidazolyl

(25)

So far, the only alkylzinc selenolate compound to be structurally characterized is the trimeric [Me_3SiCH_2ZnSe-2,4,6-*t*-$Bu_3C_6H_2$]$_3$. In contrast with the parent compound [Me_3SiCH_2ZnS-2,4,6-*t*-$Bu_3C_6H_2$]$_3$, the central Zn_3Se_3 possesses a twist structure with more pyramidal geometries at selenium.[167] However, it is worth mentioning that various diselenolato- and ditellurolatozinc compounds have been prepared and their adducts with nitrogenous bases such as TMEDA and pyridine could be structurally characterized.[168–170] Furthermore, the reaction of sterically hindered chalcogenolato compounds $[Zn(EAr^*)_2]_2$ (E = S, Se; Ar* = 2, 4, 6-*t*-$Bu_3C_6H_2$) with excess tert-butylisocyanide gave the first examples of well-characterized isocyanide complexes of zinc $Zn(EAr^*)_2$(CN-*t*-Bu)$_2$.[171]

Alkylzinc thio- and selenocarbamate derivatives are commonly air-sensitive white crystalline solids, with the thiocarbamate derivatives being more soluble in organic solvents than the selenocarbamate derivatives. They have been found to be dimers of general formula $[RZnE_2CNR'_2]_2$, in which each carbamate chelates one metal atom and bridges to the next one (Figure 41). The zinc atoms are four-coordinate with a distorted tetrahedral geometry.

Two new bonding modes have been found for the monothiocarbamato ligand in the novel tetrameric complex $[Et_4Zn_4(OSCNEt_2)_2(NEt_2)_2]$, which was prepared by reaction of $EtZnNEt_2$ with carbonyl sulfide.[172] The cage compound contains two six-membered Zn_2CNOS cycles and both the oxygen and sulfur are binucleating (Figure 42).

3.4 Organozinc Compounds Containing a Zinc–Nitrogen Bond

In recent years, the interest for the preparation of alkylzinc amides has been motivated by their potential application as catalyst for polymerization of propylene oxide, and also as precursors for the MOCVD (*see Metal–Organic Chemical Vapor Deposition*) process.

3.4.1 Preparation

Even though zincation of secondary amines was already studied by Frankland in 1856 and 1867, it is only in the past few decades that some efforts were made to isolate and characterize the products. Numerous compounds of the type $RZnNR'_2$ or $Zn(NR'_2)_2$ can now be prepared using two principal procedures, namely the zincation of amines with simple dialkylzinc compounds[173–175] (equation 26) and the metathesis reaction of alkali metal amides with anhydrous zinc dihalide (equation 27).

$$R'_2NH + R_2Zn \longrightarrow R'_2N\text{–}Zn\text{–}R + RH \qquad (26)$$

$$R'_2NLi + RZnX \longrightarrow R'_2N\text{–}Zn\text{–}R + LiX \qquad (27)$$

The first step of the zincation route is the formation of an adduct between the amine and the dialkylzinc compound. Such a complex can rarely be isolated since one of the Zn–C bonds readily suffers protonolysis. Mechanistic studies of the

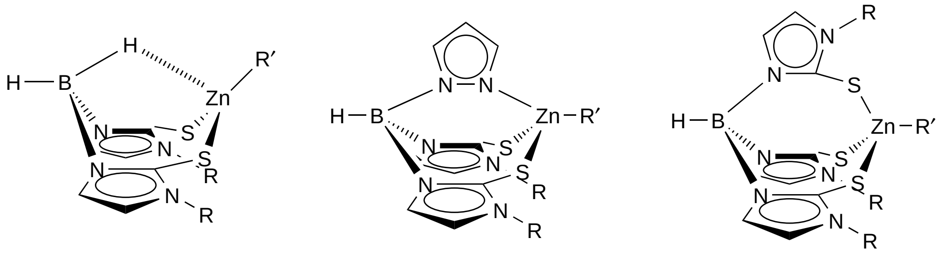


Figure 39 Zinc alkyls stabilized by (mercaptoimidazolyl)hydroborato ligands

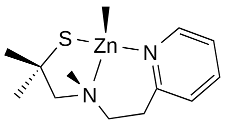

Figure 40 Structure of MeZn(PATH)

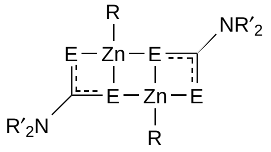

Figure 41 Dimeric organozinc thio- and selenocarbamates. E = S, Se

protonolysis step in the reaction of various dialkylzinc compounds with cyclohexylamine and *p*-toluidine, have shown an S_E1 mechanism.[176] The reaction can easily be stopped at the mono substitution product because the remaining C–Zn bond is far less reactive than in the parent dialkylzinc compounds.

A very fast reaction occurs between dialkylzinc compounds and the more acidic amide and thioamide derivatives of the

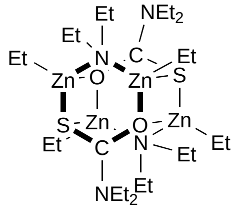

Figure 42 Structure of $Et_4Zn_4(OSCNEt_2)_2(NEt_2)_2$

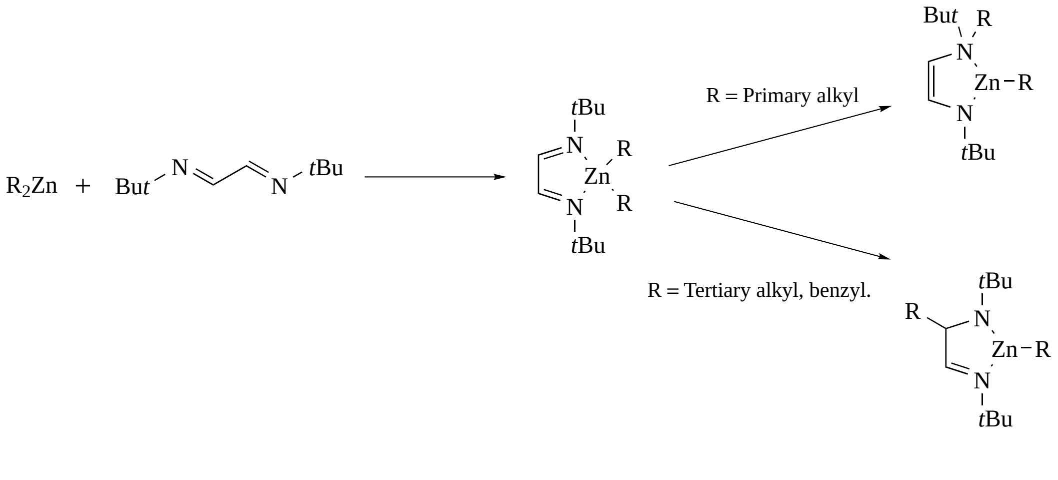
type HNPhCXR′ (X = O or S), leading to RZnNPhCXR′ complexes. An alternative route for the preparation of such compounds is the insertion reaction (*see Insertion*) of iso- and isothio-cyanates into the Zn–O and Zn–N bond of monosubstituted organozinc derivatives[161] (equations 28 and 29).

$$\text{R–Zn–OR}' + \text{R}''\text{NCX} \longrightarrow \text{R–Zn–NR}''\text{C(X)OR}' \quad (28)$$

$$\text{R–Zn–NR}'_2 + \text{R}''\text{NCX} \longrightarrow \text{R–Zn–NR}''\text{C(X)NR}'_2 \quad (29)$$

Some heteroleptic (*see Heteroleptic Compound*) alkylzinc amides have been prepared by addition reaction of dialkylzinc compounds (ZnR_2) on 1,4-di-*tert*-butyl-1,4-diaza-1,3-butadiene (*t*-BuN=CHCH=N-*t*-Bu). Extensive studies[177,178]



Scheme 8

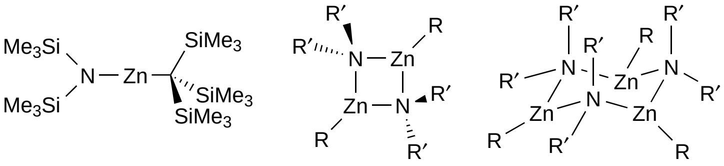


Figure 43 Structure of $(R'_2NZnR)_n$

have shown that the addition is regioselective (*see Regioselectivity*) to the *N*-alkylated product RZn(*t*-BuN(R)CH=CHN-*t*-Bu) when R is a primary alkyl group, and to the *C*-alkylated product RZn(*t*-BuNCH(R)CH=N-*t*-Bu) when R is a tertiary or benzylic alkyl group (Scheme 8). The reaction probably follows a radical mechanism subsequent to the initial formation of the coordination complex R_2Zn·(*t*-BuN=CHCH=N-*t*-Bu).

Very recently, the preparation of zinc β-diiminate derivatives became the subject of interest due to their catalytic activity in the copolymerization of CO_2 with epoxides.[179–181] They can be prepared in high yields by direct reaction of the corresponding β-diimines with dialkylzinc compounds or by treatment of the β-diimine-lithium salts with zinc halide followed by an alkylation reaction (Scheme 9).

3.4.2 Structure

Nitrogen has only one nonbonding electron pair (*see Lone Pair*); consequently, alkylzinc amide compounds generally do not form the typical cubic structure found with alkylzinc alkoxide derivatives. Various alkylzinc amides derived from secondary amines and few derived from primary amines have been structurally characterized. Depending on the steric demand (*see Steric Effect*) of the substituents at both the zinc and the nitrogen atom different degrees of association are observed in solid state. For example, the highly sterically hindered $(Me_3Si)_3CZn$–N(H)Si-*i*-Pr_3 and $(Me_3Si)_3CZn$–$N(SiMe_3)_2$ exist as monomers[182] with an almost linear C–Zn–N center for the latter. Dimers with a central planar four-membered ring are formed with less bulky primary amines such as 2,4,6-trimethylaniline, 2,6-diisopropylaniline or triisopropylsilylamine[174] (Figure 43). This coordination mode is also typical for alkylzinc dialkylamide compounds. Trimers with a chair-shaped Zn_3N_3 ring are obtained in the reaction of dimethyl- or diethylzinc with *tert*-butylamine and naphtylamine.[175] The unusual structure observed in the dimeric compound $\{(\eta^1\text{-Cp})Zn\}_2(\mu\text{-Cp})\{\mu\text{-N}(SiMe_3)_2\}$, readily prepared by combining Cp_2Zn and $Zn[N(SiMe_3)_2]_2$ in hot benzene, has already been mentioned in Section 2.3.3[54] (Figure 12). Table 11 lists some selected bond lengths found in organozinc compounds containing a Zn–N bond.

Finally, as a result of intra- or intermolecular (*see Intermolecular*) coordination, a large variety of association modes is observed when the amine residue contains electron-donating atoms in appropriate position. Two extremely rare examples of monomeric three-coordinate zinc complexes have been obtained by the reaction of R_2Zn (R = Me, Et) with *N*-(2-diphenylphosphinophenyl)-2,6-diisopropylaniline in Et_2O at – 35 °C.[183] As shown in Figure 44, the molecular

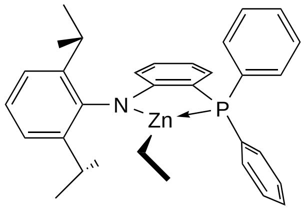

Figure 44 Structure of EtZn{*N*-(2-diphenylphosphinophenyl)-2, 6-diisopropylanilide}

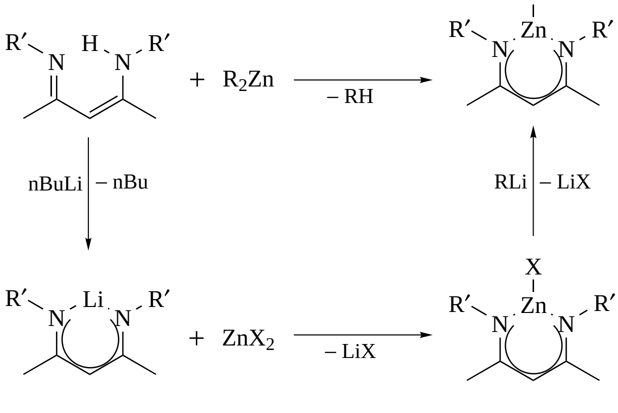
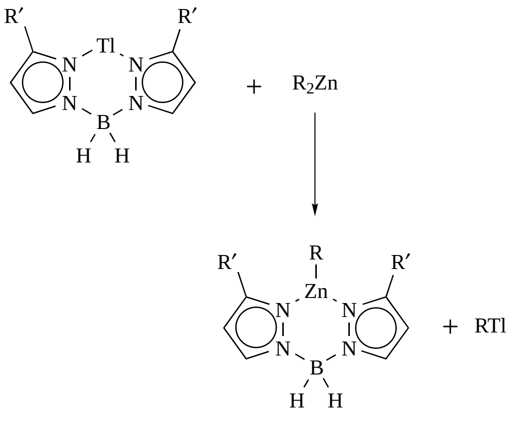


Scheme 9

structure of the ethyl derivative, determined by X-ray analysis, indicates a trigonal planar geometry at zinc (sum of the bond angles = 359.81°) and typical distances for the three different bonds Zn–C (1.956 Å), Zn–P (2.445 Å), and Zn–N (1.911 Å). The compounds were found to be highly sensitive towards hydrolysis, but thermally very stable under inert atmosphere as they do not show decomposition after three days at 100 °C in toluene.

The reaction of N,N,N'-trimethylethylene- or propylenediamine ($HNMe(CH_2)_nNMe_2$; $n = 2$ or 3) with dimethyl- or diethylzinc gives dimeric molecular units of general formula $[RZnNMe(CH_2)_nNMe_2]_2$ (Figure 45). A central four-membered ring is formed with bridging nitrogen atoms and two five- or six-membered side rings are respectively produced by intramolecular (*see Intramolecular*) coordination of the amino group.[184]

Bis- and tris(pyrazolyl)borato ligands have been widely used to stabilize a variety of alkylmetal complexes among which several alkylzinc derivatives.[185] Stable monomeric three-coordinate alkylzinc complexes, $\{\eta^2\text{-}H_2B(3\text{-}t\text{-}Bupz)_2\}ZnR$, could be prepared by reaction of R_2Zn with the thallium derivative $Tl\{\eta^2\text{-}H_2B(3\text{-}t\text{-}Bupz)_2\}$ (equation 30). In these complexes, both the B–H and the Zn–C bonds are potential reactive sites; while ketones and aldehydes react at the former, protic reagents react at the subsequent.[186] The tris(pyrazolyl)hydroborato ligand allowed the formation of monomeric four-coordinate zinc alkyl derivatives.[187] A comparison with analogous magnesium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***) complexes has shown that the Mg–C bond in these systems is more reactive than the related Zn–C bond, especially with respect to CO_2 insertion (*see Insertion*).



(30)

Although the cubic structure with a Zn_4N_4 core is not as common as with alkoxy-zinc derivatives, it was recurrently found in tetrameric organozinc phosphoraneiminato complexes $[RZn(NPR'_3)]_4$. Several compounds with different R and R′ groups (R′ = Me, Et; R = Me, n-Bu, C≡CR″) were prepared in good yields by the reaction of $[BrZn(NPR'_3)]_4$ with the corresponding organolithium reagent in hexane[188,189]

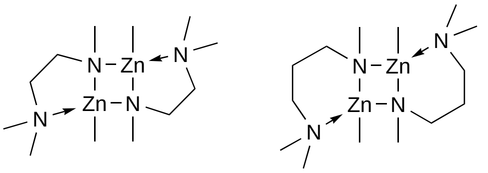


Figure 45 Intramolecular coordination in $[RZnNMe(CH_2)_nNMe_2]_2$ ($n = 2, 3$)

(equation 31). All the complexes that have been characterized by X-ray crystallography present a heterocubane Zn_4N_4 structure – only slightly distorted from the cube – where the zinc atoms are linked via μ^3-N bridges of the phosphoraneiminato groups. In the Zn_4N_4 frame, all the bond angles are close to 90° and the Zn–N bond distances have an average value of 2.07 Å (Figure 46).

3.5 Alkylzinc Compounds Containing a Zinc–Phosphorus or Zinc–Arsenic Bond

3.5.1 Preparation

Some interest in group 12 phosphide and arsenide complexes has come from their possible applications as precursors for II/V semiconductors (*see* ***Semiconductors***). They can be prepared by two different ways, namely, by metallation reaction of phosphines and arsines with diorganozinc compounds (equation 32), and by transmetallation reaction between organozinc halides and lithium salt of the corresponding phosphines and arsines (equation 33).

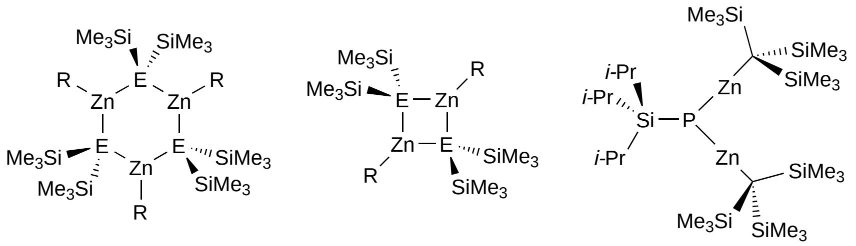

Figure 47 Structure of $(RZnER'_2)_n$ (E = P, As) and $[(Me_3Si)_3CZn]_2$ PSi-*i*-Pr_3

3.5.2 Structure

So far only few compounds of this family have been structurally characterized. The nonbonding electron pair present on the group 15 atom leads to intermolecular (*see Intermolecular*) associations similar to those observed in organozinc amides. The degree of association is controlled by the steric demand of the substituents at the zinc atom. For example, in solid state the general compound $RZn[E(SiMe_3)_2]$ (E = P or As) can form trimers[190,191] with a central cyclic Zn_3E_3 core in a twist-boat conformation (E = P, R = Me, Et, n-Butyl; E = As, R = Me, Et) or dimers[192,193] with a central planar Zn_2E_2 ring (E = P, R = CH_2SiMe_3) (Figure 47). An intermediate position is found with *i*-$PrZnP(SiMe_3)_2$ which shows in solution a temperature-dependent equilibrium of dimeric and trimeric species, and gives a 1:1 mixture of these two oligomers in crystalline state.[194] So far, the only compound found to be monomeric both in crystalline state and in solution, is the binuclear bis[tris(trimethylsylil)methylzinc]triisopropylsilylphosphandiide {$[(Me_3Si)_3CZn]_2PSi$-*i*-Pr_3} obtain in the reaction of tris(trimethylsilyl)methylzinc chloride with lithium triisopropylsilylphospanide (equation 34). The crystalline structure of this compound shows a very short zinc–phosphorus bond of 2.23 Å, owing to the low-coordination state of the phosphorus and zinc atoms.[195]

$$2(Me_3Si)_3CZn\text{–}Cl + 2Li\text{–}P(H)Si\text{-}i\text{-}Pr_3 \longrightarrow i\text{-}Pr_3SiP[ZnC(SiMe_3)_3]_2 + 2LiCl + H_2PSi\text{-}i\text{-}Pr_3 \qquad (34)$$

A series of compounds with general formula $[RMAs(t\text{-}Bu)_2]_n$ (R = Me, *t*-Bu; M = Zn, Cd, Hg) has been studied and it was found that their stability decreases in the order Zn > Cd ≫ Hg. Table 12 summarizes some representative average bond distances and bond angles found in organozinc compounds containing a phosphorus–or arsenic–zinc bond.

3.6 Alkylzinc Compounds Containing a Zinc-metal Bond

A number of compounds having a direct zinc transition metal bond are known for long time, that is, zinc-bis(transition metal) such as $Zn[Co(CO_4)]_2$[196] and transition metal zinc halides such as $(CO)_4Fe(ZnCl)_2$.[197] However, organozinc-transition metal compounds RZn–TM are comparatively more recent. They can be prepared by hydrocarbon elimination between a diorganozinc derivative and a transition metal hydride[198] (*see Hydrides*) (equation 35), but dialkyl- and diarylzinc compounds usually fail to react or react very slowly. Furthermore, when they do react they give unstable products that show a very strong tendency to disproportionate and cannot be isolated[199] (equation 36).

$$L_xMH + R_2Zn \longrightarrow L_xM\text{–}ZnR + RH \qquad (35)$$

$$L_xM\text{–}ZnR \longrightarrow \tfrac{1}{2}R_2Zn + \tfrac{1}{2}[L_xM]_2Zn \qquad (36)$$

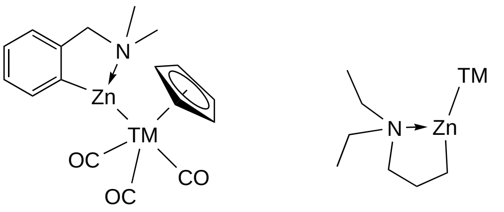
TM = Ta, Nb. R = H, Me.

Figure 48 Structure $Cp_2TMH_{3-n}(ZnCp)_n$ ($n = 1, 2, 3$)

However, it has been shown that Cp_2Zn is more reactive with transition metal hydrides (*see Hydrides*) and leads to more stable compounds. A number of complexes with different transition metals have been isolated by this route; these include derivatives of nickel (e.g. $Cp_6Ni_2Zn_4$),[200] manganese (e.g. $CpZnMn(CO)_5$),[201] rhodium (e.g. $[(dippp)Rh]_2(\mu\text{-}H)_2(\mu\text{-}ZnCp)_2$),[202] tantalum (e.g. $Cp'_2TaH_{3-n}(ZnCp)_n$, $n = 1, 2, 3$)[203] and niobium $Cp_2NbH_{3-n}(ZnCp)_n$, ($n = 1, 2$).[204] The greater reactivity of Cp_2Zn can be appreciated in its stoichiometric reaction with Cp_2NbH_3, which gives the disubstituted $Cp_2NbH(ZnCp)_2$ as the only product. The isolation of Cp_2NbH_2ZnCp requires the use of a coordinating solvent like THF to decrease the reactivity of Cp_2Zn. This last compound and the related $Cp'_2TaH(ZnCp)_2$ (Cp' = methylcyclopentadienyl) have been structurally characterized, they resemble the parent molecule Cp_2NbH_3 and Cp'_2TaH_3 with one or two hydrogens replaced by one or two ZnCp groups, respectively (Figure 48).

Stable organozinc transition metal compounds can also be obtained when the alkyl group bound to zinc is a chelating ligand (*see Chelating Ligands*) such as the (dimethylamino)propyl group $[Me_2N(CH_2)_3]$ or the 2-[(dimethylamino)methyl]penyl group $(2\text{-}C_6H_4CH_2NMe_2)$ (Figure 49). A number of complexes with different transition metals have been isolated; that is, manganese, cobalt, molybdenum, and tungsten.[59] The crystal structure of $Me_2N(CH_2)_3ZnW(Cp)(CO)_3$, determined by X-ray crystallography, shows a tricoordinate zinc atom with a zinc–tungsten bond distance of 2.685 Å.



TM = Mo, W.

TM = $Mn(CO)_5$, $Co(CO)_4$, $CpMo(CO)_3$, $CpW(CO)_3$.

Figure 49 Intramolecular coordination in organozinc transition metal compounds

Organozinc compounds containing a zinc main-group metal bond are extremely rare. With the exception of compounds containing zinc–zinc and zinc–nickel bonds such as the clusters (*see Cluster*) $Cp'_6Ni_2Zn_4$ ($Cp'_6 = Cp_6$;[200] $Cp^*_2Cp_4$;[205] $(Me_3SiC_5H_3)_6$[206]), only few zincate derivatives (see Section 4.1) containing weak contacts between zinc and different metals such as Ba,[207] Li,[208] or Na have been structurally characterized (Figure 50).

It is also worth mentioning here that two compounds containing a Zn–Sn coordinate bond have been reported. The first of these is the sole example of a dialkyltin^{II} species (*see **Tin: Organometallic Chemistry***) stabilized by coordination to zinc-β-diketonate. It was obtained by reaction of bis[3-dimethylamino)propyl]zinc with bis(dibenzoylmethanato)tin (equation 37) and its molecular structure shows a Zn–Sn bond length of 2.634 Å.[209] The second compound is

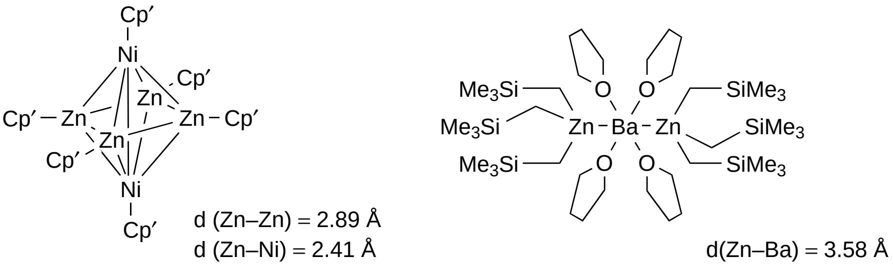


Figure 50 Organozinc compounds containing Zn main-group metal bond

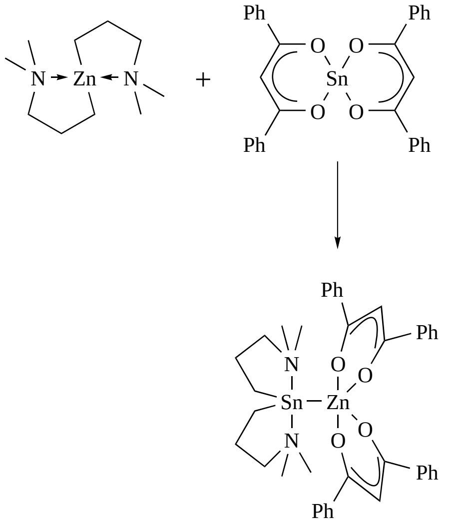
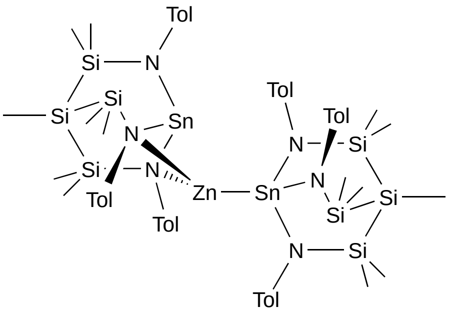
the heterodimetallic complex $[MeSi\{SiMe_2N(Tol)\}_3Sn]_2Zn$ (Tol = *p*-toluyl), which was recently prepared together with the Cd and Hg derivatives, by reaction of $[MeSi\{SiMe_2N(p\text{-}Tol)\}_3SnLi(OEt_2)]$ with the corresponding MCl_2 (M = Zn, Cd, Hg).[210] As shown in Figure 51, its molecular structure is unsymmetrical with only one stannate unit bound to zinc (d(Zn–Sn) = 2.578 Å).



(37)



d (Zn–Sn) = 2.578 Å

4 ALKYLZINC ANIONS AND CATIONS

4.1 Alkylzinc anions (*See Anion*)

The alkylzinc anions, defined as ate complexes (*see Ate Complexes*), are heterodimetallic systems which can be divided in two different classes, namely, the trialkylzincates of general formula $M^+R_3Zn^-$ and the tetraalkylzincates of general formula $M^{2+}R_4Zn^{2-}$. The first zincate derivatives, that is, $NaZnEt_3$ and $KZnEt_3$, were prepared by Wanklyn in 1858 from the reaction of metallic sodium or potassium with diethylzinc[211] (equation 38). In spite of this early discovery, many of the efforts to study this class of compounds are very recent. Today these heterodimetallic compounds are of great interest for inorganic and organic chemists because they show a unique reactivity and selectivity, different from those of either parent single-metal species. For example, they are known to achieve 1,4-conjugate addition to α,β-unsaturated ketones,[212] to metalate aromatic halide or vinyl halides,[213–215] and to reduce various carbonyl compounds.[216–218]

$$R_2Zn + \frac{2}{3}M \longrightarrow \frac{2}{3}R_3ZnM + \frac{1}{3}Zn \qquad (38)$$

M = Alkali metal

4.1.1 *Preparation*

Homoleptic (*see Homoleptic Compound*) triorganylzincates are readily prepared via the route originally used by Wanklyn, that is, the reaction of a metal with a dialkylzinc compound (equation 38). This reaction presents the advantage to avoid the incorporation of halide or pseudohalide (*see Pseudohalide*) in the products. When alkali metals (*see **Alkali Metals: Organometallic Chemistry***) are used without solvent or in hydrocarbon solvent, the homoleptic $MZnR_3$ species ($R = CH_2CMe_3, CH_2SiMe_3$; M = Na, K) are obtained in good yield.[219] In contrast, the reaction in benzene solution produces the heteroleptic (*see Heteroleptic Compound*) $MZnPhR_2$ resulting from the metallation of benzene[220] (equation 39).

$$R_3ZnM + C_6H_6 \longrightarrow R_2PhZnM + RH \qquad (39)$$

M = Alkali metal

Early studies of the reaction between diorganozinc compounds and alkaline earth metals (*see **Alkaline Earth Metals: Organometallic Chemistry***) (Ca, Sr, Ba) were reported to give complexes with general formula $R_2M{\cdot}R_2Zn$.[221] Subsequent investigations of these complexes in solution using NMR, cryoscopy and UV techniques, have shown the existence of a complex equilibrium (Scheme 10) and also suggested a tetrahedral structure for the $ZnR_4{}^{2-}$ ion.[222] While ionic species are favored in donor solvents, the free alkyl compounds and the contact ion pair $M^{2+}ZnR_4{}^{2-}$ are favored in nonpolar (*see Polar Compounds*) solvents. Recently, barium and strontium bis{tris[(trimethylsilyl)methyl]zincates}have been prepared by this route.[207]

A different approach was used to prepare the magnesium derivative $[Mg^{2+}(THF)_6][(PhCH_2)_3Zn^-]_2$, that is the addition of $(PhCH_2)_2Mg$ to a THF solution of $(PhCH_2)_2Zn$ in a 1:2 molar ratio (equation 40). It is interesting to note that the 1:1 molar ratio reaction produces the same compound with an equimolar amount of $(PhCH_2)_2Mg$ that remains in solution.[223]

$$1(PhCH_2)_2Mg{\cdot}(THF)_2 + 2(PhCH_2)_2Zn \longrightarrow Mg(THF)_6[Zn(CH_2Ph)_3]_2 \qquad (40)$$

Homo- and heteroleptic (*see Heteroleptic Compound*) triorganozincates can also be prepared by reacting an

$$MR_2 + R_2Zn \rightleftharpoons MZnR_4 \rightleftharpoons M^{2+}ZnR_4^{2-} \rightleftharpoons M^{2+}(S)ZnR_4^{2-}(S) \rightleftharpoons M^{2+} + Zn\,R_4^{2-}$$

I II III IV V

M = Akaline earth metal, I = Free alkyl compounds, II = ate complex, III = contact ion pair, IV = solvated contact ion pair, V = free ions.

Scheme 10

organometallic reagent RM (M = Li, Na; R = alkyl, dialkylamide) with a diorganozinc compound ZnR'_2 (R′ = alkyl, dialkylamide) (equation 41). When the substituents are bulky, then potentially intramolecular coordinating groups (2-$C_6H_4CH_2NMe_2$) or the presence of a strong coordinating agent (TMEDA or crown ethers) appear necessary to isolate the trialkylzincate and prevent its dissociation into dialkylzinc and the organometallic reagent.[224–226] On the other hand, it was shown that addition of TMEDA to a solution of the zincate $[(THF)_6Mg][Zn(CH_2Ph)_3]$ leads to its decomposition in the corresponding dialkylzinc and dialkylmagnesium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***) species.[227] Dialkyl(hydro)zincates ($MZnHR_2$; M = Li, Na) have been obtained in situ (*see In Situ Reaction*) when lithium hydride (*see Hydrides*) LiH or sodium hydride NaH was reacted with a diorganozinc compound in a 1:1 molar ratio.[216]

$$RM + R'_2Zn \longrightarrow MZnR'_2R \quad (41)$$
R, R′ = H, alkyl, dialkylamide; M = Li, Na

Trialkylzincate compounds exhibit an sp^2 hybridized (*see Hybridization*) zinc atom having 16 electrons in his outer shell; consequently, an empty valence orbital (*see Valence Orbitals*) remains available at the zinc atom for coordination of a fourth ligand to reach the 18-electron state (*see Eighteen Electron Compounds*). Thus, tetraalkylzincates ($M_2{}^{2+}R_4Zn^{2-}$) are usually obtained directly when organometallic reagents (MR; M = Li, Na, MgX) are reacted with dialkylzinc (R_2Zn) compounds in a 2:1 molar ratio (equation 42), as well as in direct reaction of four equivalents of an organometallic reagent with zinc dihalides (ZnX_2) (equation 43).[228] The first reaction allows the synthesis of heteroleptic tetraalkylorganozincates of general formula $M_2{}^{2+}\ (ZnR_nR'_{4-n})^{2-}$ ($n = 1$ to 3; R and R′ = alkyl, R′ ≠R; $M_2{}^{2+} = 2Li^+$, $2Na^+$, Mg^{2+}) by conveniently choosing the diorganozinc and organometallic species.

$$2RM + R'_2Zn \longrightarrow M_2ZnR'_2R_2 \quad (42)$$
R, R′ = alkyl, dialkylamide; M = Li, Na

$$4RM + ZnX_2 \longrightarrow M_2ZnR_4 + 2MX \quad (43)$$
R, R′ = alkyl, dialkylamide; M = Li, Na

It is interesting to note that the readily available dilithium teramethylzincate was found to react with trimethylsilyl cyanide (Me_3SiCN) or trimethylsilylisothiocyanate (Me_3SiSCN) to give the corresponding modified zincates $Me_3Zn(CN)Li_2$ and $Me_3Zn(SCN)Li_2$[229] (equation 44).

$$Li_2ZnMe_4 + Me_3SiR' \longrightarrow Li_2ZnMe_3R' + Me_4Si \quad (44)$$
R′ = CN, SCN

Finally, zincate complexes of general formula $M_nZn_m R_{2m+n}$ react with $LiAlH_4$ or $NaAlH_4$ in ethereal solvents to give complex metal hydrides of zinc with composition $M_nZn_mH_{2m+n}$[230,231] (M = Li, Na, K; $n = 1$ to 3; $m = 1$ or 2).

4.1.2 Structure

Zincate complexes are colorless, air- and moisture-sensitive solids; indeed the low-molecular species are pyrophoric on contact with air and react explosively with water. However, they are usually stable at room temperature when stored under a nitrogen atmosphere.

On the basis of conductivity studies, it was shown that $NaZnEt_3$ possesses a salt-like character, $Na^+\ [Et_3Zn]^-$. The X-ray structure determinations of higher molecular weight compounds $MZnR_3$ (R = CH_2Ph, M = Mg; R = CH_2SiMe_3, M = K; R = CH_2-*t*-Bu, M = Na, K; R = C≡CPh, M = Na) revealed that the metal cation is separated from the zinc center of the counterion.[219,220,223,232] All the trialkylzincates cited before have in common a ZnC_3 core in which the zinc atom is three-coordinate with an almost trigonal planar geometry (Figure 52).

A rather different situation was found in the solid-state structure of the heavier metal group 2 (*see* ***Alkaline Earth Metals: Organometallic Chemistry***) complexes[225,233] $[M{\cdot}(THF)_n]\{Zn[(CH_2SiMe_3)_3]\}_2$ (M = Sr, $n = 2$; M = Ba, $n = 4$). As shown in Figure 52, the trialkylzincate anions coordinate the metal cation like bidentate ligands (*see Bidentate Ligand*), via M–C–Zn three-center, two-electron bonds (*see Three-center Bond*), forming two four- membered MC_2Zn rings. Under application of ultrasound (*see Sonication*) in heptane, the barium derivative further reacts with additional barium metal to form a dimeric alkyldibariumtriszincate with a tetraanionic triszincate ligand and a unique $Ba_4Zn_2C_6$ core shown in Figure 53.

When the trialkylzincate contains suitably placed donor atoms, then intramolecular (*see Intramolecular*) coordination occurs. For example, the molecular structure of the complex

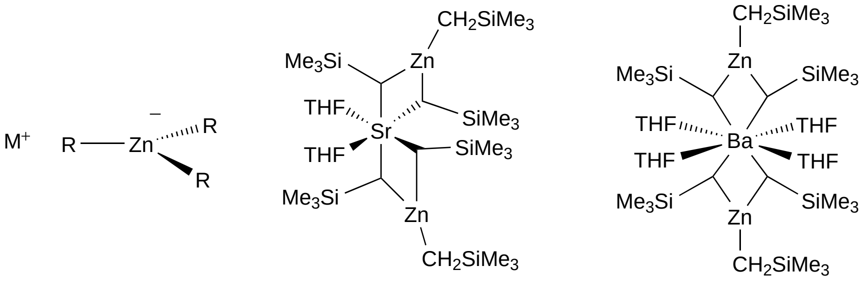

Figure 52 Structure of some triorganozincate compounds

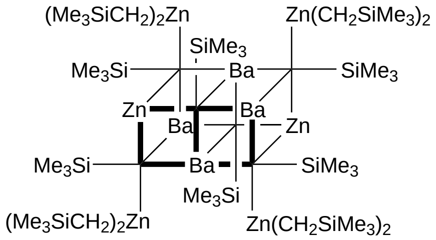

Figure 53 Structure of the $Ba_4Zn_2C_6$ in the dimeric alkyldibarium-triszincate

$(2\text{-}Me_2NCH_2C_6H_4)_3ZnLi{\cdot}THF$ exhibits a four-coordinated zinc center with a distorted tetrahedral geometry, resulting from intramolecular coordination of an amino group.[224]

Comparatively few tetraalkylzincates have been structurally characterized. The crystal structure of Me_4ZnLi_2 and Me_4ZnK_2, determined from X-ray powder diffraction studies, shows isolated $[Me_4Zn]^{2-}$ units with a four-coordinate zinc center in a tetrahedral arrangement.[234] A series of metallacyclopentane compounds of the type $[LiL_x]_2Zn[\text{-}(CHR)_4\text{-}]_2$ (R = H, Me; L = TMEDA, THF; x = 1, 2) have been prepared by treating $ZnCl_2$ with the corresponding dilithium compounds $Li(CHR)_4Li$ in diethyl ether.[208] These compounds were found to be thermally very stable. As shown in Figure 54, the structure of $[Li(TMEDA)]_2Zn[(CH_2)_4]_2$ determined by X-ray crystallography, contains a central ZnC_4 core with distorted tetrahedral geometry, which is connected to each of the two Li·TMEDA rests via two bridging carbon atoms. It is worth mentioning that the average distance Zn–Li (2.42 Å) in this complex is comparable with the sum of their covalence radii (2.48 Å). A similar structure has been found for the related $[Li(TMEDA)]_2Zn[(CH_2SiMe_2)_2]_2$ containing silicon atoms in the metallacyclopentane rings.[235]

Even if the solid-state structures known so far exhibit separated ions, the nature of the different species in solution is not yet certain. The ^1H and ^7Li NMR studies of methyllithium mixed with dimethylzinc (and dimethylmagnesium) in ether solutions have shown that complex species such as $Li_2Zn(CH_3)_4$ and $Li_3Zn(CH_3)_5$ are formed, and no 1:1 complex was observed.[236] Furthermore, other studies (conductivity, cryoscopy, NMR and UV spectroscopy) of ethyllithium solutions in diethylzinc and $MZnEt_4$ solutions (M = Ca, Ba, Sr) have shown the existence of complicated exchange equilibria between various species.

Finally, mixing toluene solutions of potassium *tert*-butoxide (*t*-BuOK) and diethylzinc results in the formation of the zincate $[Et_2Zn(O\text{-}t\text{-}Bu)]^-K^+$ (equation 45). An X-ray diffraction study of the compound reveals a dimeric structure, $(2K^+)$ $[Et_2Zn(\mu\text{-}O\text{-}t\text{-}Bu)_2ZnEt_2]^{2-}$, containing a four-membered Zn_2O_4 ring[237] (Figure 55). This Zn_4O_4 core is somewhat similar to that found for the neutral alkylzinc alkoxide $[EtZn(O\text{-}2,4,6\text{-}t\text{-}Bu_3\text{–}C_6H_2)]_2$, but with longer zinc–carbon bonds ($d(Zn\text{–}C)_{\text{neutral complex}} = 1.99$ and 1,95 Å, $d(Zn\text{–}C)_{\text{zincate complex}} = 2.07$ Å).

$$Et_2Zn + t\text{-}BuOK \longrightarrow [Et_2Zn(\mu\text{-}t\text{-}BuO)_2ZnEt_2]^{2-}2K^+ \quad (45)$$

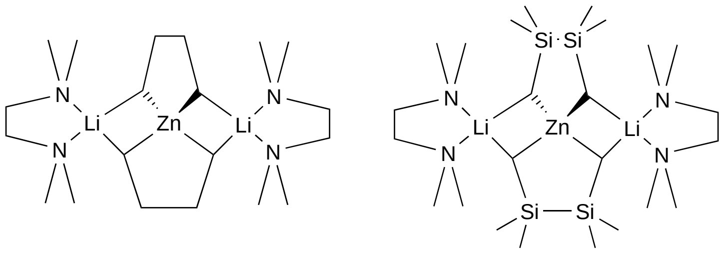

Figure 54 Structure of $[Li(TMEDA)]_2Zn[(CH_2)_4]_2$ and $[Li(TMEDA)]_2Zn[(CH_2SiMe_2)_2]_2$

4.2 Alkylzinc Cations (*See Cation*)

4.2.1 Preparation

In contrast to organomagnesium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***) compounds, dialkylzinc derivatives do not disproportionate in coordinated zincate anions and organozinc cations under addition of cryptand (*see Cryptands & Cryptates*) or crown ether (*see Crown Ethers*). However, it was shown by NMR spectroscopy that both organozinc anion and cation are formed in benzene solution when equimolar amounts of diethylzinc, diphenylzinc and a cryptand (*see Cryptands & Cryptates*) N_4-aza crown (N_4-aza crown = 1,4,8,11-teramethyl-1,4,8,11-teraazacyclotetradecane) were mixed[238] (equation 46). Furthermore, if triethylaluminum (a more effective R^- acceptor than R_2Zn) was used instead of diphenyl zinc, then the complex $[EtZn(C)]^+$ $(Et_4Al)^-$ (C = crown ether, N_4-aza crown) separated as a dense liquid phase (equation 47). Some recent studies have extended this reaction to organozinc halide and alkoxide derivatives, and also verified that the formation of ionic species is favored by nitrogen-containing macrocycles[239–241] (*see* ***Macrocyclic Ligands***). A series of ethylzinc cationic complexes has been prepared by protonolysis of diethylzinc with acidic tertiary ammonium salts of N-alkylated 1,3,5-triazacyclohexanes (R_3TAC)(R = Me, Bz, *i*-Pr, 4-fluorobenzyl). The products were found to have the general formula $[(R_3TAC)Zn(Et)]X$ ($X = ClO_4^-$, BF_4^-, $[B(C_6F_5)_4]^-$, PF_6^-) and to be sensitive to protic reagents.[242,243]

$$Et_2Zn + Ph_2Zn + C \rightleftharpoons EtZnC^+ + Ph_2ZnEt^- \quad (46)$$

C = cryptand

$$R_2Zn + R_3Al + C \rightleftharpoons RZnC^+ + R_4Al^- \quad (47)$$

C = cryptand

Actually, the presence of crown ether (*see Crown Ethers*) is not necessary to prepare a cationic zinc species. It was found that the reaction between diorganozinc compounds R_2Zn (R = Me, Et, *t*-Bu) and $[H(OEt_2)_2]^+$ $[B(C_6F_5)_4]^-$ in ether, led via alkane elimination to the salts $[RZn(OEt_2)_3]^+$ $[B(C_6F_5)_4]^-$ in quantitative yields[244] (equation 48). The compounds were isolated as colorless crystalline solids that are soluble in ether and dichloromethane.

$$R_2Zn + [H(Et_2O)_2]^+[B(C_6F_5)_4]^- \xrightarrow[-RH]{} [RZn(Et_2O)_3]^+[B(C_6F_5)_4]^- \quad (48)$$

4.2.2 Structure

The structure of the derivative $[EtZn(OEt_2)_3]^+$ $[B(C_6F_5)_4]^-$ could be determined by X-ray crystallography[244] (Figure 56). The zinc atom is tetracoordinated with a slightly distorted tetrahedral geometry, and the zinc–carbon bond length of 1.964 Å is comparable with that observed in the methylzinc alkoxide species $[MeZn(O\text{-}t\text{-Bu})]_4$ (1.955 Å).

A similar zinc–carbon bond length (1.93 Å) is found in the solid-state structure of the compound $[(Bz_3TAC)Zn(Et)](PF_6)$, in which the ethylzinc cation coordinates to three nitrogen atoms of the 1,3,5-triazacyclohexane ligand[242] (Figure 56). It is worth noting that the benzyl substituents occupy two different positions, and that the two short Zn–F distances (2.85 Å) indicate anion–cation contacts. These observations confirm the previous NMR spectroscopy studies in solution of the related series $[(R_3TAC)Zn(Et)](X)$[243] (R = Me, Bz, *i*Pr, 4-fluorobenzyl; $X = ClO_4^-$, BF_4^-, $[B(C_6F_5)_4]^-$).

5 GEMINATE ORGANODIMETALLIC SPECIES CONTAINING ZINC

The synthesis and reactivity of geminate organodimetallic compounds is a useful approach for the building of complex architectural molecules by combining multiple reactions in a single operation. These reagents, which possess two nucleophilic (*see Nucleophile*) sites on a single carbon atom, are valuable tools for organic chemists since they can form two C–C bonds in a one-pot reaction. The synthesis and reactivity of geminate organodimetallic derivatives have been recently reviewed.[245,246]

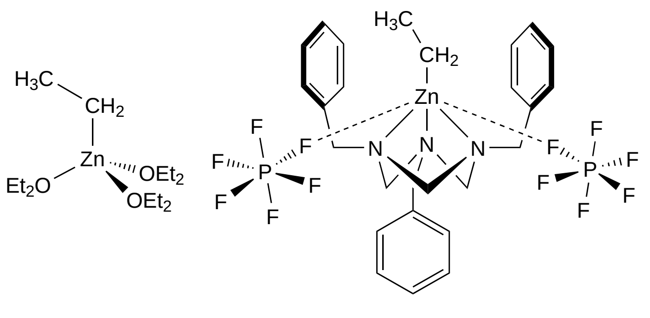

Figure 56 Structure of $[EtZn(OEt_2)_3]^+$ and $[EtZn(Bz_3TAC)]^+$ $(PF_6)^-$ cations

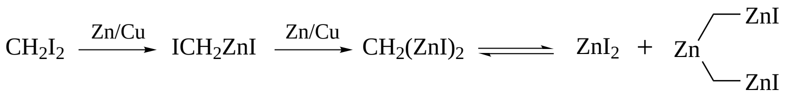
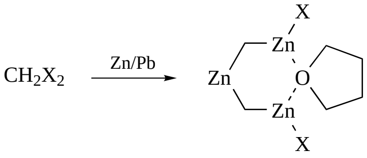


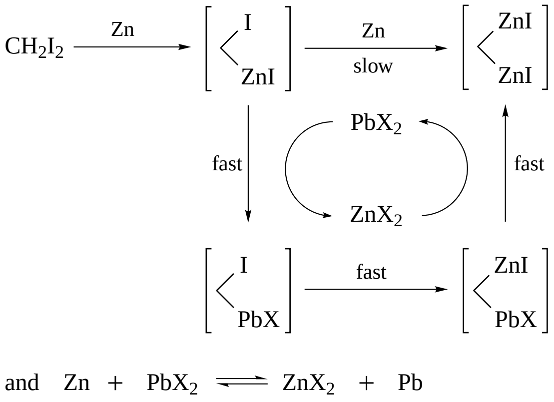
Scheme 11

5.1 Synthesis

Whereas a stoichiometric reaction of Zn/Cu couple with CH_2I_2 leads to the well-known Simmons–Smith reagent (ICH_2ZnI) (Section 6.6), the same reaction in presence of a large excess of zinc leads to an organo-*gem*-dizincio alkane (Scheme 11). The Zn/Cu couple can be efficiently replaced by a mixture of zinc dust and cuprous chloride, a mixture of zinc and Me_3Al, or a Zn/Pb couple. For example, the methylenating reagent ($XZnCH_2ZnCH_2ZnX\cdot THF$), also known as the Nysted reagent, can be obtained by reaction of CH_2X_2 (X = Br, I) with Zn/Pb couple in THF (equation 49). It has been shown that the catalytic effect of Hg in the formation of geminal dizincio alkanes follows the mechanism presented in Scheme 12. It is worth mentioning here that Charette and coworkers reported in 2002 the first evidence for the formation of a geminate dizinc carbenoid upon mixing iodoform (CHI_3) with diethylzinc (Et_2Zn) or ethylzinc iodide (EtZnI) at 0 °C. The novel compound was found very efficient to undergo cyclopropanation reactions with olefins (Section 6.7).

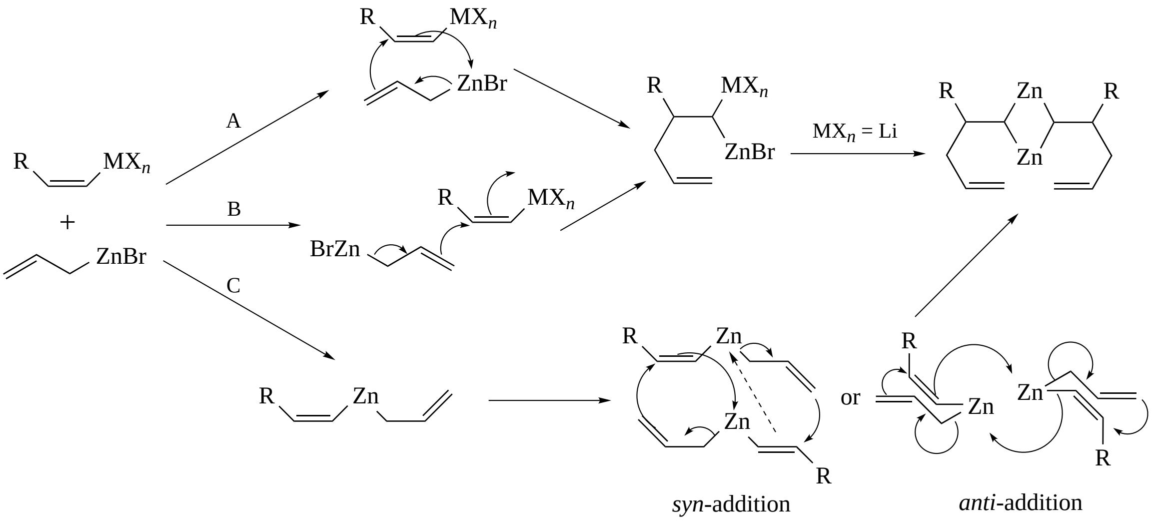


(49)



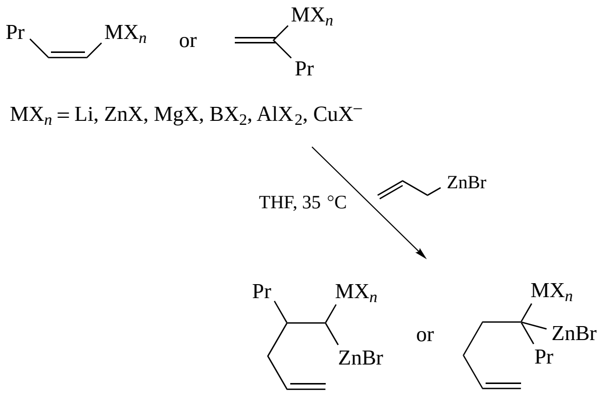
Scheme 12

The allylmetalation reaction, reported by Gaudemar, is an elegant alternative route for the synthesis of *gem*-dimetallic compounds. The addition of allylzinc bromide on substituted vinyl Grignard reagents gives the organo-*gem*-dimetallic derivative in moderate yields (equation 50). Even if the exact mechanism of the reaction remains uncertain, three hypotheses deserve consideration: a suprafacial addition of the allylic zinc bromide to the vinyl metal with further dimerization, especially when MX_n = Li (path A); an anti-allylzincation of the vinyl metal (path B); formation of a mixed vinyl–allyl zinc species which undergoes a rearrangement similar to the



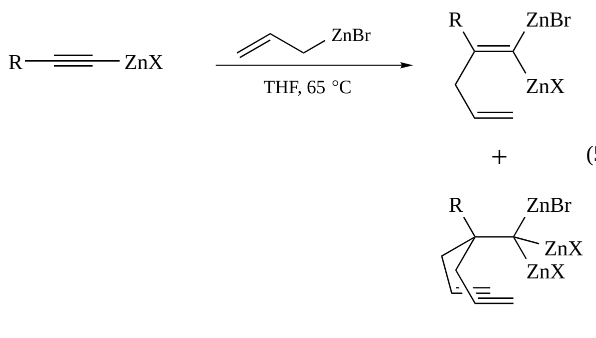
Scheme 13

Claisen rearrangement where zinc would act as the oxygen (path C) (Scheme 13). It has been found that the diastereoselectivity of allylmetalation is highly dependent on the temperature and on the nature of the solvent. Changing the solvent from THF to Et_2O considerably improves the diastereoselectivity since the poorer Lewis basicity (*see Lewis Acids & Bases*) of Et_2O accelerates the reaction and consequently allows lower temperature conditions. The different diastereomers can be independently obtained only by changing the stereochemistry of the starting vinyl Grignard reagent (Scheme 14).

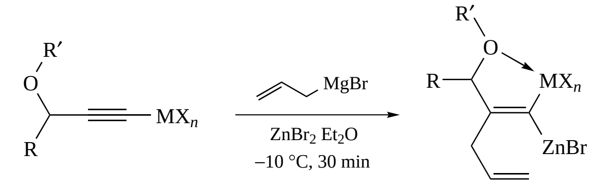


(50)

The related addition reaction of allylzinc bromide to alkynil zinc reagents in refluxing THF leads to a mixture of vinylic 1,1-organo-*gem*-dimetallic species and *gem*-trimetallic species, which respectively result from single and double additions (equation 51). The presence of a Lewis basic (*see Lewis Acids & Bases*) group suitably placed for intramolecular (*see Intramolecular*) chelation, and bearing a secondary substituent, avoids the formation of double addition products and allows the reaction to take place in mild conditions (equation 52).



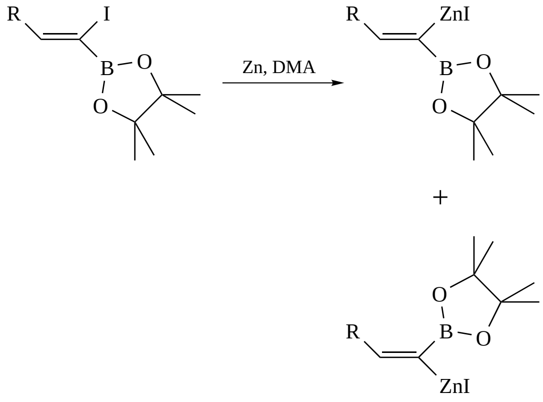
(51)



(52)

R′ = secondary substituent
MX_n = Li, ZnX, MgX

1,1-Boro zincioalkane and 1,1-boro zincioalkene can be prepared by a different route, that is, the reaction of α-haloboronic esters with zinc dust in N,N-dimethylacetamide (DMA). The zinc insertion (*see Insertion*) into α-haloalkenylboronic esters is not stereospecific, so a pure Z reagent will be converted to an E/Z mixture of the corresponding alkenylzinc iodide (equation 53).

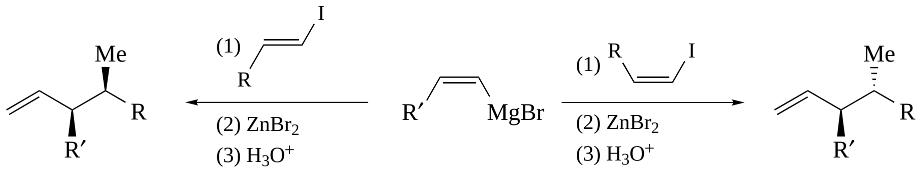


(53)

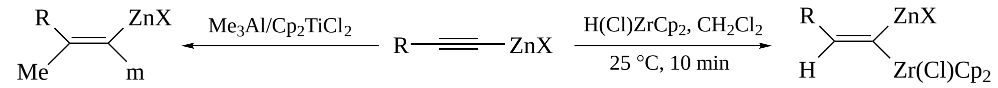
Other mixed *gem*-dimetallic compounds containing zinc and either zirconium, aluminum, or titanium have been successfully prepared from alkynylzinc halide compounds via hydrozirconation by $H(Cl)ZrCp_2$ (the Schwartz's reagent) or carbometalation by a combination of Me_3Al/Cp_2TiCl_2 (Scheme 15).

5.2 Structure

Compared with organo-*gem*-dilithio and dimagnesio compounds, the corresponding organo-*gem*-dizincio derivatives are relatively more stable and less reactive. However, they are usually prepared in situ (*see In Situ Reaction*) and directly



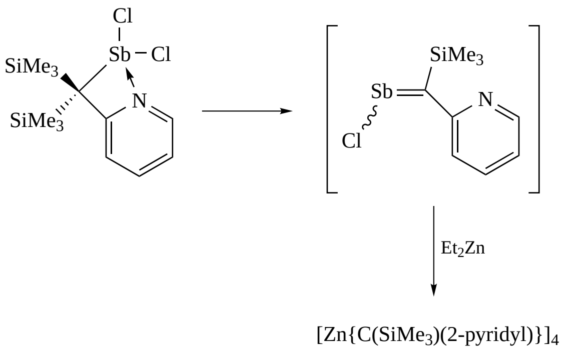
Scheme 14



m = AlL$_2$ or TiL$_3$

Scheme 15

reacted with electrophiles (*see Electrophile*); so, despite their great synthetic value, very little is known about their structure. The first structurally characterized organo-*gem*-dizincio species, namely, the [Zn{C(SiMe$_3$)(2-pyridyl)}]$_4$ tetrameric cage, has been reported only a few years ago.[84] This novel compound was obtained in low yield (20%) by reacting a distibine polymer [{(2-pyridyl)(SiMe$_3$)C}SbCl]$_\infty$ with Et$_2$Zn (equation 54). As shown in Figure 57, the compound contains a tetrameric array of {(2-pyridyl)(Me$_3$Si)C}Zn in which each ligand bridges two zinc atoms via the *gem*-C centers and bridges to a third zinc atom through the pyridyl nitrogen atom. The three-coordinate metal centers present a distorted trigonal planar geometry with a C–Zn distance of 2.032 Å. The *gem*-C centers are distorted from the tetrahedral environment with a Zn–C–Zn angle of 82.2(2)°.



(54)

The only other geminal dizincated alkane reported so far is the dimeric alkyldibarium triszincate, (4Ba^{2+})·{[(Me$_3$SiCH$_2$)$_2$ ZnCH(SiMe$_3$)]$_2$ZnCH(SiMe$_3$)}$_2$$^{4-}$, the synthesis and structure of which have already been mentioned in Section 4.1.2.[233] So as to make it clear, Figure 58 shows only the structure

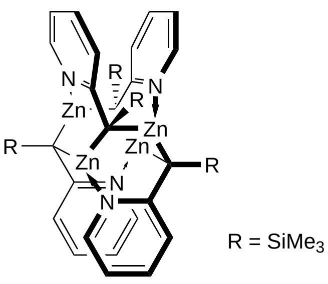


Figure 57 Schematic structure of [Zn{C(SiMe$_3$)(2-pyridyl)}]$_4$

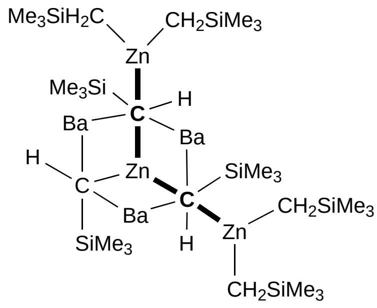

Figure 58 Structure of the tetraanionic tris(zincate) ligand of {[(Me$_3$SiCH$_2$)$_2$ZnCH(SiMe$_3$)]$_2$ZnCH(SiMe$_3$)}$_2$$^{4-}$·4Ba^{2+}

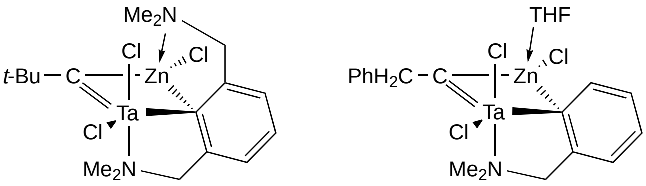

Figure 59 Structure of tantalum–zinc alkylydine complexes

of one tetraanionic tris(zincate) ligand of the dimeric complex. Owing to the special coordination situation and the presence of anionic charges, the Zn–C bond distances of the *gem*-dizincated carbons are rather long (2.15 Å) compared to the Zn–C bond distances found in dialkylzinc compounds (1.95 Å) or in the structure described before (2.03 Å). A comparable elongation of the Zn–C bond was found in the solid-state structure of different geminal organodimetallic compounds containing zinc and other metal. For example, the tantalum–zinc akylidine complexes presented in Figure 59 show bridging Zn–C bond lengths ranging from 1.11 to 1.15 Å, reflecting weak Zn–C interactions.[247,248]

6 REACTIVITY OF ORGANOZINC COMPOUNDS (*See Organic Synthesis Using Metal-mediated Coupling Reactions*)

The reactivity of organozinc compounds with various reagents such as water, amines, alcohols, and CO$_2$ has already

been mentioned in the preceding sections and will not be considered here.

6.1 Reactivity with CO

In contrast to Grignard reagents, dialkylzinc compounds are inert to carbon monoxide at atmospheric pressure either in the absence of solvents or in solution in THF, diglyme, ether, or benzene. Although Rathke and Yu reported in 1972 that the addition of potassium *tert*-butoxide in stoichiometric amounts promoted the absorption of carbon monoxide, it is now known that the actual reactive species was the corresponding zincate compound $(R_2ZnO\text{-}t\text{-}Bu)^-K^+$. The only zinc carbonyl species reported so far has been observed by ^{13}C NMR studies of ^{13}CO on zeolite ZnY and polycrystalline ZnO, at low temperature.[249] Before this report, such species were only suggested from infrared and photoelectron studies of CO weakly bound to ZnO.

6.2 Reactivity with O_2

The high reactivity of organozinc compounds towards oxygen was already noted by Frankland, who reported some 150 years ago the formation of $Zn(OEt)_2$ by the controlled oxidation of Et_2Zn.[250] Even if this reaction was successfully used to prepare alcohols and hydroperoxides (*see Peroxide*) in relatively good yields[251] (Scheme 16), the exact composition of the products and the reaction mechanism remain rather uncertain. In 1864, Lissenko proposed the formation of EtZnOEt,[252] whereas Demuth and Meyer claimed some years later the isolation of the peroxide (*see Peroxide*) EtZnOOEt, a white powder resulting from the oxidation of Et_2Zn in ligroine.[253] However, subsequent studies agreed with rapid oxidation of both Zn–C bonds and formation of compounds with general formula $(ROO)_2Zn$, ROZnOOR and $(RO)_2Zn$.[254]

Even if the free radical chain process shown in Scheme 17[255] was a commonly accepted mechanism, some very recent work published by Lewinski and coworkers strongly questions it. They initially reported the first zinc alkylperoxide structurally characterized by X-ray diffraction, the dimeric $[EtOOZn(BDI)]_2$ (BDI = β-diketiminate ligand) obtained in high yield and in a few minutes by reaction of EtZn(BDI) complex with O_2 at O °C.[256]

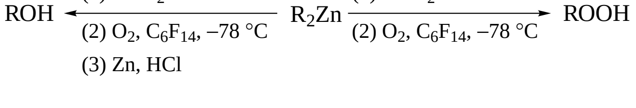
In 2003, the same group published a study of the reaction of O_2 with the chelate complex $[EtZn(azol)]_n$ (*azol* = 1-aziridineethanolate) and isolated the zinc ethylperoxide complex $[EtOOZn(azol)]_2[EtZn(azol)]_2$ in 92% yield from the reaction in benzene[257] (Figure 60). The compound was found resistant to further oxidation with O_2 and the reaction was significantly inhibited in THF solution. They also studied the controlled oxidation of Et_2Zn by O_2, which led to the compound $Me_6Zn_7(OMe)_8$ in high yield. This compound is analogous to the product of methanolysis of Et_2Zn (Section 'Structure' and Figure 34), showing that selective oxidation of dialkylzinc compounds may be a route for the preparation of zinc alkoxides.

Various modes of oxygen-capture by lithiated organozinc reagents have been described in the sequential reaction of Me_2Zn with a 2-pyridylamine $[HN(2\text{-}C_5H_4N)R$, R = Ph, 3,5-xylyl, 2,6-xylyl, benzyl, Me], *t*-BuLi and afterward O_2.[258] The nature of the products was found to be dependent on R and suggested a competition between the oxophilicity of lithium and zinc (Scheme 18). When N,N'-diphenylbenzamidine (HAm) is used instead of 2-pyridylamine, and depending on the solvent conditions, the sequential reaction leads to various triorganozincate species.[259] While the product isolated from THF solutions is the dimer $[THF{\cdot}Li(Me)OZnAm_2]_2$ corresponding to a formal insertion (*see Insertion*) of oxygen into the Zn–C bond, without donor solvent the polymer $[(LiO\text{-}t\text{-}Bu)(MeZnO\text{-}t\text{-}Bu)_3]_n$ and the oxide-encapsulation complex $(\mu_6\text{-}O)(Li_2ZnAm_3)_2$ were obtained.

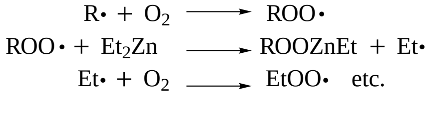
6.3 Substitution Reactions

6.3.1 *With Inorganic Halides*

As a result of their low basicity and low reducing power, organozinc reagents are more suitable than the corresponding magnesium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***) or lithium (*see* ***Alkali Metals: Organometallic Chemistry***) derivatives for the alkylation of some transition metal halides. For example, bis(trimethylsilylmethyl)zinc



Scheme 16



Scheme 17

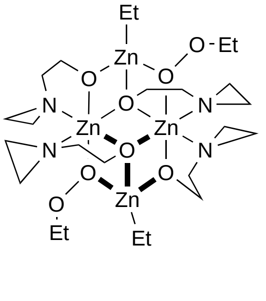


Figure 60 Structure of the zinc ethylperoxide $[EtOOZn(azol)]_2[EtZn(azol)]_2$

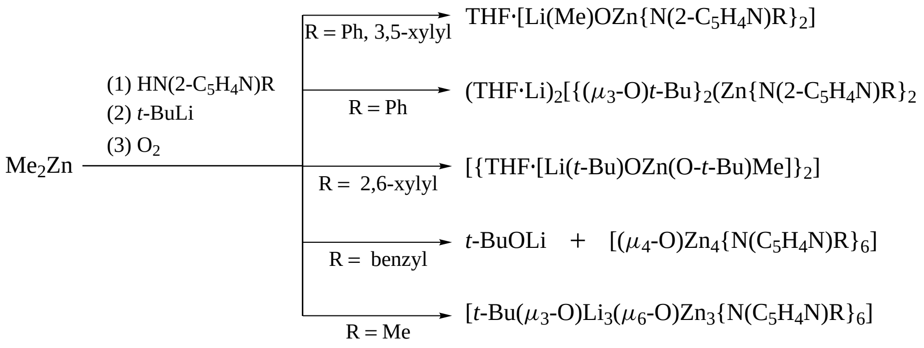


Scheme 18

$[(Me_3SiCH_2)_2Zn]$ and bis(neopentyl)zinc $[(Me_3CCH_2)_2Zn]$ react with tantalum chloride ($TaCl_5$) and niobium chloride ($NbCl_5$) to give the corresponding alkyl metal chlorides of general formula R_nMCl_{5-n} (M = Ta, n = 1–3; M = Nb, n = 2; R = Me_3SiCH_2, Me_3CCH_2)[260] (equation 55).

$$\frac{n}{2}(Me_3SiCH_2)_2Zn + MCl_5 \longrightarrow (Me_3SiCH_2)_nMCl_{5-n} + \frac{n}{2}ZnCl_2$$
$$M = Ta,\ n = 1\text{–}3; \quad M = Nb,\ n = 3 \qquad (55)$$

The oxidative alkylation of titanium compounds (Cp^*_2TiX; $Cp^* = \eta^5$-C_5Me_5, X = Me, OMe, Cl, N=CH-*t*-Bu) by dimethylzinc and dimethylcadmium has been reported to afford diamagnetic (*see Diamagnetism*) compounds of general formula $Cp^*_2TiMe(X)$ and metallic zinc and cadmium, respectively.[261]

Organozinc halides and diorganozinc compounds smoothly alkylate chlorophosphane derivatives in THF at 0 °C in good to excellent yields[262] (equation 56).

$$RZnX \xrightarrow[0\,°C,\ 1h]{Cl_nPR'_{3-n},\ THF} R_n\text{-}PR'_{3-n} \qquad (56)$$
$$X = \text{Halide, R.}$$
$$R' = Ph,\ NR''_2$$

Addition of catalytic or stoichiometric quantities of $CuCN\cdot(LiCl)_2$ radically increases the reactivity of diorganozinc (R_2Zn) and organozinc halide (RZnX) compounds. The resulting copper–zinc species (RCu(CN)ZnR or RCu(CN)ZnX) react with stannyl chlorides (R'_3SnCl) to give the corresponding alkylated stannyl derivatives (R'_3SnR) in high yields[8] (Scheme 19). It is worth mentioning that Me_3SiCl generally fails to react with either organozinc or zinc–copper compounds.

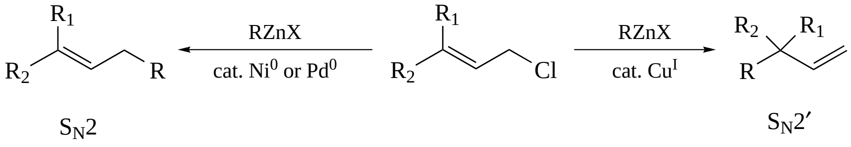
6.3.2 With Organic Halides

When diorganozinc and organozinc halide compounds react with allylic halides in the presence of Cu^I salts, the S_N2' (*see Nucleophilic Addition: Rules for Predicting Direction*) products are selectively obtained. In contrast, the reactions catalyzed by Ni^0 or Pd^0 lead to the S_N2 products (Scheme 20).

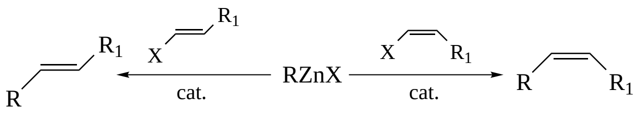
The cross-coupling reaction between organozinc halides and alkenyl or aromatic halides is efficiently catalyzed by Pd^{II} or Ni^{II} salts. Organo-copper reagents derived from organozinc halide compounds react similarly with alkenyl halides but in harsh conditions (refluxing DME several days) to give the coupling products in a stereocontrolled way (Scheme 21). It has been found that the presence of an electron-withdrawing group (NO_2, COOR, COR) in the β-position facilitates the substitution reaction via an addition-elimination mechanism. In contrast, the coupling reaction with 1-iodo- and 1-bromoalkynes takes

$$RZnX \xrightarrow{Cu(CN)\cdot 2LiCl} RCu(CN)X \xrightarrow{R'_3SnCl} R'_3SnR$$
$$X = \text{Halide, R.}$$

Scheme 19



Scheme 20



Cat. = Cu^{I}, Pd^{II}, Ni^{II} salts.

Scheme 21

place in mild conditions (−80 to 0 °C, few hours) (equation 57).

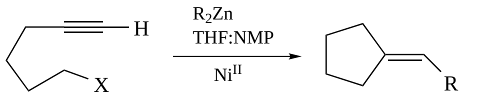
$$R_1\text{–C≡C–X} \xrightarrow{\text{RCu(CN)ZnX}} R_1\text{–C≡C–R} \qquad (57)$$

While the reaction of acid chlorides with organozinc halide compounds is relatively inefficient, the reaction with the corresponding copper−zinc reagents or the catalysis with Pd^{II} salts represents a smooth route for the preparation of ketones in very good yields (equation 58).

$$R_1\text{COCl} \xrightarrow{\text{RCu(CN)ZnX}} R_1\text{COR} \qquad (58)$$

The more difficult cross-coupling reaction between C*sp*^{3}-C*sp*^{3} can be accomplished by mixed zincate compounds, prepared by the reaction of diorganozinc derivatives with $Me_2CuMgCl{\cdot}MgCl(CN)$ (equation 59). Substitution reaction at C*sp*^{3} centers are also efficiently catalyzed by Ni^{II} salts when the alkyl halide contains a double bond in remote position (Scheme 22). Changing the double bond for a triple bond leads to an intramolecular carbozincation reaction (equation 60).

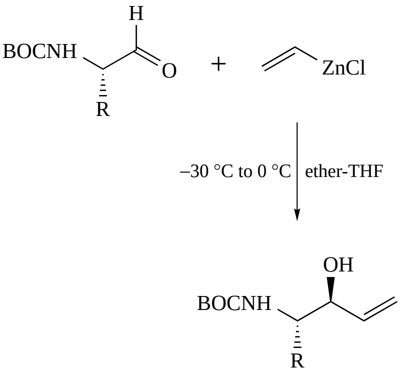
$$\text{R–X} \xrightarrow[\text{3) R}'\text{X, }-78\,^\circ\text{C}]{\text{1) Et}_2\text{Zn, CuCN(0.3 mol\%)} \quad \text{2) Me}_2\text{Cu(CN)(MgCl)}_2\text{, DMPU, }-50\,^\circ\text{C}} \text{R–R}' \qquad (59)$$



(60)

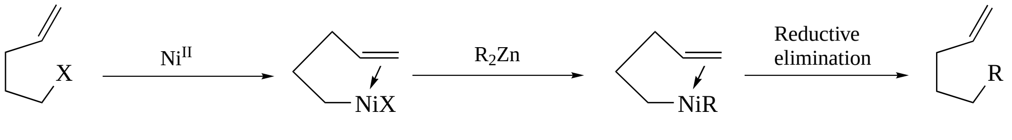
6.4 Addition to Carbonyl Compounds

In contrast to organomagnesium (*see* ***Beryllium & Magnesium: Organometallic Chemistry***) and organolithium (*see* ***Alkali Metals: Organometallic Chemistry***) reagents, dialkylzinc compounds react only slowly with aldehydes to give addition products. Moreover, when the zinc compounds bear hydrogens in β-position a competitive reduction reaction can take place. Reduction is also the main reaction with ketones. Thus, the addition of organozinc derivatives with carbonyl compounds usually requires the presence of metal salts, Lewis acids (*see Lewis Acids & Bases*) $[Ti(O\text{-}i\text{-}Pr)_nCl_{4-n}$, Me_3SiCl, $BF_3{\cdot}OEt_2]$, donor ligands or auxiliaries. However, it has been shown that aryl-, vinyl-, and alkynylzinc reagents are more reactive than the saturated organozinc reagents. They react smoothly with carbonyl derivatives in the absence of catalysts. For example, alkenylzinc chlorides add to α-amino aldehydes to give unsaturated 1,2-amino alcohols with acceptable yields and good stereoselectivity (equation 61). More generally, highly reactive allylic zinc reagents add to a wide range of carbonyl functionalities. In contrast, the reaction of propargylic zinc derivatives with aldehydes or ketones always give mixtures of rearranged products.



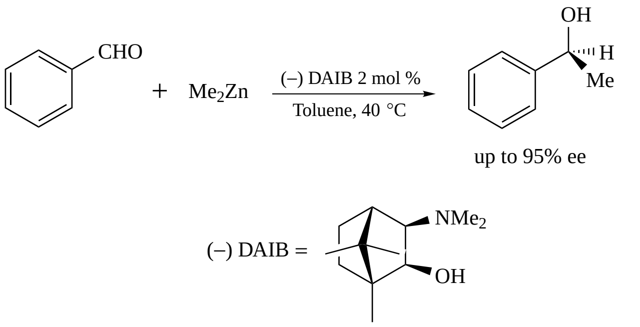
(61)

The research on asymmetric organozinc additions to carbonyl compounds started in 1984 when Oguni and Omi obtained 49% e.e. in the reaction of diethylzinc with benzaldehyde catalyzed by (*S*)-leucinol. Since then, a huge number of chiral (*see Chiral*) catalysts, mostly derived from amino alcohols, have been developed and the subject has been extensively reviewed.[263,264] The first highly enantioselective (*see Electrophile*) ligand (−)-3-exo-dimethylaminoisoborneol [(−)-DAIB] developed by Noyori and coworkers in 1986 is still used even if its application is mostly limited to aromatic and heteroaromatic aldehydes (equation 62). As shown by previous studies, chiral (*see Chiral*) ligands have a dual



Scheme 22

function: they control the stereochemistry of the organozinc addition and increase the nucleophilicity (*see Lewis Acids & Bases*) of the alkyl groups bound to zinc through their coordination to the zinc center.



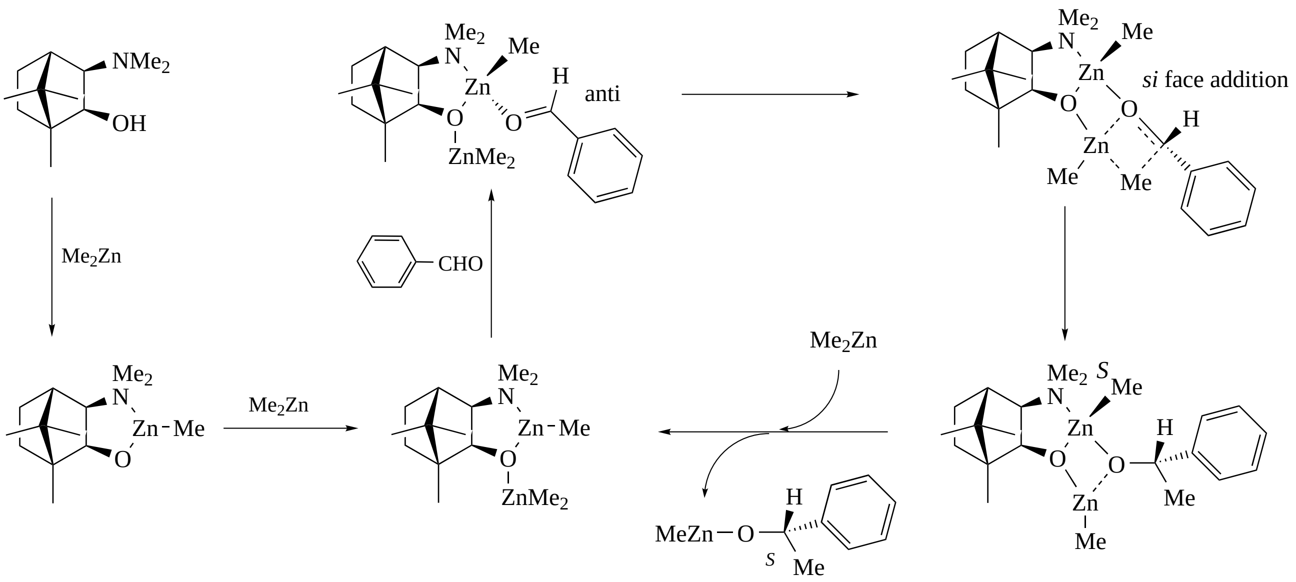
(62)

The amino-alcohol promoted addition of dialkylzinc to aldehydes has been extensively studied and several types of transition states have been proposed (Figure 61 and 62). Some years ago, Yamakawa and Noyori characterized two tricyclic transition states (syn- and anti-orientation) and suggested the mechanism shown in Scheme 23.[265] In the first step, a complex between Me_2Zn and (−)-DAIB is formed. This complex, which has no alkylating properties, further coordinates a second Me_2Zn molecule trough the oxygen atom. After that, a benzaldehyde molecule coordinates to the former zinc atom in *anti* position with respect to the chiral (*see Chiral*) ligand. A following methyl migration to the *si* face of the aldehyde produces the asymmetric center. Finally further reaction with Me_2Zn can regenerate the bis(dimethylzinc)·(−) DAIB complex and liberate (S)-(1-phenyl)ethoxy−ZnMe which gives (S)-1-phenylethanol under aqueous workup.

Theoretical investigations have shown that the most favored tricyclic transition state has the *anti*-configuration, which is 12−13 $kJmol^{-1}$ more stable than the *syn*-configuration and 29 $kJmol^{-1}$ more stable than the bicyclic transition state (Figure 61). However, few years later Rasmussen and Norrby[266] could characterized two new six-membered transition states, *env* and *chai*r (Figure 62), which are lower in energy (respectively by 19 and 50 $kJmol^{-1}$) than the more stable *anti* form characterized by Yamakawa and Noyori.

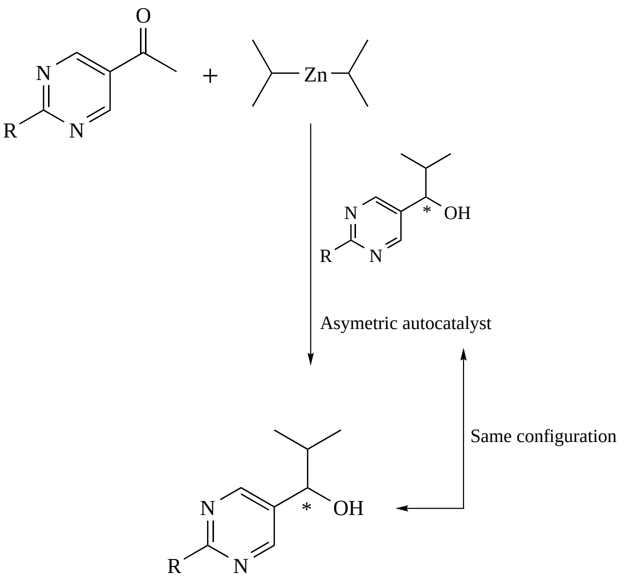
Interestingly, it was found that this reaction shows a large positive nonlinear effect with the enantiomeric purity of the DAIB ligand. In other words, higher enantioselectivity is obtained with lower enantiomeric purity of the ligand. For example, when diethylzinc was added to benzaldehyde in presence of DAIB with 100% e.e., the addition product was obtained in 98% e.e., whereas DAIB with only 15% e.e. led to the addition product with 95% e.e. In addition, if a racemic DAIB mixture was used instead of an enantiomerically pure ligand, the reaction rate was reduced by 13 times. This behavior can be explained by the formation of two different dimeric species, in the first step of the reaction, when DAIB is not enantiomerically pure, that is, the homodimer $[RZn\{(-)\text{-DAIB}\}]_2$ with C_2 symmetry and the heterodimer with C_i symmetry, which was found to be the more stable and less reactive one (Figure 63). Thus, the observed nonlinear effect comes from the consumption of the minor enantiomer through formation of the stable and faintly reactive heterodimer.

In 1995, Soai and coworkers reported a highly enantioselective asymmetric autocatalysis of pyrimidyl alkanol in the enantioselective addition reaction of i-Pr_2Zn to pyrimidine-5-carboxaldehyde[267] (equation 63). When a 5-pyrimidyl alkanol with a small enantiomeric excess such as 5×10^{-5}% is added to i-Pr_2Zn and pyrimidine-5-carboxaldehyde, then the reaction



Scheme 23

gives the alkanol of the same absolute configuration with up to 99.5% e.e. The autocatalytic feature of the reaction has been proven by recent kinetic analysis[268] (*see Kinetic Methods*).



(63)

Recently, it has been found that shifting the NMe_2 moiety in (−)-DAIB to a morpholine group (MIB) gives a much more stable derivative, which also displays a wider reactivity[269]

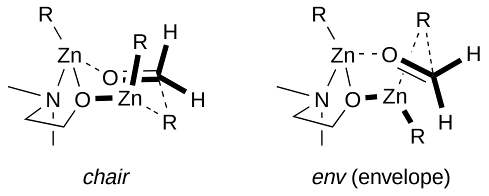


Figure 62 New transition states characterized by Rasmussen and Norrby

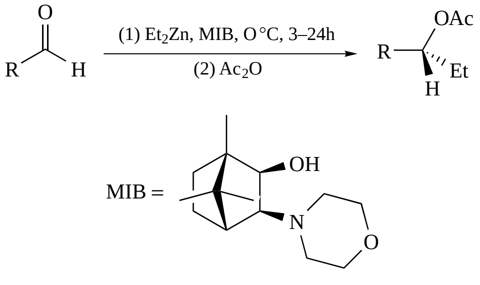
(equation 64).



(64)

In addition to amino alcohols, numerous other ligands such as amines, amino thiols, diols, disulfides, and diselenides have been developed and tested. Several have shown a very good enantioselectivity for dialkylzinc additions to a variety of aldehydes. In contrast, the addition of aryl-, vinyl-, and alkynylzinc compounds was not so extensively studied and more work is still needed in

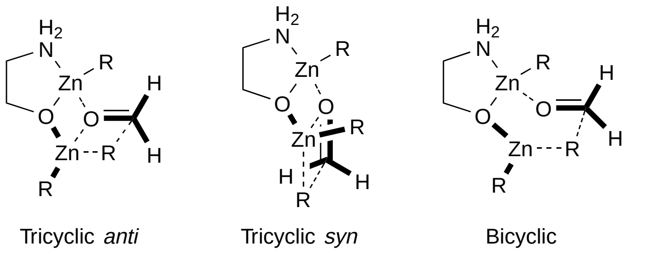


Figure 61 Transition states characterized by Yamakawa and Noyori

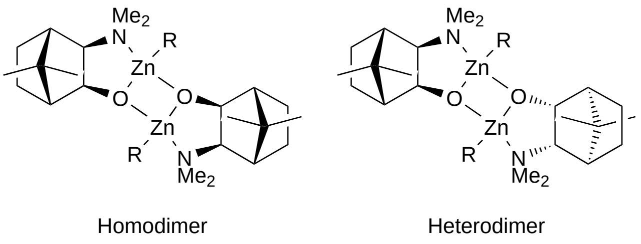

Figure 63 Structure of the homo- and heterodimer $[RZn(DAIB)]_2$

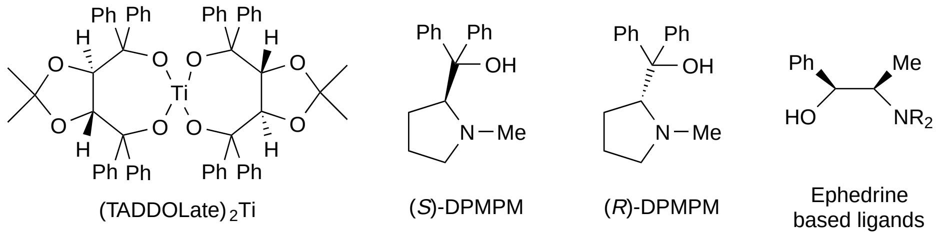

Figure 64 Structure of some enantioselective ligands for vinyl- and alkynylzinc additions to aldehyde

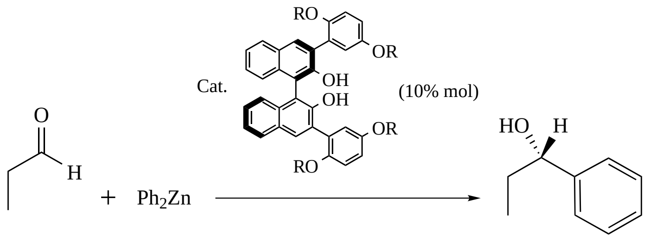
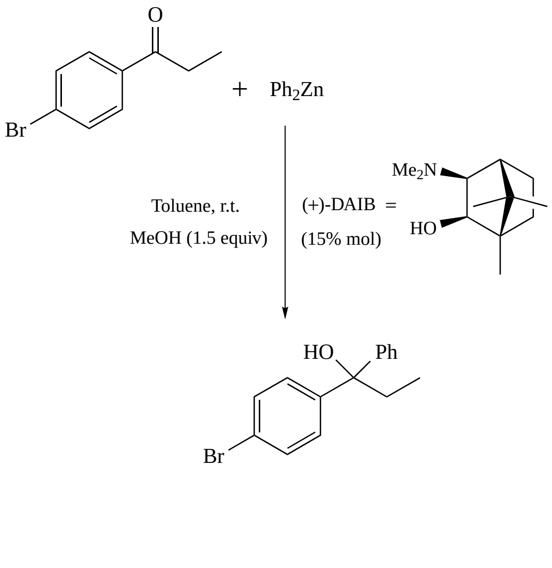
this area. Nevertheless, some highly enantioselective catalysts have been recently obtained.[264] For example, Ph_2Zn reacts with propionaldehyde in the presence of 10 mol % of the chiral (*see Chiral*) binaphtyl ligand (*R*)-3,3′-bis(2″,5″-dihexyloxyphenyl)-1,1′-binaphthol to give (S)-1-phenylpropanol with 87% e.e. (equation 65). The spirotitanate complex $(TADDOLate)_2Ti$ (TADDOLate = α,α,α', α'-tetraaryl-1,3-dioxolane-4,5-dimethanolate) was reported to give 84% e.e. in the reaction of divinylzinc with benzaldehyde. Even higher e.e., up to 92%, have been obtained for the addition of diisopropenylzinc to aromatic aldehydes catalyzed by proline based ligands such as DPMPM [diphenyl(1-methylpyrrolidin-2-yl)methanol] and ephedrine based ligands (Figure 64). Addition of stoichiometric amounts of *N*-methylephedrine to the reaction of terminal alkynes with different aromatic and aliphatic aldehydes containing α-substituents led to very high enantioselectivity.

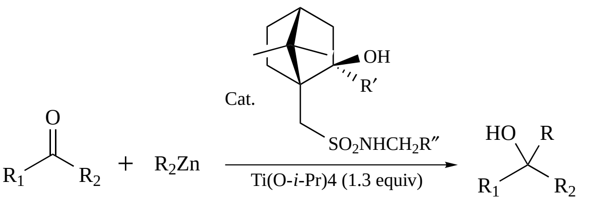


(65)

Compared to the well-developed organozinc addition to aldehydes, the related addition to ketones has been far less studied. However, the first catalytic addition of dialkylzinc to ketones has been achieved few years ago using camphorsulfonamide alcohols ligands and Ti(O-*i*-Pr)$_4$ salt (equation 66). In the same year, it was also discovered that 15 mol % of (+)-DAIB catalyze the diphenylzinc addition to ketones to generate chiral (*see Chiral*) tertiary alcohols with up to 91% e.e. (equation 67).



(66)

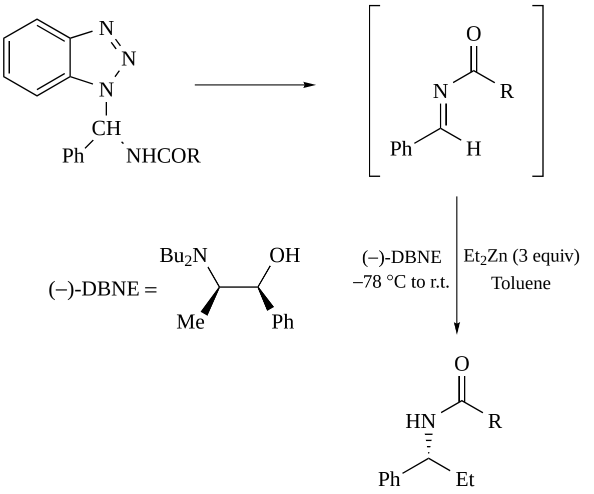


(67)

6.5 Addition to C=N bonds

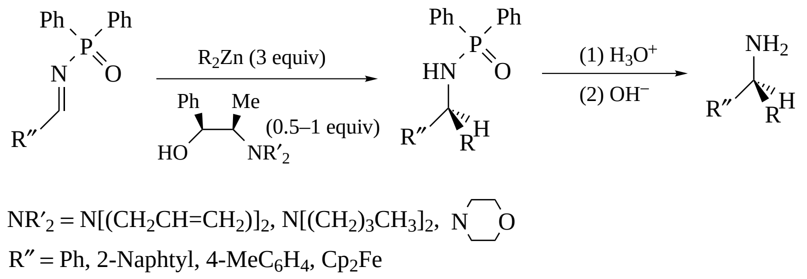
The development of organozinc addition reactions to imines and imine derivatives has been somewhat limited by both the poor electrophilicity of the azomethine carbon and the low reactivity of organozinc reagents.

Even the very efficient enantioselective catalysts used in organozinc addition reactions to carbonyl compounds failed to catalyze the corresponding addition reactions to nonactivated imines such as *N*-silyl-, *N*-phenyl-, or *N*-benzyl-imines. However, enantioselective additions of dialkylzinc compounds to more activated imines, like *N*-acyl- or *N*-phosphinoyl-imines, in the presence of catalytic or stoichiometric amounts of chiral (*see Chiral*) aminoalcohols, have been recently reported. For example, in presence of 1 equiv of (*N*,*N*-dibutylnorephedrine) (DBNE) diethylzinc reacts with masked *N*-acyl imines like *N*-(amidobenzyl)benzotriazoles, to give chiral *N*-(1-phenylpropyl)amides with up to 76% e.e.[270] (equation 68).

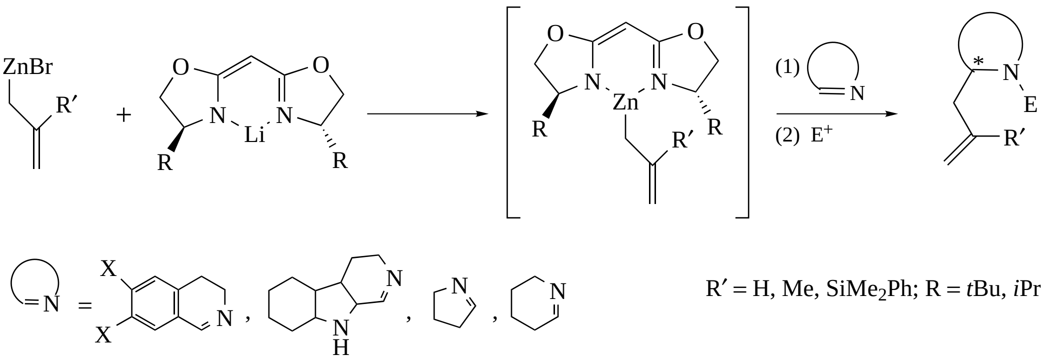


(68)

N-diphenylphosphinoyl imines also react with dialkylzinc in the presence of stoichiometric or catalytic amounts of different chiral (*see Chiral*) ligands[271] (Scheme 24). Acid hydrolysis of the resulting phosphinamides occurs without racemization and gives enantiomerically enriched primary amines. The allylation of various cyclic imines was obtained with high enantioselectivity (*see Electrophile*), 77 to 99% e.e., in the presence of lithiated bis-oxazoline ligands (Scheme 25).



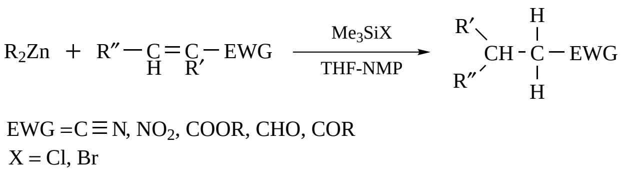
Scheme 24



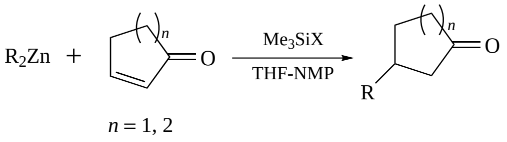
Scheme 25

6.6 Reactions with Carbon–Carbon Multiple Bonds

Saturated organozinc halides are usually unreactive towards alkenes and nonterminal alkynes, but as already mentioned in previous reactions, allylic zinc derivatives were found to be more reactive towards such functionalities. Furthermore, the reactivity of diorganozinc derivatives can be enhanced by the use of polar (*see Polar Compounds*) solvents, or the addition of diverse Lewis acids[8,9,262] (*see Lewis Acids & Bases*). For example, conjugate addition reactions (or 1,4-additions) involving a variety of double bonds in conjugation with an electron-withdrawing group (EWG) work well in *N*-methylpyrrolidine (NMP) and in the presence of Me_3SiX (equation 69). A 1,4-addition pathway is also observed in the reaction of diorganozinc compounds with cyclic enones (equation 70). Even if only one of the two R groups is transferred to the substrate, mixed organozinc compounds bearing a nontransferable group such as R–Zn–CH_2SiMe_3 are usually preferred in order to avoid the waste of an R group.

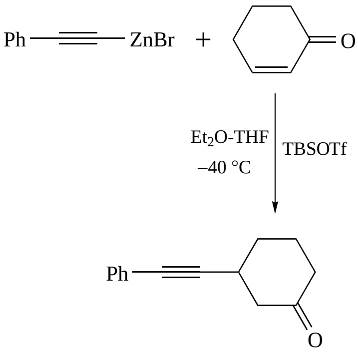


(69)



(70)

Cyclic enones were also found to react with alkynylzinc halides in the presence of *tert*-butyldimethylsilyl triflate (equation 71).



(71)

The addition of diorganozinc compounds to alkynes can be promoted by different metallic species such as Cp_2ZrI_2 and $Ni(acac)_2$ to give the corresponding vinylic zinc compounds (equation 72). A subsequent hydrolysis leads to the alkene, whereas iodinolysis provides the vinyl iodide derivative. Copper–zinc species, readily obtained by the

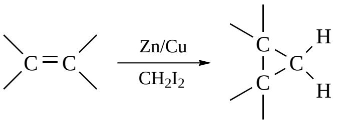
reaction of organozinc compounds with the THF soluble copper salt $CuCN \cdot 2LiCl$, add to a variety of conjugated alkenes and alkynes with 1,4-regioselectivity (*see Regioselectivity*) (Scheme 26). Addition to conjugated unsaturated aldehydes usually needs the presence of a Lewis acid catalyst, which nature also determines the regioselectivity (*see Regioselectivity*) of the reaction. While Me_3SiCl promotes 1,4-additions, reactions with $BF_3 \cdot Et_2O$ lead only to 1,2-addition products. It is worth mentioning that the 1,2-addition pathway was also observed in the reaction of diallylzinc with both linear and cyclic enones (Scheme 27). The peculiar dynamic properties of allylic zinc compounds (see Section 2.3.2) may be the origin of this behavior.

$$R_2Zn + R'{-}C{\equiv}C{-}H \xrightarrow{\text{Cat.}} R'RC{=}C(H)ZnR \qquad (72)$$
$$\text{Cat.} = Ni(acac)_2,\ Cp_2ZrI_2$$

Organozinc addition reactions to unsaturated systems lead to an intermediate zinc compound which is in most cases further hydrolyzed to give the corresponding protonated organic compound. This intermediate can also be trapped by reaction with electrophiles (*see Electrophile*) (E^+) such as aldehydes, acyl chlorides, organic halides, silyl halides, and so on. Depending on the nature of the electrophile (*see Electrophile*) used, zinc enolate intermediates obtained in organozinc addition to enones can be either *O*-trapped or *C*-trapped (Scheme 28).

6.7 The Simmons–Smith Reaction

The original Simmons–Smith reaction is a cyclopropanation reaction of olefins, achieved by an ethereal solution of a zinc–copper couple and diiodomethane[272] (equation 73). It is without doubt one of the most important applications of organozinc reagents in organic synthesis. Its synthetic value emerges from the following features: mild conditions; broad generality with regard to the olefin structure; stereospecificity with respect to the olefin geometry; stereoselectivity with allylic alcohols, acetals, and enol ethers (equation 74). Furthermore, although some insertion (*see Insertion*) of methylene groups into the α-C–H bond of the ethereal solvent occurs, insertion into vinylic C–H bond has never been observed.



(73)

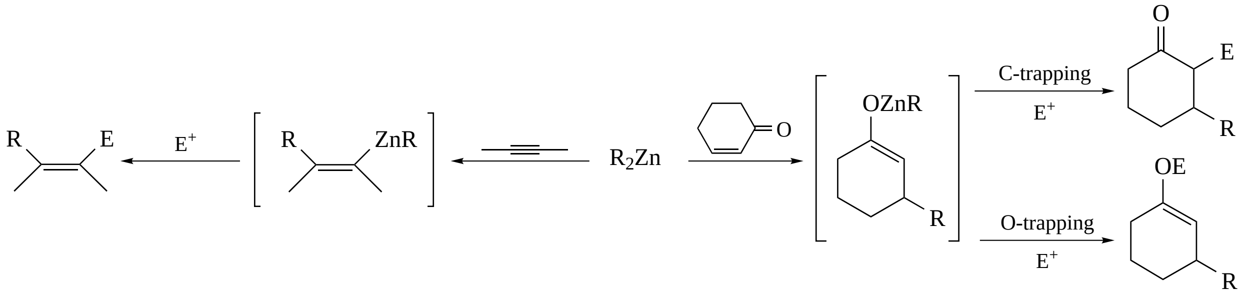
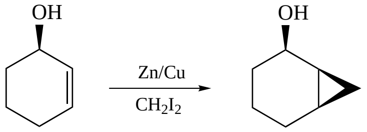
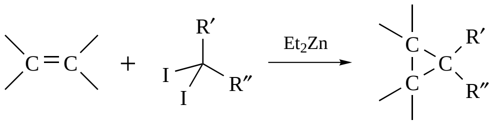


Scheme 28



(74)

Over the past 40 years, several modifications of the original procedure have been reported. Wittig and coworkers first reported that carbenoid reagents of the type XCH_2ZnX or $(XCH_2)_2Zn$ could also be prepared by the reaction of Zn^{II} salts with diazoalkane.[273] Later, a significant improvement was made by Furukawa when he found out that diethylzinc could advantageously replaced activated zinc in the reaction with diiodomethane.[274] This procedure, in contrast to the original one, allows the preparation of substituted carbenoid reagents (equation 75). More recently, it was shown that (chloromethyl)zinc reagents are generally more reactive than the (iodomethyl)zinc analogues when 1,2-dichloroethane was used as the solvent.[275]



(75)

A detailed comprehension of the mechanism and the exact structure of the species responsible for the cyclopropanation are still the subject of controversies. Since the participation of free carbenes (*see* ***Carbene Complexes***) is unlikely, the reagents are frequently referred to as carbenoids. Simmons and Rickborn first proposed that $(ICH_2)_2Zn{\cdot}ZnI_2$, resulting from the Schlenk equilibrium of ICH_2ZnI, was the reactive species, whereas Dauben concluded from his studies that ICH_2ZnI should be responsible for the cyclopropanation. Relating to the system Et_2Zn/CH_2I_2, Furukawa took an intermediate position when he stipulated that 'the active species may include $EtZnCH_2I$, ICH_2ZnI and/or $Zn(CH_2I)_2$ or associated complexes containing these molecules'.[276] In fact, during the past decade the solid-state structure of both $ICH_2ZnI{\cdot}L$ and $Zn(CH_2I)_2{\cdot}L$ (L = crown ether, glycol bis-ether) has been unambiguously characterized by X-ray crystallography (see Section 2.4.1 Table 4 and Section 3.1.2 Table 7). Moreover, Charette and Marcoux could differentiate the three reagents $EtZnCH_2I$, ICH_2ZnI and $(ICH_2)_2Zn$ by low-temperature ^{13}C spectroscopy in CD_2Cl_2 and in the presence of a chiral (*see Chiral*) complexing agent.[277] In these conditions, they found that ICH_2ZnI did not rearrange in ZnI_2 and $(ICH_2)_2Zn$, and also that the Furukawa's reagent $EtZnCH_2I$ was in equilibrium with Et_2Zn and $(ICH_2)_2Zn$. Finally, it is interesting to note that Charette reported few years ago a storable complex, bipyridine·$Zn(CH_2I)_2$, which could efficiently cyclopropanate olefins upon addition of ZnI_2.

An investigation of the potential energy surface for the model reaction between ethylene and $ClCH_2ZnCl$ reveals the existence of two reaction pathways:[278] the addition process (leading to the cyclopropane product) and the insertion (*see Insertion*) process (leading to the cyclopropene product). However, the energy barrier for the addition process (24.75 kcal mol^{-1}) is found to be smaller than for the insertion process (36.01 kcal mol^{-1}). Thus, at this point both computational and experimental results agree in that the addition pathway is favored and the insertion (*see Insertion*) negligible. This theoretical study also validates the three-centered transition state first suggested by Simmons to account for the stereochemical features of the reaction (Figure 65).

The last few years have seen some development in the preparation of carbenoid reagents. In 1998, Shi and coworkers reported that a new class of (iodomethyl)zinc compounds ($RXZnCH_2I$), readily obtained by the reaction of RXH (ROH, RCO_2H) with $RZnCH_2I$, can efficiently cyclopropanate olefins.[279] The carbenoid reactivity was found to increase with the acidity of RXH. For example, $CF_3CO_2ZnCH_2I$

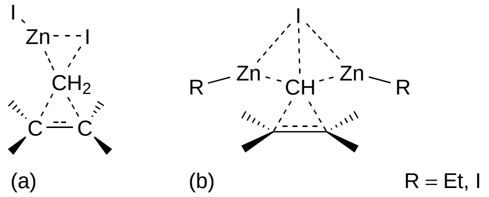


Figure 65 Transition states in the cyclopropanation of ethylene with mono zinc carbenoids (a) and with *gem*-dizinc carbenoids (b)

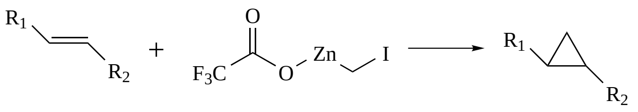
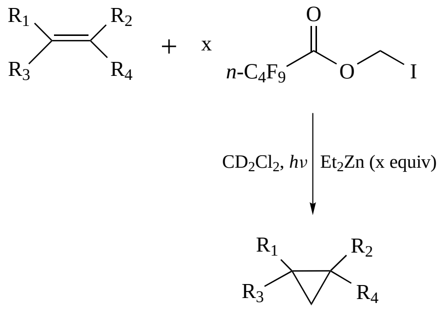
could cyclopropanate *trans*-β-methylstyrene at room temperature within 30 min[280] (equation 76). Two years later, Charette showed that ethylzincmethyl perfluoropentanoate ($C_4F_9CO_2CH_2ZnEt$), obtained quantitatively by the reaction of diethylzinc with iodomethyl perfluoropentanoate is a highly reactive carbenoid reagent owing to internal Lewis acid (*see Lewis Acids & Bases*) activation[281] (equation 77). This acyloxymethylzinc compound can cyclopropanate poorly reactive alkenes, such as *trans*-stilbene, in moderate yield. In addition, from ^1H NMR and GC analysis he attributed the improved reactivity of Shi's reagent ($CF_3CO_2ZnCH_2I$) to the in situ (*see In Situ Reaction*) formation of the corresponding acyloxymethylzinc ($CF_3CO_2CH_2ZnI$) (Scheme 29).



(76)



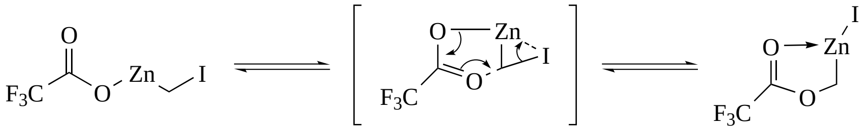
(77)

Alkylbenzenes undergo a remarkable ring expansion reaction with zinc carbenoid reagents derived from CHI_3, which results in the formation of cycloheptatrienyl derivatives (Scheme 30). In 2002, the group of Charette reported that CHI_3 reacts with Et_2Zn or EtZnI at 0 °C to form *gem*-dizinc carbenoids with general formula $ICH(ZnR)_2$ (R = Et, I) which are very reactive and provide access to substituted cyclopropanes in excellent yields.[282] A density functional theory investigation for the cyclopropanation of ethylene has shown that these *gem*-dizinc carbenoids, compared to their corresponding mono zinc carbenoids, react with lower barriers to reaction (about 15 kcal mol^{-1}) which can further be lowered upon addition of ZnI_2 as a Lewis acid.[283] The authors also identified transition states on the way to cyclopropanation products for the reaction of *gem*-dizinc carbenoids with C_2H_2 which present the general schematic structure shown in Figure 65.

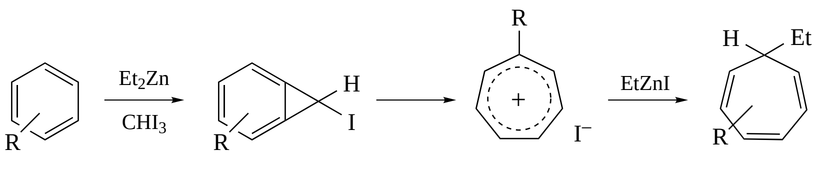
A novel application of Simmons–Smith reagents designed for the epoxidation of carbonyl compounds has been reported a few years ago[284] (Scheme 31). The zinc reagents react with sulfides to give the corresponding sulfur ylides, which are then used to generate epoxides from aldehydes. The reaction takes place in mild conditions and works well with aromatic or aliphatic aldehydes. It is interesting to note that unsaturated aldehydes also give the epoxidation compound without undergoing cyclopropanation.

6.8 The Reformatsky Reaction

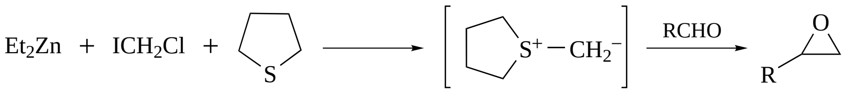
In its original version the so called Reformatsky reaction was the preparation of β-hydroxy esters, or their deshydratation products, by reacting a mixture of activated zinc, an α-bromo ester and a carbonyl compound in ethereal



Scheme 29

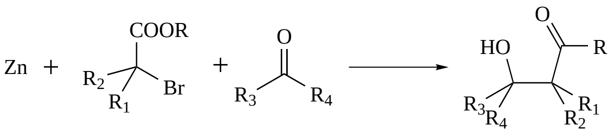


Scheme 30



Scheme 31

solvent with subsequent hydrolysis (equation 78). The reaction between zinc and the α-halo ester generates in situ (*see In Situ Reaction*) an organozinc species which further reacts with the aldehydes or ketones to give the corresponding β-hydroxy ester. However, the actual synthesis is typically carried out in two stages with the previous formation of a zinc enolate derivative followed by the addition of a carbonyl compound. The reaction has been extended to other α-halogeno compounds, such as α-halo-nitriles and -amides, and to a large variety of substrates.

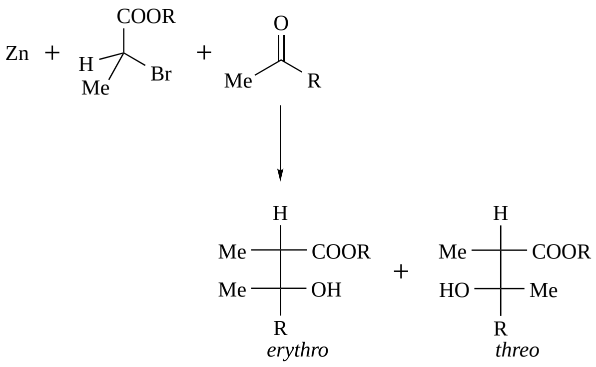


(78)

There has been considerable discussion concerning the nature of the Reformatsky reagent with suggestions for an *O*-metalated species or alternatively a *C*-metalated species. However, as shown by the solid-state structure of $[BrZnCH_2CO_2\text{-}t\text{-Bu(THF)}]_2$ the real situation is best described as a combination of both species (see Section 3.1.2 Figure 30 and Section 3.2.2).

An underlying problem associated with the traditional procedure, which uses zinc dust, is the low reactivity of this metal towards α-halo esters; consequently initiation of the reaction requires an activation of zinc such as Riecke zinc, Zn–Cu couple, Zn/Ag–graphite or Zn/Hg amalgam. It has been shown recently that high-intensity ultrasound (*see Sonication*) irradiation of the reaction mixture in presence of I_2 leads to very high yields in short reaction time, without activation of zinc and even using undistilled reagent-grade dioxane.[285] A variety of other low-valent metals (Ba,[286] Mg, Cd, Ni, In, Ce, Li, $FeCO_5$) or metal derivatives such as Cp_2TiCl,[287] $Li[Bu_2SnI_3]$,[288] SmI_2,[289,290] can efficiently substitute zinc dust. However, because of their susceptibility to oxidation and hydrolysis these reagents need to be freshly prepared. Therefore, efforts are now focused on developing catalytic versions of the Reformatsky reaction. For example, it was found that a number of metal salts such as $RhCl(PPh_3)_3$,[291] $CeCl_3$,[292] Cp_2TiCl_2[293] allow inter- and intramolecular Reformatsky reactions to be achieved under mild condition and with better yields.

In most cases, the Reformatsky reaction is not very stereospecific and mixtures of *erythro*- and *threo*-β-hydroxyesters are obtained when asymmetric α-haloesters are used as reagents (equation 79). The erythro:threo ratio appears to depend on the solvent polarity and the reaction time. However, it is of current interest to develop highly stereocontrolled asymmetric Reformatsky reactions. To date, high diastereoselectivities could be achieved only in a few cases either by substitution of zinc with other metal salts[288,289,290] or by addition of chiral (*see Chiral*) ligands.[294]



(79)

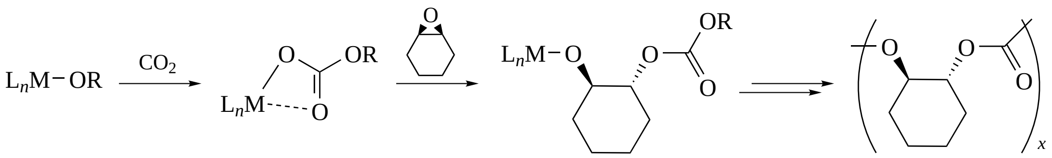
6.9 Oligomerization and Polymerization (*See Oligomerization & Polymerization by Homogeneous Catalysis*)

Organozinc compounds are efficient catalysts in the polymerization of vinylic monomers, but they have found more applications as catalysts/initiators for ring opening polymerization of heterocyclic monomers[295] such as lactides,[296] lactones, and epoxides[297] (Scheme 32). The organozinc derivatives are usually combined in various stoichiometries with cocatalysts like water, alcohols, carboxylic acid, or amines. The active catalysts are proposed to be complexes with general formula L_nZnX, where X is an active initiating group such as OR, NR_2, or alkyl, and L_n is a ligand that coordinates the Zn^{II} center. As shown in Scheme 32 for the copolymerization of CO_2 and epoxides and in Scheme 33 for the polymerization of lactides, it is generally accepted that the reaction occurs via coordination of a monomer to the coordinatively unsaturated zinc center of the catalyst, followed by insertion (*see Insertion*) into the Zn–X bond.

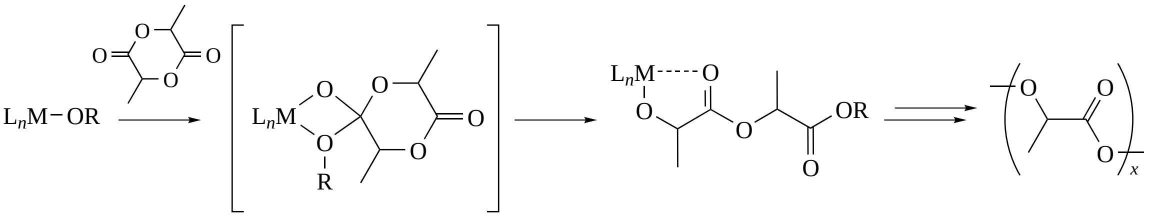
During the last decade, the design and synthesis of new ligands for specific polymerization reactions has been the focus of much interest. Among the different ligands tested so far, β-diiminates (see Section 3.4.1) have shown the highest activity reported for the copolymerization of CO_2 and epoxides.[179]

When chiral (*see Chiral*) complexes are used as catalysts, they can exhibit some diastereoselectivity. For example, optically active polycarbonates have been prepared by asymmetric copolymerization of cyclohexene oxide and carbon dioxide in the presence of a mixture of Et_2Zn and a chiral amino alcohol[298] (Scheme 34). Even achiral complexes have been found to exhibit some diastereoselectivity in polymerization reactions. For instance, monomeric Zn^{II} complexes with tris(pyrazolyl- and indazolyl-)hydroborate ligands (see Section 3.4.2) polymerize preferentially *meso*-lactide over D-lactide and L-lactide in CH_2Cl_2 at 22 °C.[299] The compound EtZnN(*t*-Bu)ZnEt, which is easily prepared by reaction of Et_2Zn with *t*-$BuNH_2$, was found to be an excellent catalyst for the stereospecific polymerization of propylene oxide.[300]

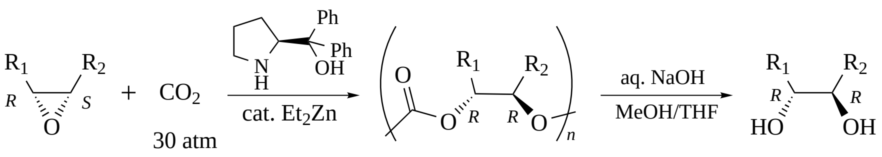
The construction of chiral (*see Chiral*) zinc complexes in order to perform stereoselective polymerizations has



Scheme 32



Scheme 33



Scheme 34

been recently undertaken by Chakraborty and Chen.[301] They have found that the tetranuclear complex $\{(\pm)$-*trans*-$Cy(NSiMe_3)_2\}_2Zn_4Et_4$ and the dinuclear complex $\{(\pm)$-*trans*-$Cy(NHSiMe_3)(NSiMe_3)\}_2Zn_2Et_2$ are obtained in good yields from the reaction of racemic $(\pm)$-*trans*-1,2-$(NHSiMe_3)_2$-cyclohexane ($(\pm)$-trans-cy$(NHSiMe_3)_2$) with two equiv of Et_2Zn and one equiv of Et_2Zn, respectively. In both cases, only one diastereomer was formed and its molecular structure determined by X-ray crystallography (Figure 66). Whereas the two complexes were shown to be efficient initiators for polymerization of ϵ-caprolactone and L-lactide, only the tetranuclear complex was efficient for the polymerization of methyl methacrylate upon activation with $Al(C_6F_5)_3$.

Cationic organozinc compounds are expected to be good catalysts for ring opening polymerization reactions of epoxides and lactones because the enhanced Lewis acidity (*see Lewis Acids & Bases*) of the zinc center favors its coordination to the monomer. For example, Walker and coworkers have found that the cationic zinc substituted cyclopentadienyl complex $[3,5\text{-}Me_2C_6H_3CH_2CMe_2C_5H_4Zn(TMEDA)]^+ [EtB(C_6F_5)_3]^-$ is an active initiator species for the polymerization of cyclohexene oxide and ϵ-caprolactone.[302]

6.10 Reactivity of *Gem*-Dimetallic Species

Organo-*gem*-dimetallic compounds that possess two nucleophilic (*see Lewis Acids & Bases*) sites on one carbon atom

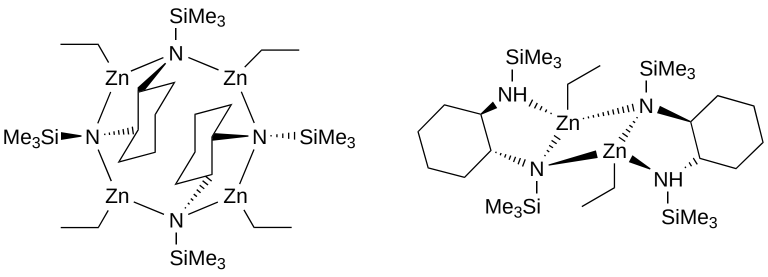


Figure 66 Structures of $\{(\pm)$-*trans*-$Cy(NSiMe_3)_2\}_2Zn_4Et_4$ and $\{(\pm)$-*trans*-$Cy(NHSiMe_3)(NSiMe_3)\}_2Zn_2Et_2$

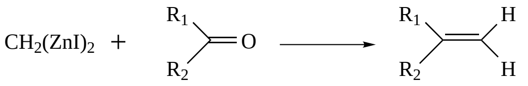
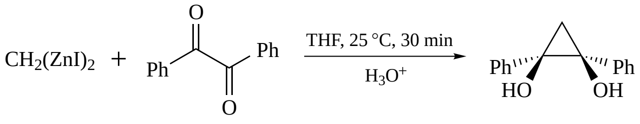
can undergo multiple transformations in one-pot reactions and form two new C–C bonds. This is particularly attractive for organic chemists who need new strategies with a minimum of chemical steps for the building of complex molecules. In recent years, *gem*-dizincio reagents in particular have been the focus of much interest because their relative stability and moderate reactivity, compared to the related *gem*-dilithio and -dimagnesio derivatives, permit the control of both chemoselectivity and stereoselectivity during the transformations. The synthesis and synthetic applications of 1,1-sp^3 and 1,1-sp^2 organodimetallic derivatives have been specifically covered in two different reviews.[245,246]

The simplest *gem*-dizincio alkane bis(iodozincio)methane [$CH_2(ZnI)_2$] reacts with aldehydes, and with ketones in presence of a suitable activator or catalyst, to produce the corresponding olefinated compounds in good yields (equation 80). It has been shown that the nucleophilicity of the zinc atom in $CH_2(ZnI)_2$ can be enhanced by coordination of a heteroatom from a ligand or a solvent. Substrates which contain a suitably placed donor atom also lead to activation. For example, 1,2-diketones (*see Diketones*) such as benzil (PhCO-COPh) undergo efficient [2+1] cycloaddition reactions with $CH_2(ZnI)_2$[303] (equation 81). The reaction is stereoselective, leading only to *cis*-diol derivatives.



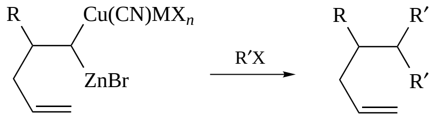
(80)

$R_1 = R_2$ = Alkyl or R_1 = H, R_2 = Alkyl



(81)

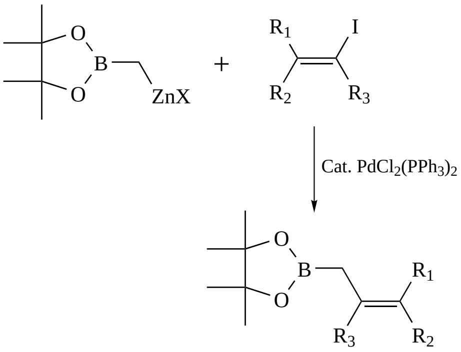
Substituted *gem*-dimetallic compounds, readily obtained via allylation of alkenyl organometallics, react with aldehydes in the presence of $BF_3{\cdot}Et_2O$ but do not react with ketones. When alkylidenemalonates are used instead of aldehydes, the Z-olefins (*see (E) & (Z) Isomers*) are obtained with a very high stereoselectivity (Scheme 35). A transmetallation reaction with copper cyanide significantly increases the reactivity of *gem*-dimetallic derivatives via formation of 1,1-zinca cyanocuprates. Indeed, when these compounds react with alkylating or allylating reagents, they give products of double alkylation or allylation (equation 82).



(82)

MX_n = ZnBr, Li, MgBr
R′X = Me_3SnCl, MeI, $CH_2{=}CHCH_2Br$

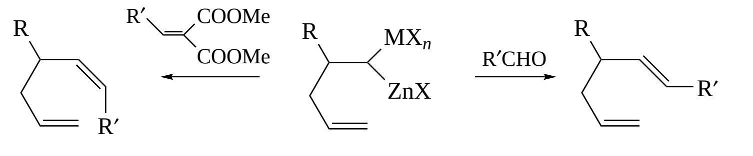
When *gem*-dimetallic reagents contain zinc and a metal of different nature MX_n (MX_n = MgBr, Li), they can react successively with two different electrophiles (*see Electrophile*) E_1^+ and E_2^+, with the more reactive C–M bond reacting first (Scheme 36). Consequently, the vinylation of 1,1-borio zincioalkanes, catalyzed by Pd^{II} salts, is an excellent procedure for the preparation of reactive allylboranes (equation 83).



(83)

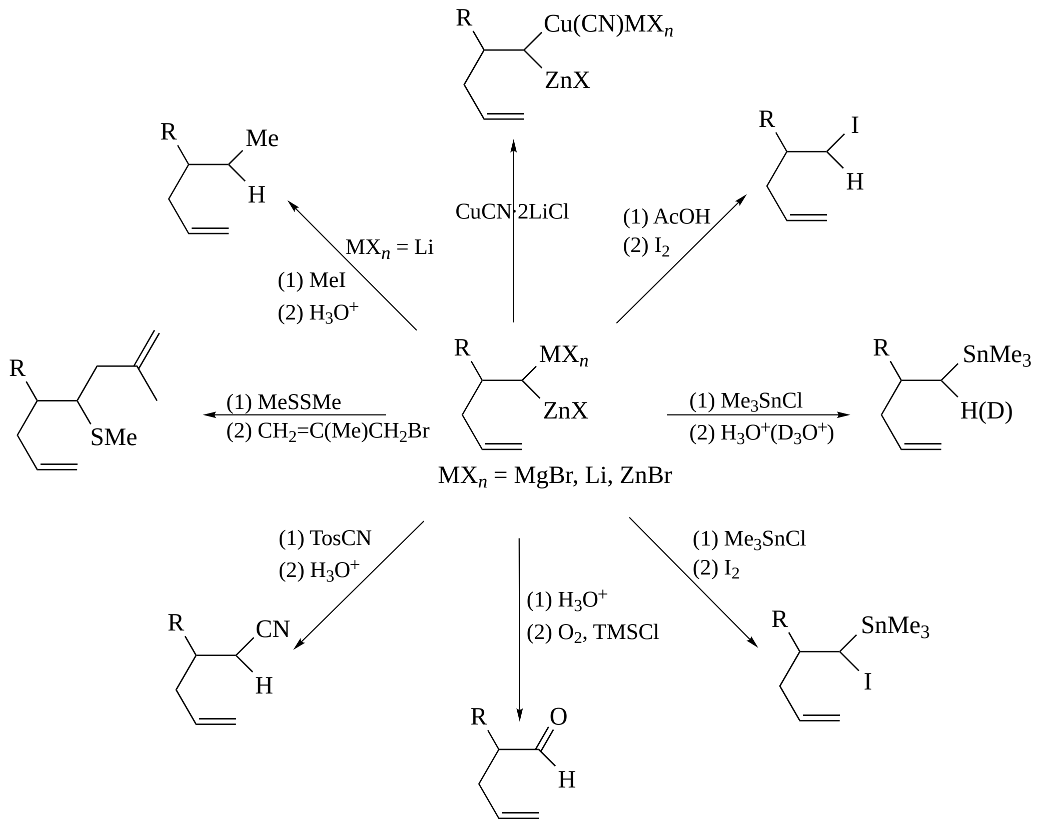
A strong intramolecular chelation (*see Chelate Effect*) of a donor group to one of the zinc atoms leads to a good selectivity between the two metallic centers in sequential addition reactions, and also leads to a good diastereoselective reactivity of the organo-*gem*-dimetallics. As seen in Section 5.1 concerning allylmetalation of vinyl organometallic compounds, the intramolecular coordination of a basic atom (sulfur < oxygen < nitrogen) to the metal of the starting vinyl reagent allows the creation of two stereogenic centers in the resulting *gem*-dimetallic derivatives. Thus, a third stereogenic center can be produced by diastereoselective reactivity of the two metals (Scheme 37). Nevertheless, it was shown that the stereoselectivity depends strongly on the nature of the first electrophile (*see Electrophile*) used.

When the intramolecular chelating group (*see Chelating Ligands*) is a methoxy-methyl-ether (MOM) in γ-position, an

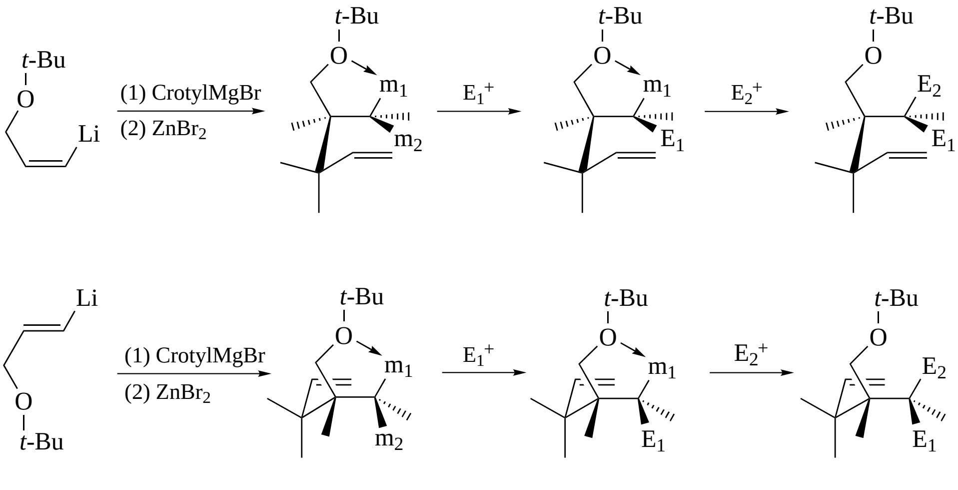


Z = 100% MX_n = MgBr, ZnBr E/Z = 92/8 to 99/1

Scheme 35

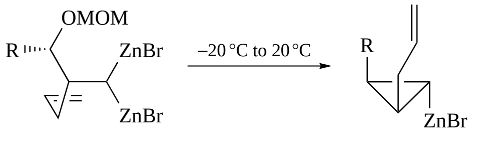


Scheme 36



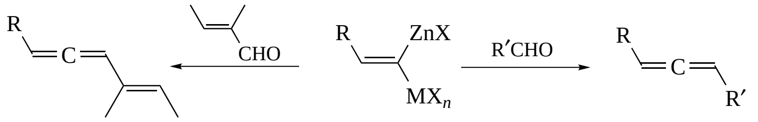
Scheme 37

internal nucleophilic substitution occurs at room temperature and products of cyclopropanation are obtained in good yields (equation 84).

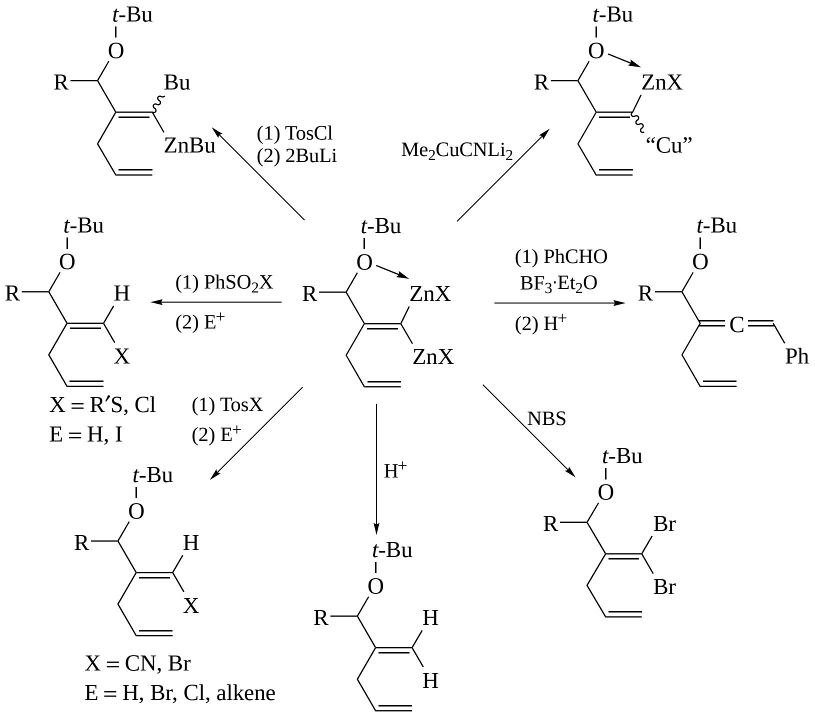


(84)

The reactivity of *gem*-dizincioalkenes (prepared by metal allylation of alkynyl metals (see Section 5.1)) with aldehydes leads to the corresponding allene derivatives in moderate yields (Scheme 38). As already seen for *gem*-dizincioalkanes, an internal chelation of the 1,1-dimetalloalkene with a Lewis functional group allows differentiation of the reactivity of the two metal centers towards electrophile (*see Electrophile*) reagents. Scheme 39 summarizes the reactivity



Scheme 38



Scheme 39

of 1,1-dizincioalkene compounds containing a *tert*-butylether group in γ-position.

gem-Dizincioalkenes derivatives containing a suitably placed alkyl halide group can also be used for the synthesis of cyclobutene and cyclopentene compounds via intramolecular (*see Intramolecular*) nucleophilic substitution reactions (equation 85).

Homoatomic: same element
Pnictide: group 15 anion
Pnicogen: group 15 element

Abbreviations

A^I = Alkali metal; A^{II} = alkaline earth metal; en = Ethylenediamine; crypt = 4,7,13,16,21,24-hexaoxa-1,10-diazatricyclo[8.8.8]hexacosane; Pn = Group 15 element (pnicogen).

1 INTRODUCTION

Zintl phases make up a class of compounds which are electronically positioned between the class of intermetallic compounds and insulating valence compounds.[1] These compounds are made up of electropositive elements from groups 1, 2 that, in a formal sense, donate their electrons to the electronegative elements from groups 13, 14, and 15, which use them to form the correct number of bonds such that each element has a filled shell. A more succinct definition of Zintl compounds is that they are normal valence compounds in which there is both ionic and covalent bonding. If the anionic units have enough electrons, they will form isolated anionic atoms. If there are not enough electrons to provide a closed shell of electrons (eight total for a main group element), then the main group element forms two-center–two-electron bonds. Zintl compounds are normally considered to be semiconductors, although the class also includes compounds whose structures can be described by the Zintl concept and are metallic. Pearson[2] classifies these as a subset of intermetallics that obey the rules of valence; however, they are better classified as Zintl phases.[3] Because of the ionic nature of bonding between the cations and anions in Zintl compounds, they are soluble in polar, basic solvents. Anionic clusters of the heavier main group elements isolated from reactions of Zintl phases are known as Zintl anions.[4,5] The reactivity of these anions has been explored and this work has produced new cluster compounds[6–12] as well as novel materials.[13–18]

The description of bonding within these compounds has been treated by several different approaches that come to the same conclusion. The $(8 - N)$ rule that is generalized by Mooser and Pearson[19–21] uses a covalent model with collective counting of electrons. The generalized $8 - N$ rule can be easily defined for simple binary compounds of the general formula, M_mX_x as $8x$ electrons are required in order to achieve the octet shells for the x X atoms. The valence electron count, VEC(X) can be defined as the total number of all valence electrons in relation to the number of the anionic atoms: $\mathrm{VEC(X)} = [m{\cdot}\mathrm{e(M)} + x{\cdot}\mathrm{e(X)}]/x$, where an M atom has e(M) valence electrons. If covalent bonds exist between M atoms, the M atoms cannot donate all of their electrons and if covalent bonds exist between X atoms, the X atoms require fewer electrons. Typically, there are no bonds between M for a Zintl phase, and bonds are formed between X. The number of bonds, b(XX), can be accounted for in the equation and results in the equation: $\mathrm{b(XX)} = 8 - \mathrm{VEC(X)}$.[22] Zintl[23] and Klemm[24] examine local configurations in a setting of formal ions. Once the formal charges are assigned, the anionic lattice can be described as a pseudoelement that exhibits structural chemistry closely related to the isoelectronic element. The definition of a Zintl phase has undergone several revisions and has been expanded to include ternary[25–27] and transition metal compounds.[27–32] Although the bonding description originally proposed by Zintl has been augmented and is sometimes referred to as the Zintl-Klemm concept,[33] or Zintl-Klemm-Busmann concept,[25] the term Zintl concept is generally considered to be inclusive of those revisions. For transition metals, an estimation of the number of electrons which are localized on the metal and do not take part in the bonding must be considered, as described by Pauling.[34] Since bonding descriptions are effective only to the extent that they adequately relate structure and properties, only those transition metal compounds that are understood according to the Zintl model will be described herein. The reactivity and uses of Zintl phases for the synthesis of Zintl ions, new compounds, and novel materials by means of solution chemistry will also be presented.

2 BACKGROUND

Compounds of alkali and alkaline earth metals with elements of groups 16 and 17 are usually described as ionic compounds or salts with respect to their physical and chemical

properties, as well as their structures. The compounds with elements of groups 14 and 15 become increasingly metallic with increasing atomic number of the electronegative element and occur in stoichiometries not readily described by valence rules.[20] Many of these compounds were thought to be best classified as intermetallics. Hume-Rothery phases are certain alloys with the structures of different types of brass. Hume-Rothery found that valence electron concentration (number of valence electrons)/(number of atoms) dictated the structure. Shortly after the presentation of the Hume-Rothery rules concerning the relationship of electron concentration to crystal structure in intermetallic phases,[35] Eduard Zintl proposed that a subgroup of the intermetallic compounds were, in fact, not well represented within the descriptions of intermetallic phases. Zintl had prepared a number of alkali and alkaline earth metal groups 13, 14, and 15 binaries and investigated their structures.[23] The majority of these phases adopt the β-brass structure, while some crystallize in the NaTl structure type, both derivatives of the W structure. Hume-Rothery rules predicted an optimal electron concentration of $3/2e^-$ per atom for compounds crystallizing in this structure type, but most of these compounds show electron concentrations of $(1-5/2)e^-$ per atom. In addition, for these phases, significant contraction of the volume compared to the volume of the elements occurs; this is attributed to the ionic interactions between the electropositive and electronegative element that forms the correct number of homoatomic bonds, such that each element has a complete octet. The prototype Zintl compound, NaTl, could be described by Na^+Tl^-, where the polyanion or Zintl anion ${}^3{}_\infty[Tl^-]$ forms a diamond framework. ${}^3{}_\infty[Tl^-]$ can be thought of as a pseudoelement of group 14, recognizing that the diamond structure is a preferred structure type for this element. Laves listed all the intermetallic compounds whose structures were known in 1941 that obeyed the rules of valence under the heading ‘Zintl phases’, in recognition of Zintl’s contribution to the study of these compounds.[36]

The ability of Zintl compounds to dissolve in coordinating solvents such as ammonia and ethylenediamine (en) is another property that sets these compounds apart from intermetallics. At the same time that much of this investigation of the solid state was occurring, several scientists, including Zintl, also were studying the solution chemistry of alkali metals in liquid ammonia with a variety of the heavy main group metals.[4,5] Electrochemical investigations indicated that there existed discrete anion clusters in these solutions and provided the first evidence for the so-called Zintl ions. The isolation of a solid derivative of a Zintl anion was first accomplished by Kummer and Diehl[37] with the compound, $Na_4Sn_9{\cdot}7en$. A large advance was made in this area by the use of crypt to sequester the cation and this allowed the isolation of a number of salts containing Zintl anions. Many of these solvated Zintl anions have been isolated and their structures determined. In addition, many have been used as precursors for the synthesis of new organometallic compounds, in the metallization of polymer substrates, and in the synthesis of novel magnetic colloids. The classification of Zintl ions is normally limited to polyatomic anions of the metals of groups 14 and 15.[4,38]

3 STRUCTURE AND BONDING

3.1 Solid-state Binary Compounds

Laves proposed that all intermetallic compounds that obeyed valence or the $(8-N)$ rule should be classified as Zintl compounds. These alkali and alkaline earth main group compounds typically crystallize in salt-like structures such as antifluorite, *anti*-Mn_2O_3, and *anti*-La_2O_3. For example, the compounds $A^I{}_3Pn$ or $A^{II}{}_3Pn_2$ can be formed; they consist of isolated A cations and Pn anions. The corresponding situation occurs for group 14 only with some of the alkaline earth cations. The term ‘isolated’ is used to describe atoms that do not form part of a polyatomic unit; the distance to another atom of the same type is too large to be considered a bond. Although these structures can be described as salt-like, the atoms have high coordination numbers typical of metals and the heavier groups 14 and 15 compounds are metallic. Many of the $A^I{}_3Pn$ compounds have the hexagonal Na_3As (*anti*-LaF_3) structure in which equal numbers of Na and As form hexagonal nets (as in boron nitride) and the remaining Na atoms are arranged in layers on either side of these nets. Each As has five neighbors at the corners of a trigonal bipyramid and six other Na atoms tin a trigonal prismatic arrangement, making the total coordination number of As to be 11. The Na atoms have two types of environment. The Na in the NaAs net has three As atoms and six Na atoms, whereas the Na in between the nets has four As and six Na nearest neighbors. Binary compounds with lithium have been excluded because in many cases they show unique behavior with respect to their structure and stoichiometries.[33] Table 1 gives some examples of binary Zintl compounds with salt-like structures.

The prototype Zintl compounds are those with the NaTl structure type. As more X-ray structure analyses were performed, the number of structure types that could be interpreted in such as manner increased. Klemm and Busmann[39] formalized this interpretation: the electropositive element transfers electrons to the electronegative element, which then uses these electrons to form an anion partial lattice that resembles the elemental lattice with the same number of valence electrons. The coordination in the anion partial lattice analogy conforms to the $(8-N)$ rule. In many of these structures, an analogy to the corresponding elemental lattices can be made. By obtaining one electron from an alkali metal, the group 13 elements can form a diamond lattice and are isostructural (and isoelectronic) with the corresponding group 14 elements. There has been a significant amount of research on the composition and properties of compounds that crystallize in the NaTl structure type.[40] These compounds show properties that are characteristic of covalently bonded

Table 1 Structure types of binary solids with salt-like structures[a]

	P	As	Sb	Bi
Li	Na_3As	Na_3As	Na_3As, Li_3Bi	Li_3Bi
Na	Na_3As	Na_3As	Na_3As	Na_3As

Ba	*anti*-$PbCl_2$	*anti*-$PbCl_2$	*anti*-$PbCl_2$	*anti*-$PbCl_2$

[a] – , compound unknown; ?, structure unknown.

compounds, although it has been shown that there are deviations in stoichiometry that give rise to metallic behavior. In addition to the example given above, further comparisons between polyatomic anions found in Zintl compounds and the isoelectronic elements can be made. For example, in the case of NaSi,[41] the Si is given a formal charge of −1. The structure contains isolated $(Si_4)^{4-}$ tetrahedra that are isoelectronic and isostructural with P_4. Figure 1 shows a view of the unit cell. In addition, there are compounds whose anion lattices are not isosteric with elemental lattices having the same number of valence electrons. However, the coordination of the anion partial lattice conforms to the (8 − N) rule and thus can be described by normal valence rules. Table 2 gives a partial listing of some compounds obeying this rule.

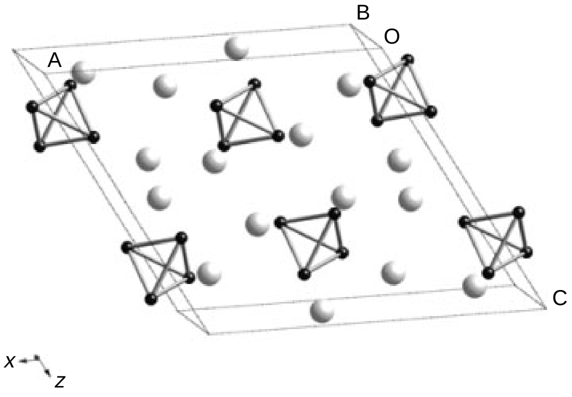

Figure 1 A view of the unit cell for NaSi showing the $Si_4{}^{4-}$ tetrahedral

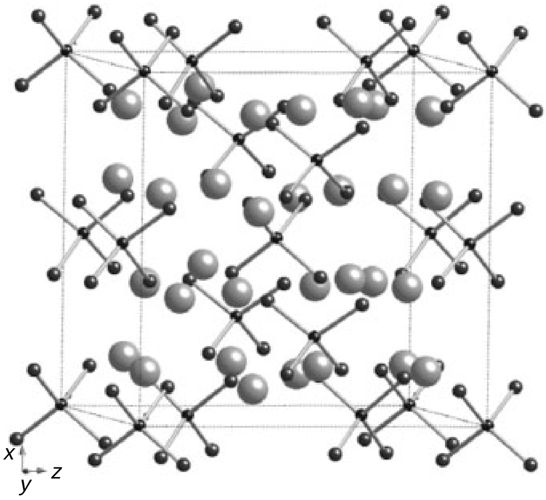

Figure 2 The structure of Ba_4SiAs_4

3.2 Solid-state Ternary Compounds

The structure and bonding of ternary compounds can also be described within the Zintl concept. Some ternary Zintl compounds have structures that can be described as complex salts. For example, Ba_4SiAs_4,[42] whose structure is shown in Figure 2, is composed of $SiAs_4{}^{8-}$ tetrahedra whose charge is balanced by the alkaline earth cation. Such isolated tetrahedra are also formed with group 13 atoms in combination with group 14 or group 15 atoms. There are discrete $GeAs_4{}^{8-}$, $GeP_4{}^{8-}$, and $SiP_4{}^{8-}$ tetrahedra in this structure type whose charges are balanced by the alkaline earth cations. The term orthophosphido- or orthoarsenidosilicates or -germanates has been used to describe these anions because they are isoelectronic with the ordinary silicate ($SiO_4{}^{4-}$), with the O^{2-} ions being replaced by As^{3-} or P^{3-} ions.[27] According to the (8 − N) rule, Ge or Si is given a formal charge of zero and the As or P is assigned a formal charge of −2, giving rise to the overall charge of −8 on the polyatomic unit. The compound $A^I{}_2SiAs_2$ (A^I = K, Rb, Cs)[43–45] can be prepared and is composed of anionic chains of ${}^1{}_8[SiAs_{4/2}{}^{2-}]$ (edge-sharing tetrahedral) (Figure 3). The anionic lattice is isoelectronic and isostructural with SiS_2.

Synthesis with cations of different sizes provides two new structures in the system A^{II}–Si–As: $Sr_3Si_2As_4$ and $Ca_3Si_2As_4$, Figures 4 and 5[46,47] These two structures contain Si_2As_6 units that are linked in different ways. The Si_2As_6 anions found in $Sr_3Si_2As_4$ are connected by a common edge as shown in Figure 4 and can be described by the notation ${}^1{}_\infty[(SiAsAs_{2/2})_2{}^{6-}]$. In the case of $Ca_3Si_2As_4$, one of the Si has all three of the As bonded to another Si_2As_4 unit, whereas the Si in the other half has only one As bonded to another Si_2As_4 unit (Figure 5). The anionic unit can be described as consisting of ${}^1{}_\infty[As_2As_{1/2}SiSiAs_{3/2}{}^{6-}]$ chains. Many of these ternary compounds are classified as Zintl compounds. However, few transport properties have

Table 2 Examples of binary compounds obeying the Zintl concept

N	Compound	Formal charge	Coordination	Structure of anion lattice	Structure type
4	LiAl	−1	4	Diamond	NaTl
	LiIn				NaTl
	NaIn				NaTl
	$CaIn_2$			3D network of distorted tetrahedrally coordinated atoms	$CaIn_2$
	$SrTl_2$				$CaIn_2$
	$SrAl_2$				KHg_2
5	NaSi	−1	3	P_4 (isolated X_4 tetrahedra)	NaSi
	KSi				KGe
	RbGe				KGe
	CsSn				NaPb
	CsPb				NaPb
	$SrGe_2$				$BaSi_2$
	$CaSi_2$			As (layers of infinite puckered hexagonal networks)	$CaSi_2$
	$SrSi_2$			3D network of 3-coordination Si atoms	$SrSi_2$
6	CaSi	−2	2	Planar zigzag chains	CrB
	BaSn				CrB
	LiP			Se (spiraled chains)	LiAs
	KSb				LiAs

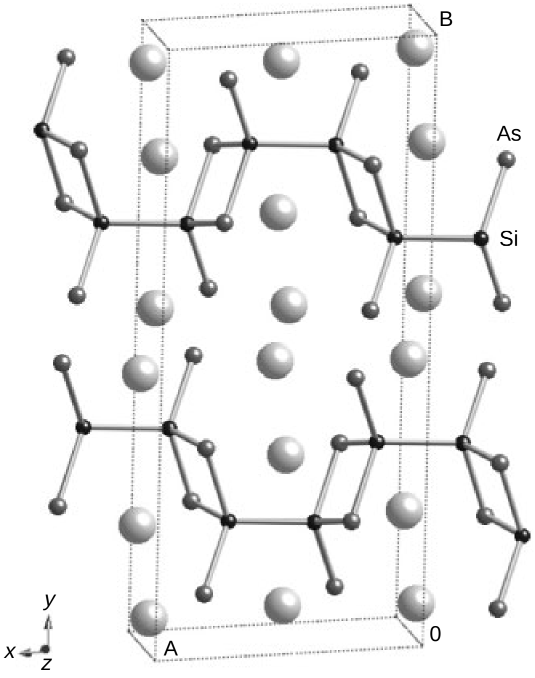

Figure 4 A view of the structure of $Sr_3Si_2As_4$ showing the $^1_\infty[(SiAsAs_{2/2})_2{}^{6-}]$ chains

been measured, because their structures can be interpreted according to the (8 − N) rule. Table 3 gives a partial listing of ternary Zintl phases with complex anions.[25–27,48,49] In addition, exploring the Zintl boundary has led to the discovery of novel cluster solid-state compounds.[5,50]

3.3 Transition Metal Zintl Compounds

The Zintl concept has been extended to include transition metal compounds, with some success.[1,18,28,31,32,51,52] Although many main group metal Zintl compounds are known,[25–27,33] there are relatively few examples of isostructural transition

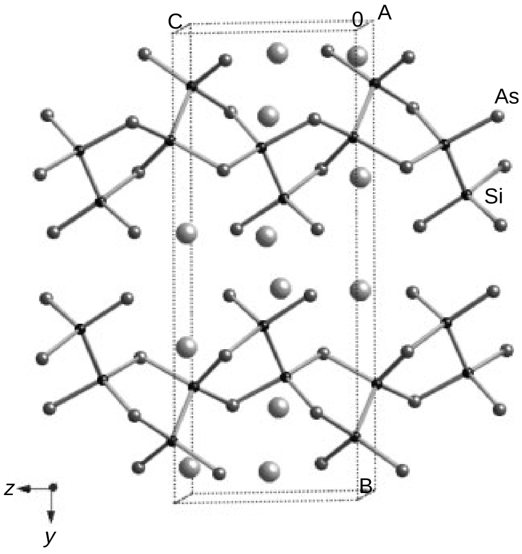

Figure 5 A view of the structure of $Ca_3Si_2As_4$ showing the ${}^1_\infty[(As_2As_{1/2}SiSiAs_{3/2})^{6-}]$ chains

Table 3 Examples of ternary compounds obeying the Zintl concept

Compound	Structure of anion lattice	Structure type
Ba_4SiAs_4	$SiAs_4{}^{8-}$ isolated tetrahedra	Ba_4SiAs_4
Ba_4GeAs_4		
$Ca_3Si_2As_4$	${}^1_\infty[As_2As_{1/2}SiSiAs_{3/2}{}^{6-}]$ chains	$Ca_3Ge_2As_4$
$Sr_3Ge_2As_4$		
$Sr_3Si_2As_4$	${}^1_\infty[((SiAsAs_{2/2})_2)^{6-}]$ chains	$Sr_3Si_2As_4$
$BaGe_2As_2$	${}^3_\infty[(Ge_2As_2)^{2-}]$ 3D network	$BaGe_2As_2$
Ca_3AlAs_3	${}^1_\infty[(AlAs_2As_{2/2})^{6-}]$ chains	Ca_3AlAs_3
Sr_3GaSb_3		
$Ca_3Al_2As_4$	${}^2_\infty[(AlAs_{4/2})_2{}^{6-}]$ layers	$Ca_3Al_2As_4$
$Ca_5Al_2Sb_6$	${}^1_\infty[(AlSbSb_{2/2}(Sb_2)_{1/2})_2{}^{10-}]$ chains	$Ca_5Al_2Sb_6$

$Ca_{11}InSb_9$	$InSb_4{}^{9-}+Sb_2{}^{4-}+$ isolated Sb^{3-} anions	$Ca_{11}InSb_9$
$Ca_{11}AlSb_9$		

metal analogs. Some transition metal sulfides have been described by the Zintl rules.[28] Binary and ternary transition metal complexes with metals having filled d orbitals can also be described according to the Zintl concept, although inclusion of the d orbitals complicates the bonding description.[28] The Zintl concept has also been used to explain the structure and properties of ternary transition metal pnictides crystallizing in the $ThCr_2Si_2$ structure type.[51,52] Two structure types that appear to be amenable to having a transition metal replacing the main group metalloid are the $A^{II}{}_{14}MPn_{11}$ (M = Al,[53,54] Ga,[55,56] In,[57] Mn,[30–32] Zn,[58] Nb,[59] and Pn = P, As, Sb, Bi) compounds and the $A^{I}{}_5MPn_3$ (M = Si, Ge,[60] Sn, Hf[61]) compounds. There have also been a number of new transition metal Zintl phases prepared which have no structure type equivalent to the main group elements, but appear to be valence precise and semiconducting.[62–67]

The structure and bonding in the $A^{I}{}_5HfPn_3$ can be easily understood in terms of the Zintl rules, since the Hf is formally a +4 ion. In this structure, two $HfAs_4$ tetrahedra are connected by a common edge to form $(Hf_2As_6)^{10-}$ anions. The structure and bonding in the $A_{14}MPn_{11}$ series of compounds is more complicated. In the framework of the Zintl rules, the structure of these compounds, $A_{14}MPn_{11}$ can be understood as consisting of 14 A^{2+} cations, four Pn^{3-} anions, a $MPn_4{}^{9-}$ tetrahedron, and a linear $Pn_3{}^{7-}$ unit. Figure 6 shows a perspective view of the unit cell. The $Pn_3{}^{7-}$ unit is well described as a three-center-two-electron bond and is isoelectronic with $X_3{}^-$ (X = halogen)[68] (*see* ***Hypervalent Compounds***). These compounds are isostructural with the main group Zintl compounds, and so the transition metal Mn has been proposed to be Mn^{3+}.[30–32] A more recent understanding of the bonding has recently lead to a different picture with the Mn better considered to be formally Mn^{2+}.[69,70] In this view, the charge counting of the tetrahedron can be explicitly stated as $[Mn^{2+}\ (Sb_4)^{11-}]$ rather than $[Mn^{3+}\ (Sb_4)^{12-}]$. In either description, the paramagnetic temperature-dependent magnetic susceptibility data is consistent with four unpaired electrons. However, this electronic structure leads to unusual magnetic and electronic transport properties (*see* ***Magnetism of Transition Metal Ions***).[32]

Recent publications on other transition metal Zintl phases[62–67] suggest that this is a rich area for study with applications for magnetic and electronic devices.

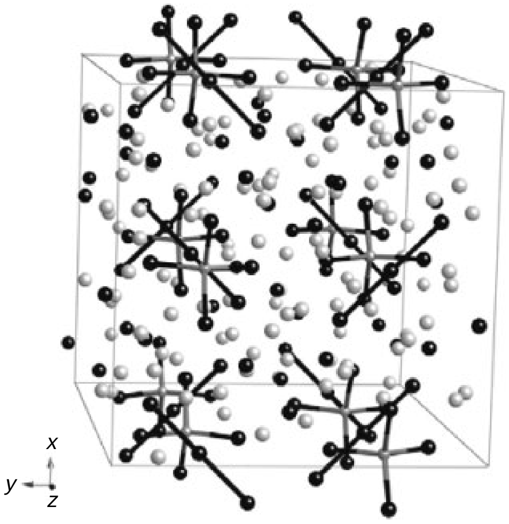

Figure 6 A perspective view of the structure of $A_{14}MPn_{11}$

3.3.1 *Zintl Ions*

This subtopic of Zintl compounds relates to those homo- and heteropolyanions that have been isolated and characterized. Although clusters containing the heavier group 16 chalcogenides, such as Se and Te, are sometimes considered to be Zintl anions, those compounds are not considered here. Chalcogenides have extensive cluster chemistry and are traditional anions. It has been known for some time that sodium and lead or their alloys dissolve in liquid ammonia to yield an intensely colored green solute.[71] Electrochemical investigations of these solutions led to the hypothesis that the Pb exists as Pb_9^{4-} in solution.[72] Zintl and coworkers extensively studied these types of solutions and were able to identify Sn_9^{4-}, Pb_7^{4-}, Pb_9^{4-}, Sb_5^{3-}, Sb_7^{3-}, Bi_3^{3-}, Bi_5^{3-}, and Bi_7^{3-}.[73] However, structural studies were not possible owing to decomposition of the solids isolated by solvent evaporation. There was little work in this area again until 1970, when several Zintl anions were isolated from ethylenediamine (en) solutions.[4,38] A structural study of one of these compounds, $Na_4Sn_9{\cdot}7en$, showed a Sb_9 polyhedron.[37] Two other compounds, $Na_3Sb_7{\cdot}4en$ and $Na_4Ge_9{\cdot}5en$, were prepared by this method.[74] A significant number of Zintl anions were discovered by the use of a *Macrocycle*, crypt, to stabilize the polyatomic anions, which allowed for their isolations and structural characterization. In addition, heteropolyatomic anions are also possible and have been synthesized and characterized. Table 4 gives some examples of Zintl anions that have been structurally characterized.

3.3.2 *Reactivity*

Incorporation of transition metals into the Zintl anions described above has been somewhat successful, although in many cases, the emphasis has been on the solution chemistry of the metal chalcogenides. The heavier group 14/15 anion clusters, such as Sn_9^{4-}, Sb_7^{3-}, and As_{11}^{3-}, have received much less attention but have proved to be equally interesting.[38,50] More recently, there has been renewed interest in exploring Zintl ions prepared from dissolving Zintl phases with an aim towards understanding cluster growth and the solution chemistry of these phases.[10,11,38,75–77]

Table 4 Examples of Zintl anions

Anion	Symmetry	Isoelectronic analog
Ge_9^{2-}	C_{2v}	$B_9H_9^{2-}$
Ge_9^{4-}	C_{4v}	Bi_9^{5+} (D_{3h})
Sn_9^{4-}	C_{4v}	Bi_9^{5+} (D_{3h})
Sn_9^{3-}	D_{3h}	
Sn_5^{2-}	D_{3h}	Pb_5^{2-}, Bi_5^{3-}
Sb_4^{2-}	D_{4h}	Bi_4^{2-}, $Pb_2Sb_2^{2-}$, Te_4^{2+}, Se_4^{2+}
As_{11}^{3-}	$\sim D_3$	P_{11}^{3-}
Sb_7^{3-}	C_{3v}	As_7^{3-}
$Sn_2Bi_2^{2-}$	$\sim T_d$	
$Tl_2Te_2^{2-}$	C_{2v}	
$TlSn_8^{3-}$	C_{2v}	Ge_9^{2-}
$TlSn_9^{3-}$	C_{4v}	$B_{10}H_{10}^{2-}$

The reactivities of the binary Zintl compounds have been explored for the synthesis of new compounds.[78] There have been new compounds prepared by the reaction of Zintl phases with a metal or metal carbonyl to produce new compounds such as $[Rb(NbAs_8)]^{2-}$.[6] The compounds contains chains of alternating Rb^+ cations and $[NbAs_8]^{3-}$ units that each consist of a monocyclic crown shaped polyanion As_8^{8-} with a Nb^V ion in the center. More recently, the series of compounds with ME_8^{n-} anions (M = Cr, Mo; E = As, Sb) have been crystallized and their properties explored.[79] $Sn_9Cr(CO)_3^{4-}$ was prepared by reacting $Cr(CO)_3(Mes)$ with a deep red en extract of K_4Sn_9. The crystals were isolated by the use of the crypt complexing agent to give $[K(crypt)_4][Sn_9Cr(CO)_3]$.[8] The structure consists of a *nido*-Sn_9^{3-} cluster (isoelectronic and isostructural with $B_{10}H_{10}^{2-}$) which is bonded in an η^4 fashion to the $Cr(CO)_3$ fragment. $As_7Cr(CO)_3^{3-}$ can be prepared in an analogous manner as described above from a Zintl phase dissolved in en and a metal carbonyl.[9] The structure consists of an open As_7 cage that is bound in an η^4 fashion to the $Cr(CO)_3$ fragment.

Reactions of metal carbonyls with Zintl phases do not always yield the desired result. An example is the reaction of KSi with the metal carbonyls $M(CO)_6$ (M = Cr, Mo, W) and the chromium complex $Cr(CO)_5NMe_3$.[80] Instead of forming a structure with a Si_4 anion, KSi reduces these transition metal compounds to form the anions, $[M_2(CO)_{10}]^{2-}$. In addition, certain organometallic transition metal clusters have been synthesized that contain Zintl anions coordinated to the metal,[81–84] but Zintl compounds are not used as the reagents.

The salt-like description of bonding between the cations and polyatomic anions of Zintl compounds adequately accounts for their solubility in polar solvents. As mentioned above, a large number of binary Zintl compounds will dissolve in ammonia or amine solvents. Some Zintl phases will even dissolve in methanol (e.g. K_4SnTe_4).[15] These Zintl anions have been studied in solution and can react with transition metal cations to give new intermetallic phases. The reaction consists of electron transfer from the Zintl polyanion to the transition metal cations, resulting in the rapid precipitation of the neutral solid product. The intermetallic solids formed by this route are often amorphous and metastable. Using this simple metathesis reaction with, for example, K_4SnTe_4, a series of ternary transition metal chalcogenides of the formula M_2SnTe_4 (M = Cr, Mn, Fe, Co, Ni, and Cu) have been synthesized and characterized.[15,17] In addition, the compounds $M_5(InTe_4)_2$ (M = Cr, Mn, Fe, Co, and Ni) have been synthesized and characterized.[85–87] These materials exhibit remarkable properties, including a spin glass transition at temperature ranging from 5 to 18 K.

Zintl ion solutions have been explored for the metallization of polymers.[14] Oxidizing polymers such as polyimide can be topochemically metallized by reaction with Zintl ion solutions.

In addition, the reactivity of Zintl ion solutions with layered materials have been reported. Solutions of K_4Sn_9 in en reduce graphite and HfTe; the potassium is intercalated into the structure and tin metal is deposited on the edges of the layered substrate.[13]

More recently Zintl phases have been used to prepare novel semiconducting phases such as nanocrystals.[7,88–90] Group IV nanoparticles have been prepared either by metathesis route or an oxidation of a binary Zintl phase.

4 CHARACTERIZATION

The results of X-ray crystal-structure determinations have assumed great significance in discussions of the bonding in these phases. Relatively speaking, this is the field with the greatest amount of experimental material. In addition, in recent years the requirement of additional characterization by most Journals has resulted in more property measurements and theoretical calculations on Zintl phases published.

Theoretical calculations on compounds crystallizing in the NaTl structure type have been performed and their properties reviewed.[40] In addition to the crystal structure, the thermodynamic behavior, electrical conductivity, magnetic susceptibility, nuclear magnetic resonance (NMR) data, elastic constants, and optical properties have been studied. Based upon experimental data, the bonding in Zintl phases is considered to be a mixture of covalent, ionic, and metallic contributions. In many cases, the transport properties indicated metallic behavior arising from deviations from ideal stoichiometry. However, the thermal and elastic behavior of these phases indicates strong covalent bonding. Most theoretical studies have focused on compounds in which the Zintl concept does not appear to hold, such as $Ba_7Ga_4Sb_9$[91] or $A_{14}MPn_{11}$.[68,69] Theoretical calculations have also been performed on Zintl anions such as X_2Y_2 type clusters,[92,93] as well as the more classic structures that are considered to be Zintl ions.[4,38]

A few IR and Raman spectroscopic investigations on Zintl ions have been reported. The assignment of the observed frequencies is determined by normal coordinate analysis and force constants for such compounds as $Cs_6M_2Pn_4$ (M = Al, Ga; Pn = P, As),[94] Cs_6MPn_3 (M = In, Al; Pn = As, Sb),[95] and M_3Pn_{11} (M = Na, K, Rb, Cs; Pn = P, As).[96] Some properties of the homoatomic nine-atom Zintl ions of group 14 (Si−Pb) have been reviewed.[38]

Nearly all information on the solution chemistry of the Zintl ions has come from NMR studies.[97–101] The majority of these were carried out in en without the addition of crypt. Clusters that have been identified by ^{119}Sn, ^{205}Tl, or ^{207}Pb NMR include $Sn_{9-x}Pb_x{}^{4-}$ ($x = 0 - 9$), $Sn_{9-x}Ge_x{}^{4-}$ ($x = 0 - 9$), Sn_8Tl^{5-}, $Sn_4{}^{2-}$, $SnTe_4{}^{4-}$, $Sn_{8-x}Pb_xTl^{\hat{n}-}$ ($x = 1 - 4$, n probably 5), and $Sn_2Bi_2{}^{2-}$.

1 INTRODUCTION

Zirconium (atomic number 40) and hafnium (atomic number 72) are members of group 4 of the *periodic table* (*see Periodic Table*), below titanium (atomic number 22) and above Rutherfordium, (element 104). Zirconium (named from the Arabic *zargun*, meaning gold-colored) was discovered in 1789 by the German chemist Martin Heinrich Klaproth (1743–1817), who prepared zirconium oxide from the mineral zircon, $ZrSiO_4$. Gems that contain zirconium were known in the ancient world and were known by such names as hyacinth, jacinth, jargon, and zircon. It was such a specimen of zircon from Ceylon (Sri Lanka) that Klaproth heated with alkali to produce a new oxide, which he called *zirconia*. The Swedish chemist Jöns Jacob Berzelius isolated zirconium in the free state by reduction of potassium hexafluorozirconate (K_2ZrF_6) with potassium in a sealed iron tube to obtain a black powder.

Dimitri Mendeleev predicted the existence and the main properties of the 72nd element in 1870, and George Urbain in 1911 mistakenly thought he had discovered it, calling it celtium. Henry Moseley deduced the presence of element 72 (among the other undiscovered elements 43, 61, and 75) from X-ray spectra, but was misled thinking that it was the recently announced celtium. Celtium was discredited, but in 1923 Dirk Coster of the Netherlands and George Charles de Hevesy of Hungary used Moseley's method of X-ray analysis on a sample of Norwegian zircon and observed the spectrum for the element, which proved to be hafnium. It was named after Hafnia, the Latin name for Copenhagen where the discovery was made. Pure metallic hafnium was first obtained in 1925 by decomposing hafnium tetraiodide (HfI_4) over a hot tungsten wire.[1]

In most of their compounds, zirconium and hafnium exist in the oxidation state IV (*see Oxidation Number*). Compared with titanium, their M^{III} chemistry is limited,[2] but they show much greater ability to form M–M bonds in oxidation states ≤ III (for example, in dimers, layered compounds, and M_6Cl_{12} clusters). The basicities of the group 4 elements increase in the order Ti < Zr < Hf. Therefore the MX_4 compounds with d^0 configuration (*see* d^n *Configuration*) readily produce high CN neutral or anionic coordination complexes (*see Coordination Complexes*) with Lewis bases. Zirconium and hafnium compounds are rather hard Lewis acids and yield stable complexes with hard bases, such as O- and N-donor ligands (*see Ligand*). The coordination and organometallic complexes of zirconium and to a lesser extent, hafnium, have found use in both hetero- and homogeneous catalysis. In aqueous solutions, Zr and Hf ions are extensively hydrolyzed, and their cations form polynuclear species. In contrast to niobium and tantalum, their neighbors in the periodic table, and titanium, their lighter congener, zirconium and hafnium do not form $M{=}O^{2+}$ species (*see* ***Periodic Table: Trends in the Properties of the Elements***). The chemistry of zirconium and hafnium is characterized by their remarkable resemblance, which is due to their almost identical atomic sizes owing to the lanthanide contraction and their analogous electronic structures.[3,4]

The development of nuclear power opened a new chapter in the inorganic chemistry of these two elements. They show useful but diametrically opposite abilities to transmit thermal neutrons, a fact that stimulated the development of methods for their isolation, careful separation, and metal analysis (*see Metal Analysis*).

2 PROPERTIES OF THE ELEMENTS

2.1 Physical Properties

Table 1 summarizes some of the properties of zirconium and hafnium. Each element has several naturally occurring isotopes. The least abundant of these are ^{96}Zr (2.76% natural abundance) and ^{174}Hf (0.162% n. a.), which are radioactive with half-lives of 3.6×10^{17} y and 2.0×10^{15} y, respectively. The man-made isotopes ^{95}Zr ($t_{1/2} = 65.3$ d), ^{175}Hf ($t_{1/2} = 70$ d), and ^{181}Hf ($t_{1/2} = 70$ d) are used as tracers in scientific research.

In appearance, the metals are lustrous, silvery, and ductile and have high melting points. Their structures are typically hcp, which transform to bcc at high temperatures (870 °C for Zr and 1760 °C for Hf). Owing to the lanthanide contraction (*see Lanthanide Contraction*), the metallic and ionic radii of the two elements are almost identical. As a result, the properties of the metals are very similar.

2.2 Chemical Properties

Zirconium and hafnium possess nearly identical chemistry. No other pair of congeners has chemical properties so similar to each other. This is mostly a result of the metals possessing nearly identical atomic and ionic radii (1.45 and 1.44 Å for Zr and Hf, and 0.86 and 0.85 Å for Zr^{4+} and Hf^{4+}) as a result of the lanthanide contraction. They are relatively electropositive, but less so than the group 3 metals. The metals themselves are highly pyrophoric when finely divided. However, in the bulk form at room temperature they are resistant to corrosion, which is due to the formation of a dense protective oxide film. At high temperature, they react directly with most nonmetals, especially oxygen, hydrogen, and the halogens. For example, the metals burn in oxygen and chlorine gas to yield MO_2 and MCl_4, respectively. Mineral acids (with the exception of hydrofluoric acid) have little effect on the metals unless hot. Oxidizing agents such as nitric acid frequently reduce the activity of the metals by stabilizing the adherent oxide film. Aqueous alkalis have no effect, even at elevated temperatures.

Table 1 The main properties of zirconium and hafnium

Property	Zirconium	Hafnium
Atomic number	40	72
Mass numbers of natural isotopes (%)	90 (51.5)	174 (0.2)
	91 (11.2)	176 (5.2)
	92 (17.1)	177 (18.6)
	94 (17.4)	178 (27.1)
	96 (2.8)	179 (13.7)
		180 (35.2)
Relative atomic mass	91.22	178.49 (3)
Electronic configuration	$[Kr]4d^25s^2$	$[Xe]4f^{14}5d^26s^2$
Electronegativity	1.4	1.3
Metal radius (pm)	160	159
Covalent radius (pm)	148	147
Ionic radius (M^{4+}) (pm)	72 (6)	71 (6)
Melting point (°C)	1857	2222
Boiling point (°C)	4377	4602
Density ($g\,cm^{-3}$)	6.51	13.28
ΔH_{fus} ($kJ\,mol^{-1}$)	19.2	(25)
ΔH_{vap} ($kJ\,mol^{-1}$)	567	571 (25)
ΔH_f (monoatomic gas) ($kJ\,mol^{-1}$)	612 (11)	611 (17)
Ionization potential (V)	6.835	7.003
Electrical resistivity (20 °C) ($\mu\Omega$ cm)	40.0	35.1

3 NATURAL ABUNDANCE AND PRODUCTION

3.1 Natural Abundance

Zirconium comprises 0.016% (162 ppm) of the Earth's crust and, as a transition element, is only less abundant than Fe, Ti, and Mn. Hafnium is much less abundant at 2.8 ppm, but is still comparable in quantity to Cs and Br. The most important minerals of zirconium are zircon ($ZrSiO_4$), which is mostly mined in Australia, South Africa, the USA, and Sri Lanka, and baddeleyite (ZrO_2), found mostly in Brazil. The estimated reserves exceed a billion tonnes. Australia and South Africa account for about 80% of zircon mining. All zirconium minerals are contaminated by small quantities of hafnium (0.5–2% of Zr content), but in a few (such as alvite, $MSiO_4 \cdot xH_2O$, M = Hf, Zr, Th) the content of Hf is comparable with that of Zr. The above-mentioned similarities in the chemical behavior of these metals explain their close association in Nature and the similarity of their isolation procedures.

3.2 Industrial Isolation and Production

There are three industrial routes used for the extraction of zirconium and hafnium from ores: (1) caking of zircon with K_2SiF_6, alkaline extraction of the cake, separation of K_2HfF_6 from K_2ZrF_6 by fractional crystallization, and reduction of the complex fluorides to the metal; (2) chlorination of zircon in the presence of coke, purification of MCl_4 (for example, by distillation of adducts with $POCl_3$), and their reduction by metallothermy; (3) caking of zircon with lime, soda, or NaOH, acid extraction of the cake, extractional separation by hexone as the thiocyanates or by tributyl phosphate as the nitrates, and precipitation of the tetrafluorides by HF and their reduction to the metal.

The most important commercial methods of production of metallic zirconium and hafnium are based on furnace reduction, either of MCl_4 with magnesium or a Na–Mg mixture (the Kroll process), yielding a metal sponge, or of metal fluorides with Ca at 2000 °C to give an ingot. The

elimination of oxygen and nitrogen impurities is achieved by the van Arkel–de Boer process, which involves the heating of a crude sponge metal *in vacuo* with iodine to give volatile MI_4, and the decomposition of the iodide at a filament heated above 1300 °C. The annual world production of zircon exceeds 900 000 tonnes and that of zirconium metal is about 7000 tonnes. Industrial production of hafnium metal is about 50 tonnes a year.

3.3 Separation

Despite zirconium and hafnium being among the most difficult elements to separate, some highly effective methods have been developed to purify the metals.[5] The most effective method is a liquid extraction. Fractional crystallization of the fluorides K_2HfF_6 and K_2ZrF_6 (mentioned above) is used now only for the concentration of hafnium. The solubilities of K_2HfF_6 in water and $KHfF_5$ in 0.7 M HF are about 1.5 and 2.2 times as much as those of K_2ZrF_6 and $KZrF_5$ in the respective solvent thereby allowing the accumulation of Hf in solution. The different solubilities of the zirconium and hafnium phosphates in strong acid media, of the cupferronates (*see Cupferron*) in HF solutions, and of their hydroxides allow their separation by fractional precipitation.

Separation of the tetrahalides can be achieved from their solutions in molten salts (K_2ZrF_6, NaCl, $SnCl_2$) or under pressure (10–70 atm). However, distillation of the adducts of the tetrachlorides with $POCl_3$ is a more convenient route. Borohydrides and alkoxides of Zr and Hf are more volatile, but their complicated syntheses and high air-sensitivity limit their usefulness.

There are a few differences in the chemical behavior of zirconium and hafnium that can be exploited for their separation. The equilibrium constant of the reaction shown in equation (1) for Zr is greater than 10 orders of magnitude larger than for Hf. Therefore, reaction of a mixture of MCl_4 vapors with O_2 and Cl_2 at 500–900 °C selectively oxidizes Zr to ZrO_2 and leaves $HfCl_4$. On heating a mixture of MCl_4 with Zr or Al metal in vacuo at 400–450 °C, most of the $ZrCl_4$ is reduced to nonvolatile $ZrCl_3$ while $HfCl_4$ is left unchanged and can be distilled from the reaction mixture. Electrolysis of K_2MF_6 in molten NaCl–KCl mixture at 650–700 °C first gives MCl_2 but ultimately yields mainly metallic Zr.

$$MCl_4 + O_2 \rightleftharpoons MO_2 + Cl_2 \qquad (1)$$

Ion exchange and chromatography are used most often in analytical chemistry, due to the low concentration of the final solutions. Zr and Hf can be separated in anionic forms in sulfuric acid or concentrated HCl or HF with anion exchange resins like Dowex 2, or in cationic forms in diluted acids with cation exchange resins like Dowex 50.

Liquid extraction methods are based on the differential distribution coefficients of Zr and Hf between aqueous and organic phases. For example, hexone and other ketones (such as cyclohexanone) are used to extract hafnium into the organic phase from acid rhodanide solutions while tributyl phosphate (tbp) extracts zirconium into the organic phase from nitric acid or its mixture with HCl as complexes with one or two tbp ligands. The composition of the extracted species depends on the composition and pH of the aqueous phase. In 5 M HCl/HNO_3 (1:1), the composition of the extracted complex is $ZrOCl(NO_3)\cdot n(tbp)$, while in concentrated nitric acid it is $Zr(NO_3)_4\cdot n(tbp)$. It is assumed that hafnium is extracted as $Hf(NO_3)_4\cdot 2(tbp)\cdot nHNO_3$. From chloric acid solutions the metals are effectively extracted with fluorinated diketones (*see Diketones*), such as thenoyltrifluoroacetone (tta).

3.4 Uses

Zirconium metal has a very high corrosion resistance except toward fluoride ions, *aqua regia*, concentrated sulfuric acid, wet chlorine, and iron(III) and copper(II) chlorides. It has found use alongside stainless steel, titanium, and tantalum in the production of chemical apparatus. Zirconia has a very high melting point (above 2500 °C) and is used to make heat-resistant crucibles, ceramics, and abrasives. The generally low toxicity (except to individual allergic reactivity) has given zirconia use in cosmetics, antiperspirants (as zirconium hydroxychloride in roll-on deodorants), and food packaging.

In the 1940s, zirconium and hafnium metals were brought to prominence by their use in the nuclear industry in nuclear reactors and submarines. Zirconium and hafnium differ completely in their ability to transmit thermal neutrons. Zirconium is practically transparent to these particles (with a cross section for thermal neutron capture of 0.18 barns) whereas hafnium is a powerful absorber (105 barns). Both metals, therefore, are used in the nuclear industry: zirconium is used as a cladding for the uranium dioxide fuel rods of water-cooled nuclear reactors, while hafnium is used as a material for reactor control rods (for example, in nuclear submarines) and for protective screens in reactors. The nuclear industry consumes about 90% of the total world zirconium and hafnium output. The corrosion resistance of pure zirconium is insufficient for nuclear technology, so a series of alloys containing Sn, Fe, Cr, and Ni ('Zircaloys', the cross section of which is only 0.22 barns) have been developed.[6] Zirconium is also used as a getter, as an electrode material, and as a component of a variety of alloys including superconducting niobium-based alloys that retain their superconductivity (*see* ***Superconductivity***) in strong magnetic fields. Zirconium–zinc alloys become magnetic at temperatures below 35 K. The addition of 0.1% Zr to steel increases its hardness and toughness and the element is therefore used in the production of steel armor plate. Zirconium alloys exhibit catalytic activity for ammonia synthesis and conversion of SO_2 to SO_3 (*see Catalysis*).

The uses of zirconium and hafnium compounds based on their thermal and corrosion stability are described in related sections (see below). The most dramatic use of zirconium

(in the form of zirconia) is in ultrastrong ceramics. This was developed from the need for tank engines that would tolerate very high temperatures without the need of lubrication or a cooling system. Consequently, these tough, heat-resistant ceramics that are sharper than toughened steel make excellent industrial high-speed cutting tools. They have also found use in consumer goods such as knives, scissors, and golf irons, in addition to medical use as bioceramics in prosthetic joint replacement.

4 OXIDATION STATES, COORDINATION NUMBERS, AND STEREOCHEMISTRY

The chemistry of hafnium has not been studied to nearly the same extent as zirconium, but its behavior very closely resembles that of the lighter metal. The most important oxidation state of these metals is almost exclusively the group oxidation state of IV. Lower oxidation states are only sparsely represented in contrast to titanium for which oxidation state III is also characteristic (*see* ***Titanium: Inorganic & Coordination Chemistry***). The M^{III} state has no aqueous chemistry, since it readily reduces water. Nevertheless, lower oxidation states of zirconium and hafnium have been reported in a few inorganic solids (III, II, I) and recently in organometallic and coordination compounds in nonaqueous solutions (III, II, 0, −II). Ligands such as cyclopentadienyl (*see Cyclopentadienyl*) or dienes (*see Diene Complexes*) effectively stabilize lower oxidation states of Zr and Hf, and a large number of bis- and monocyclopentadienyl M^{III} and M^{II} complexes have been reported (*see* ***Zirconium & Hafnium: Organometallic Chemistry***).

The standard electrode potentials of Zr/Zr^{4+} and Hf/Hf^{4+} couples in aqueous solution are −1.529 and −1.70 V versus SHE, where SHE is the standard hydrogen electrode (*see Redox Properties & Processes*). Hafnium has the most negative reduction potential among the transition metals (*see Transition Metals*). In alkaline solution, the standard electrode potentials (equation 2) shift to the anodic region (−2.36 and −2.50 V, respectively), becoming (for Hf) more negative than those of the actinides. The standard electrode potentials, including intermediate oxidation states, measured in a molten NaCl–KCl mixture at 1000 K are −1.338 V (Zr^{2+}/Zr^0), −0.954 V (Zr^{3+}/Zr^{2+}), and −0.377 V (Zr^{4+}/Zr^{3+}) vs. Ag/AgCl, while the potentials of the Zr^{4+}/Zr^0 and Hf^{4+}/Hf^0 couples are −1.002 and −1.185 V respectively.

$$MO(OH)_2 + H_2O + 4e^- \rightleftharpoons M + 4OH^- \qquad (2)$$

Coordination numbers (CN) of zirconium and hafnium range from 4 to 12, but because of the large values of their ionic and covalent radii (*see Covalent Radii*) (Table 1), their complexes typically have CNs of 6–8 (*see* ***Coordination Numbers & Geometries***). They have a varied stereochemistry (*see Stereochemistry*), as a result of the spherical symmetry of their d^0 configuration and the consequent absence of ligand field effects. Typical coordination polyhedra are listed in Table 2. Thus, for CN 8, the coordination polyhedra most often observed are the dodecahedron (*see Dodecahedral*) and the square antiprism (*see Square Antiprism*). Chelating ligands (*see Chelate Effect*) forming five-membered metallacycles (such as $C_2O_4{}^{2-}$) tend to give a dodecahedral structure, while the preferred geometry for ligands that form six-membered metallacycles (such as acac) is the square antiprism.[7] Analogously, replacing the rather small bidentate ligand $NO_3{}^-$ by the larger $IO_3{}^-$ causes a change from a dodecahedral arrangement of the metal atom to a square antiprismatic one. Maximum CN values of 10 and 12 are noted for the very small hydride ligand, typically in the form of borohydride, $BH_4{}^-$, complexes (*see* ***Hydride Complexes of the Transition Metals***). Coordination numbers of 8 and 7 are typical for small ligands like F^-, O^{2-}, or OH^-, while in most chloride and alkoxide complexes the metal atom has an octahedral arrangement (*see* ***Structure & Property Maps for Inorganic Solids***). An increase of substituent bulk in a second coordination sphere reduces the CN to 5 or even 4 (*see Coordinative Saturation & Unsaturation*).

It should be noted that zirconium and hafnium usually form electron deficient complexes (*see Electron Deficient Compound*), which do not obey the Effective Atomic Number Rule (EAN rule) (*see Effective Atomic Number Rule*) and have a maximum of only 16 electrons. Monomers MX_4 with monodentate ligands are rather strong Lewis acids and readily yield adducts with two, three, or four donor ligands. In MX_4 monomers with π-donor ligands X (*see π-Base*), there is a noticeable shortening of the M−X distances in comparison with the sum of the covalent radii (0.26 Å for X = F; 0.15 Å for X = Cl, NMe_2), thus pointing to some multiple bond character in these compounds.

Structures of di- and monovalent zirconium and hafnium compounds contain octahedra, chains, or layers of metal atoms with metal−metal bonds. It is this that differentiates these compounds from those of M^{III} (MX_3 or molecular $M_2X_6L_4$ complexes) with isolated M–M bonds. A recent reinvestigation of the ZrI_3 structure showed two distinct Zr–Zr distances (3.507 and 3.172 Å); the latter is typical for a Zr–Zr bond (*see Bond Length*).

5 BINARY AND MIXED COMPOUNDS

5.1 Hydrides

Zirconium and hafnium react with hydrogen at temperatures above 700 °C, yielding an α-phase and hydrides with a limiting M:H ratio of 1:2 (*see* ***Hydrides: Solid State Transition Metal Complexes***). Under hydrogen pressure, absorption

Table 2 Coordination numbers and polyhedra of zirconium and hafnium

Oxidation state	Coordination number	Coordination polyhedron	Examples of compounds
IV	4	Tetrahedron	$ZrCl_4$ (gas), $Zr(NMe_2)_4$ (gas and solution, dimeric in solid state), $ZrCl(OAr')_3$
	5	Square pyramid	K_2ZrO_3, $PhNZr(OAr')_2py'_2$
	6	Octahedron	$ZrCl_4{\cdot}2L$, $Tl_2Zr(O^fR)_6$ $[Ph_3C]_2[Hf_2Cl_{10}]$

takes place with the formation of MH_x hydrides by a transformation of the hcp lattice first to distorted cubic ($x < 1.53$), then to face-centered cubic ($1.53 < x < 1.70$), face-centered tetragonal ($1.70 < x < 1.980$), and finally to a body-centered tetragonal lattice for MH_2. During hydrogenation the density of the metal decreases to 5.5 (Zr) and 11.4 (Hf) g cm^{-3} for the dihydride. This is accompanied by cracking of the solid, and this reaction can therefore be used as a method for converting the bulk metals to fine powders. Both hydrides are stable to air and can replace the metals as convenient starting materials for obtaining other binary compounds, and in the manufacture of ceramics and of foam aluminum using zirconium hydride.[8]

5.2 Borides

Both elements form borides of composition MB and MB_2, but only zirconium yields a dodecaboride, ZrB_{12}. The structure of the MB phase contains zigzag chains of boron atoms, and planar hexagonal nets of boron atoms exist in the structure of the MB_2 phase. In contrast, the ZrB_{12} phase has an fcc NaCl-type structure (*see* ***Borides: Solid-state Chemistry***).

5.3 Carbides and Silicides

Both metals and their dioxides react with carbon at high temperatures, yielding carbides, ZrC and HfC, with a NaCl structure type. Their enthalpies of formation are 200.6 and 217.4 kJ mol^{-1}, respectively. Very high melting points (3735 and 3890 °C) are characteristic of these compounds and the alloy of composition HfC·4TaC is the highest melting substance known (mp 3990 °C) (*see* ***Carbides: Transition Metal Solid-state Chemistry***). The conductivities of these are as high as those of metals. They resist mineral acids up to 230 °C (100 °C in HNO_3), but they react with halogens, oxygen, and nitrogen when heated.

There are several examples of M–Si systems. Silicides of composition M_2Si, MSi, and MSi_2 are known for both metals. Zirconium also forms the Zr_3Si_2 phase and hafnium the Hf_5Si_3 phase (*see* ***Silicon: Inorganic Chemistry***). All the silicides are insoluble in all mineral acids (except HF), and, unlike $TiSi_2$, in 10% aqueous KOH.

5.4 Pnictides

Yellow nitrides MN are produced by direct interaction of the elements. It is interesting that the rate of reaction of zirconium with nitrogen is higher than that with oxygen, so the burning of the metal in air yields a mixture of nitride, oxide, and oxonitride, Zr_2ON_2. The reaction of MN with carbon is reversible. The nitrides also have a bcc structure, forming an uninterrupted series of solid solutions with the MC carbides. Their melting points are 2950 °C (Zr) and 2980 °C (Hf), and hafnium nitride is the most fire-resistant of all the metal nitrides (*see* ***Nitrides: Transition Metal Solid-state Chemistry***). A

brown intermediate zirconium nitride of composition Zr_3N_4 is produced by heating $ZrCl_4$ at 700 °C in a flow of ammonia (equation 3). Decomposition of the adduct $ZrCl_4(NH_3)_2$ also yields Zr_3N_4 via a nitridochloride (ZrClN) stage.[9] Further heating of Zr_3N_4 gives blue ZrN_x ($x = 0.86$–0.94) above 750 °C and ZrN above 1000 °C. Treatment of ZrI_4 with ammonia at 500 °C gives a yellow ZrIN phase, whose structure is made up of Zr–N and Zr–I chains. These phases exhibit a 'metallic' conductivity that is higher than that of the pure metals, and ZrN is a superconductor below 8.9 K.

$$ZrCl_4 + 4NH_3 \longrightarrow ZrCl_4{\cdot}4NH_3 \longrightarrow Zr(NH_2)_4 \longrightarrow Zr_3N_4 \quad (3)$$

Zirconium and hafnium nitrides dissolve in cold 6 M HF but are stable in other acids except when heated (equation 4).

$$2HfN + 3H_2SO_4 + 2H_2O \longrightarrow 2HfOSO_4 + (NH_4)_2SO_4 + H_2 \quad (4)$$

With phosphorus, zirconium and hafnium form phosphides of composition M_3P, MP, and MP_2, which dissolve only in HF/HNO_3 mixtures (*see* ***Phosphides: Solid-state Chemistry***). ZrP_2 can be also obtained by reaction of $ZrCl_4$ with phosphine.

Arsenides of composition MAs and MAs_2 are also known (*see* ***Arsenic: Inorganic Chemistry***).[10]

5.5 Chalcogenides

Zirconium and hafnium react with *Chalcogens* on heating to give compounds of composition ME_2, ME_3, and ME_5. Their thermal stability decreases in the order E = S > Se > Te. Oxochalcogenides, MOE, are formed on treatment of the metal dioxides with H_2S. The MS_2 sulfides dissolve in hot hydrochloric acid, but the MS_3 compounds do not react. $ZrTe_2$ has a metallic conductivity, but ZrS_2, $ZrSe_2$, and $HfTe_2$ are semiconductors (*see* ***Semiconductors***), and HfS_2 is an insulator (*see* ***Sulfur: Inorganic Chemistry***). The chalcogenides $(Cu,Cr)ME_4$ with spinel structures are semiconductors. Phases of the compositions $Ba_5Hf_4S_{13}$ and $Ba_6Hf_5S_{16}$ with perovskite blocks are considered as probable prospective materials for superconductors.[11] In the phase $K_4M_3Te_{17}$, the metal atom has a bicapped trigonal prismatic arrangement, as in $HfTe_5$.[12]

5.6 Oxides and Hydroxides

5.6.1 Oxides

Besides the dioxide MO_2, suboxides of zirconium and hafnium of composition M_6O, M_3O, and metastable MO are known (*see* ***Oxides: Solid-state Chemistry***). The dioxides are high melting (mp ZrO_2 = 2850 °C, HfO_2 = 2900 °C), nonvolatile solids and find uses in the manufacture of fireproof or chemical resistant products. Besides the monoclinic crystal modification stable at room temperature, there are also two high-temperature modifications, tetragonal and cubic. In the presence of a little CaO a stable fluorite structure is formed, which avoids the injurious mechanistic consequences of the phase changes on repeated heating and cooling. Zirconia and hafnia possess an ionic conductivity via O^{2-} ions, in particular as solid solutions with other oxides, such as Y_2O_3 (*see* ***Ionic Conductors***). Zirconium and hafnium dioxides can be obtained both in the direct interaction of metals with oxygen and in the reaction of the tetrachlorides with water at 250 °C, followed by heating in air at 500 °C, or in oxygen at 350 °C on a fluidized bed. Amorphous dioxides suitable for the manufacture of ceramics are produced by the hydrolysis of Zr and Hf alkoxides (see below). At elevated temperatures zirconia and hafnia can be reduced by Ca to the metals and by carbon to the carbides. Anhydrous zirconia is used as a support for metal and oxide catalysts (*see* ***Oxide Catalysts in Solid-state Chemistry***).

5.6.2 Hydroxides

Zirconium hydroxide is precipitated by bases at lower pH than the hafnium compound. Zr and Hf are obviously unable to form true hydroxides, and these compounds are more correctly formulated as $MO_2{\cdot}xH_2O$. Amorphous hydrous zirconia and hafnia (α-phase) transform to microcrystalline forms (β-phase) with noticeable heat evolution. They lose water up to the composition $MO_2{\cdot}H_2O$ at 140 °C (Zr) or 155 °C (Hf). Hydrous zirconia has excellent absorptive capacity, particularly for oxygen-containing anions. For example, the concentration of $SO_4{}^{2-}$ anions over hydrous zirconia is so low that no precipitate forms on the addition of barium salts to the filtrate. While the hydroxides of composition $M(OH)_4$ are not stable, in alkaline solutions, $M(OH)_5{}^-$ are present and even $M(OH)_6{}^{2-}$ anions have been reported in very concentrated alkalis. Salts of these anions, such as $Na_2Hf(OH)_6$, can be isolated.

5.6.3 Zirconates and Hafnates

Zr and Hf hydroxides are rather amphoteric (*see Amphoterism*). The metazirconates and -hafnates, Q_2MO_3, (where Q is a cationic counterion) and the corresponding poly compounds, $Q_2M_2O_7$, $Q_2M_3O_9$, and $Ln_2M_7O_{17}$ (Ln = La, Nd), are known. A common route for their preparation is the firing of zirconia and hafnia with the appropriate metal carbonate or nitrate. In K_2ZrO_3, zirconium has a tetragonal pyramidal arrangement. Zirconates and hafnates of M^{II} cations of composition $M^{II}ZrO_3$ usually possess a perovskite structure, whereas $M^{II}_2ZrO_4$ compounds often have a spinel structure. Lead zirconate, $PbZrO_3$, is a segnetoelectric material, like $PbTiO_3$.

5.6.4 Heteropolyacids

Zirconium forms heteropolyacids with molybdenum, such as $H_8[Zr(Mo_2O_7)_6]$, whose alkali metal derivatives have been isolated. In the first member of the series, of composition $ZrMo_2O_7(OH)_2(H_2O)_2$, the zirconium atom has a pentagonal bipyramidal arrangement (*see* ***Polyoxometalates***).

5.6.5 Peroxo Compounds

Zirconium and hafnium tetrahalides react with hydrogen peroxide in alkali solution to yield $M(OH)_3OOH$. The maximum content of peroxo units per metal atom has been observed in $K_4Zr(O_2)_4{\cdot}6H_2O$, which is a derivative of the unknown orthoperzirconic acid $Zr(OOH)_4$.

5.7 Halides and Oxohalides

Zirconium and hafnium form halides of composition MX_4 and also MX_3, MX_2, and MCl (see below) (*see* ***Fluorides: Solid-state Chemistry*** and ***Halides: Solid-state Chemistry***). All the tetrahalides are colorless (except for the red-brown HfI_4) and volatile solids, melting only under pressure. The tetrachlorides are produced by chlorination of the dioxides in the presence of coke. The tetraiodides are formed in a direct reaction of iodine with the metal, but the use of the hydrides is more convenient. The halides of hafnium are more stable to heat than those of zirconium. Decomposition of tetraiodides to yield pure metals is used in the van Arkel–de Boer process. The tetrahalides (except for the fluorides) readily dissolve in water, with formation of the oxohalides MOX_2. The reaction of MF_4 with water yields $MF_4{\cdot}3H_2O$, which is stable to hydrolysis. $ZrF_4{\cdot}3H_2O$ contains dimers, $(H_2O)_3F_3Zr(\mu\text{-}F)_2ZrF_3(H_2O)$, while the hafnium complex is a polymer with double Hf–F–Hf bridges (*see Bridging Ligand*).[13] The tetrahalides have a monomeric, tetrahedral structure in the gas phase (except for HfF_4, which forms a dimer). In the solid state, the tetrafluorides have a structure with an antiprism of eight fluorides around each metal atom, while tetrachlorides are composed of chains of edge-sharing distorted octahedra of six chlorides.

Depending on the temperature, heating $HfF_4{\cdot}3H_2O$ in air gives oxofluorides that are mostly isomorphous with the corresponding zirconium compounds: Hf_4OF_{14}, $HfOF_2$ or Hf_2OF_6 (no zirconium analog), $Hf_3O_2F_8$, and HfO_2. The differences between Zr and Hf are also evident in the diverse composition of the products of hydrolysis and thermal decomposition of $MF_4{\cdot}3H_2O$:$Zr_4F_{10}(OH)_6{\cdot}3H_2O$ and $Hf_4F_{12}(OH)_4{\cdot}4H_2O$, $Zr_4F_{10}O_3$ and $Hf_4F_{12}O_2$. Anhydrous hygroscopic oxochlorides of zirconium and hafnium $MOCl_2$ were obtained according to equation (5). On heating they disproportionate (equation 6). The hydrated oxochlorides $MOCl_2{\cdot}8H_2O$ decompose above 65 °C, yielding the dioxides.

$$3MCl_4 + Sb_2O_3 \longrightarrow 3MOCl_2 + 2SbCl_3 \qquad (5)$$

$$2MOCl_2 \xrightarrow{65\,^\circ C} MCl_4 + MO_2 \qquad (6)$$

6 SALTS OF OXOACIDS

6.1 Silicates

Silicates of zirconium, $ZrSiO_4$ (zircon), and hafnium, $HfSiO_4$, are the only crystalline phases in the MO_2–SiO_2 system. Their fusion with molten Na_2SiO_3 yields double silicates, Na_2MSiO_5 and $Na_4MSi_2O_8$.

6.2 Nitrates

Anhydrous volatile nitrates $M(NO_3)_4$ are obtained by the interaction of the chlorides with N_2O_5 (equation 7):

$$MCl_4 + N_2O_5 \longrightarrow M(NO_3)_4 + NO_2Cl \qquad (7)$$

They have monomeric structures with bidentate NO_3 groups. $M(NO_3)_4$ and $MO(NO_3)_2$ react with water more slowly than do the titanium analogs, yielding hydrates of composition $M(NO_3)_4{\cdot}5H_2O$ and $MO(NO_3)_2{\cdot}nH_2O$ ($n = 2$, 6); both can be isolated from cold concentrated nitric acid. As in the case of other $MOX_2{\cdot}nH_2O$ salts, there are no ‘zirconyl’ or ‘hafnyl’ units (MO^{2+}) in the structures of these compounds. The absorbance bands around 850–900 cm^{-1} in the IR spectra of these compounds, which were earlier considered evidence for the presence of zirconyl or hafnyl M=O bonds, are now assigned to bridging M–O–M linkages. The eight-coordinate metal atom in $MO(NO_3)_2{\cdot}2H_2O$ is surrounded by two hydroxyl groups, four water molecules, and two monodentate NO_3 groups; in anhydrous $ZrO(NO_3)_2$, on the other hand, oxygen bridged chains are present. ‘Dizirconyl’, $Zr_2O_3(NO_3)_2{\cdot}5H_2O$, and ‘dihafnyl’, $Hf_2O_3Cl_2{\cdot}5H_2O$, salts have no terminal M=O bonds either. Hafnium nitrate forms a volatile adduct $Hf(NO_3)_4{\cdot}N_2O_5$; zirconium nitrate, however, does not. Mixed nitrates, $Q[M(NO_3)_6]$, are known, where $Q = NR_4^+$.

6.3 Phosphates

The orthophosphates $M(HPO_4)_2$ are practically insoluble in mineral acids (except HF) and can be precipitated from strong acid solutions as hydrates with one or two water molecules. This is a method for separating Zr and Hf from other metals (except Pa). The Hf salts are less soluble than those of Zr and accumulate in the precipitate from sulfuric acid solution. Both $Zr(HPO_4)_2{\cdot}nH_2O$ phases have a layered structure and can be intercalated by quite large molecules, such as phen or aminoferrocene.[14] The pillared materials so obtained have pore dimensions approaching those found in

zeolite Y and can be used as sorbents or catalysts. Heating the orthophosphates transforms them to pyrophosphates, $M(P_2O_7)$. Mixed phosphatosilicates of zirconium and sodium, such as $Na_3Zr_2Si_2PO_{12}$, are Na superionic conductors (*see* ***Phosphates: Solid-state Chemistry***).

6.4 Sulfates

The anhydrous sulfates $M(SO_4)_2$ are produced as white solids by the reaction of the dioxides with $NaHSO_4$. They are relatively stable to heat, but above 500 °C they decompose to yield MO_2. $Zr(SO_4)_2$ has a polymeric structure with two bidentate and three monodentate sulfate groups bound to the seven-coordinate Zr atom. Evaporation of their aqueous solutions or crystallization from 6 M sulfuric acid gives the compounds $M(SO_4)_2{\cdot}4H_2O$. Hydrates of composition $M(SO_4)_2{\cdot}nH_2O$ ($n = 1, 5, 7$) are also known. X-ray analyses of zirconium salts show a polymeric structure with bridging sulfate groups and seven- ($n = 1$) and eight-coordinate zirconium ($n = 4$) and a dimeric structure with eight-coordinate zirconium ($n = 5, 7$). Basic sulfates of composition $MOSO_4{\cdot}2H_2O$, $M_2(OH)_2(SO_4)_3{\cdot}4H_2O$, $M(OH)_2SO_4{\cdot}H_2O$, $M(OH)_2SO_4{\cdot}2H_2O$, and $M_2O(SO_4)_3{\cdot}5H_2O$ have been detected in the MO_2–SO_3–H_2O system. Zirconium sulfates of the composition $4ZrO_2{\cdot}3SO_3{\cdot}15H_2O$ (Hauser's salt) and $5ZrO_2{\cdot}3SO_3{\cdot}15.5H_2O$ are of industrial importance. In most such complexes the metal atom is eight-coordinate, but in $Zr(OH)_2SO_4{\cdot}H_2O$ the zirconium has a pentagonal bipyramidal arrangement with four bridging OH groups and a water molecule in the equatorial plane. It is interesting that the peroxosulfate $Zr_2O_6SO_4{\cdot}8H_2O$ has no Hf analog. Mixed sulfates $Q_2[M(SO_4)_3]{\cdot}nH_2O$ are known for Zr, Hf, and Ti whereas $Q_4[M(SO_4)_4]{\cdot}nH_2O$ are isolated only for Zr and Hf. The structure of $Q_2[Zr(SO_4)_3]{\cdot}nH_2O$, like that of $Zr(SO_4)_2{\cdot}nH_2O$ ($n = 5, 7$), consists of dimeric $[Zr_2(SO_4)_6(H_2O)_4]^{4-}$ units with eight-coordinate Zr. In $[NH_4][Hf(SO_4)_4(H_2O)_2]{\cdot}2H_2O$, the Hf atom is dodecahedrally coordinated by eight oxygen atoms from two water molecules and two bidentate and two monodentate sulfate groups.

6.5 Salts of Other Acids

The anhydrous perchlorates of zirconium and hafnium, $M(ClO_4)_4$, are colorless volatile crystalline solids. The action of water yields the hydrates $MO(ClO_4)_2{\cdot}8H_2O$, which decompose to MO_2 on heating. Mixed perchlorates, $Q_n[M(ClO_4)_{n+4}]$, are documented. Iodates of zirconium and hafnium, $M(IO_3)_4$, with a square antiprismatic anion are, like the phosphates, insoluble in nitric acid.

Ammonium carbonatozirconate, $[NH_4]_3[Zr(OH)(CO_3)_3]{\cdot}2H_2O$, is used in crosslinking of polymers such as polyacrylates. The dialkylcarbamates $M(O_2CNR_2)_4$, prepared by treating MCl_4 with a CO_2–NHR_2 mixture in toluene, have a slightly distorted dodecahedral arrangement around the metal atom (the X-ray structures are known for M = Hf; R = *i*-Pr).[15] Their reaction with anhydrous HCl yields complexes with a $MCl_6{}^{2-}$ anion (equation 8).

$$M(O_2CNEt_2)_4 + 8HCl \longrightarrow [NH_2Et_2]_2[MCl_6] + 2[NH_2Et_2]Cl + 4CO_2 \quad (8)$$

A dodecahedral anion is also present in trioxalatozirconic acid, $H_4[ZrO(C_2O_4)_3]{\cdot}7H_2O$, and the mixed oxalates $K_4[Zr(C_2O_4)_4]{\cdot}5H_2O$ and $Na_4[Zr(C_2O_4)_4]{\cdot}3H_2O$. It should be noted that very stable oxalate complexes of Zr and Hf are stable to alkalis. α-Hydroxycarboxylic acids react with zirconium ions to form tri- and tetracarboxylatozirconylic acids. In acid solutions, complexones yield very stable eight-coordinate complexes ($K_{ML} = 10^{20}$–10^{35}) with ratio M:L = 1:1 (such as $[M(EDTA)]{\cdot}3H_2O$) and, rarely, 1:2 (such as $[M(NTA)_2]^{2-}$). A recent X-ray analysis showed that EDTA is a true octadentate ligand in these complexes.[16] In neutral solutions, complexes of formula $[M(EDTA)(OH)]_n{}^{n-}$ ($n = 1, 2$) exist, because of hydrolysis. Alkalis precipitate the metal hydroxides from these complexes at pH >9.

The zirconium salts of organic acids are widely applied in industry. Carboxylatozirconylic acids are used in treating dermatitis and in making textiles water repellent, while zirconium acetate, $Zr(OAc)_4$, and the trilactozirconate $Na_2H[Zr(OH)(MeC(OH)CO_2)_3]$ are components of body deodorants, and the 2-ethylhexanoate and naphthenate are used as siccatives.

7 AQUEOUS CHEMISTRY

All salts of zirconium and hafnium tend to hydrolyze in aqueous solutions, though less so than those of titanium. In highly dilute solutions ($<10^{-4}$ M), Zr and Hf exist as the aqueous ions $[M(OH)_n]^{(4-n)+}$, where n is pH-dependent. The hydration energies are 7001 and 7169 kJ mol^{-1} for Zr and Hf respectively. In chloride, perchlorate, and nitrate solutions, hafnium is less hydrolyzed than zirconium, while the reverse is true in sulfate solutions. This is connected with the lower solubility of hafnium compounds in sulfate solutions, even in only slightly acid media. It should be noted that the sulfate anion has a strong affinity for Zr and Hf.

In perchlorate or chloride solutions of moderate ($>10^{-3}$ M) concentration, Zr and Hf are present as $4MO_2{\cdot}16H_2O{\cdot}nH^+$, which is a cyclic tetramer, usually $[M_4(OH)_8(H_2O)_{16}]^{8+}$, in which the metal atoms are bound by two hydroxyl bridges. This moiety has been found in solid $MOCl_2{\cdot}8H_2O$. There is some evidence for the existence of Zr_3 species, probably $[Zr_3(OH)_6(H_2O)_{12}]^{6+}$, in 2.8 M HCl solution. In these solutions, the metal migrates toward the cathode under the influence of an electric field. Their cationic nature prevents them from reacting with cation exchange resins; they form colored precipitates with acid organic dyes. As well as chloride

and perchlorate, tetrameric cations also exist in solutions of Zr and Hf salts in the presence of other weakly coordinating anions (bromide, iodide, thiocyanate). An increase in the acidity or the chloride ion concentration converts Zr and Hf into an anionic form. Solutions with an HCl concentration >6 M do not react with cation exchange resins, and complexes of composition $QMCl_5$ and Q_2MCl_6 can be isolated. The stability of the anionic complexes $[MX_{4+n}]^{n-}$ changes in the sequence $X = F \gg Cl > Br > I$, in line with the trend in M–X bond energies. In aqueous solution, the stable complexes MF_5^-, MF_6^{2-}, and MF_7^{3-} have been detected, and their salts with NH_4^+ and alkali metal cations have been obtained.

In the electrolysis of solutions of $M(SO_4)_2 \cdot 4H_2O$, protons move toward the cathode and the metal to the anode, so these compounds can be formulated as $H_2[MO(SO_4)_2] \cdot 3H_2O$ (disulfatozirconic and -hafnic acids). The reaction of sodium acetate with $ZrOCl_2 \cdot 8H_2O$ yields diacetatozirconic acid (equation 9). They do not precipitate with acid dyes, and they react with anion exchange resins rather than with their cation exchange counterparts.

$$ZrOCl_2 \cdot 8H_2O + 2NaOAc \longrightarrow HZrO(OH)(OAc)_2 + 2NaCl \quad (9)$$

8 COORDINATION COMPOUNDS

8.1 Hydride Complexes

The Zr and Hf tetrahydroborates $M(BH_4)_4$ are the most volatile compounds of these elements, with boiling points of 123 and 118 °C; they are also very sensitive to oxidation and hydrolysis. They can be obtained by the reaction of the chlorides with alkali metal borohydrides or of the complex fluorides $NaMF_5$ with aluminum borohydride (the fluorides MF_4 do not react), followed by distillation from the reaction mixture. According to low-temperature X-ray data, all the borohydride groups are tridentate in both $M(BH_4)_4$ complexes, which have T_d symmetry. The same is true for their substituted $M(BH_3Me)_4$ derivatives, that is, the metal atom is 12-coordinate. Proton NMR indicates fast exchange of bridging and terminal protons on the NMR timescale in these fluxional molecules (*see Fluxional Molecule*).

Treatment of $M(BH_4)_4$ with PMe_3 gives $M_2H_3(BH_4)_5(PMe_3)_2$, in which two metal atoms are bridged by three hydrides. One of them also has three trihapto (*see Hapticity*) BH_4 groups (CN 12) while the second, besides three bridging hydrides, has two phosphines and two dihapto borohydride groups (CN 9).[17] A similar structure with nonequivalent hafnium atoms (CN 9 and 10) has been found for $Hf_2[N(SiMe_2CH_2PMe_2)_2]_2H_3(BH_4)_3$. Reaction of $M(BH_4)_4$ with bidentate phosphines (P–P) gives the mononuclear $MH_2(BH_4)_2(P\text{–}P)_2$ complexes.

Surface bound hydrides of zirconium, obtained by the reaction sequence in equation (10) ($n = 2, 3$) (*see* ***Supported Organotransition Metal Compounds***), are of interest because of their high catalytic activity in the polymerization of alkenes, cyclization of dienes and alkynes, and even methane C–H bond (*see* ***Alkane Carbon–Hydrogen Bond Activation***) activation (equation 11).[18]

$$[Si](OH)_n + ZrNp_4 \xrightarrow{-nCMe_4} [Si]O_nZrNp_{4-n} \xrightarrow{+H_2,\ -CMe_4} [Si]O_nZrH_{4-n} \quad (10)$$

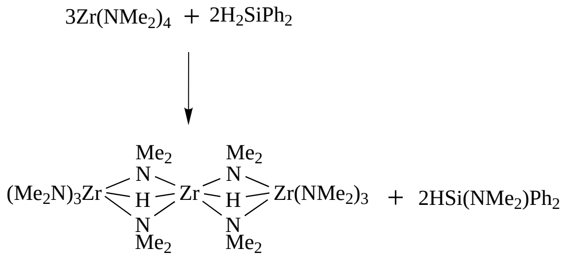
$$[Si]O_3ZrH + CH_4 \longrightarrow [Si]O_3ZrMe + H_2 \quad (11)$$

Hydride-containing clusters can be prepared under very mild conditions by reacting $ZrCl_4$ and various amounts of $HSnBu_3$ followed by the addition of phosphines or halide salts (phosphonium or ammonium) (equation 12).[19]

$$ZrCl_4 + HSnBu_3 \xrightarrow{[R_4E]Cl} [R_4E]_3[Zr_6Cl_{18}H_5] \quad (E = N, P)$$
$$ZrCl_4 + HSnBu_3 \xrightarrow{PR_3} Zr_5Cl_{12}H_4(PR_3)_5 + Zr_6Cl_{12}H_4(PR_3)_4 + [HPR_3]_3[Zr_6Cl_{18}H_5] \quad (12)$$

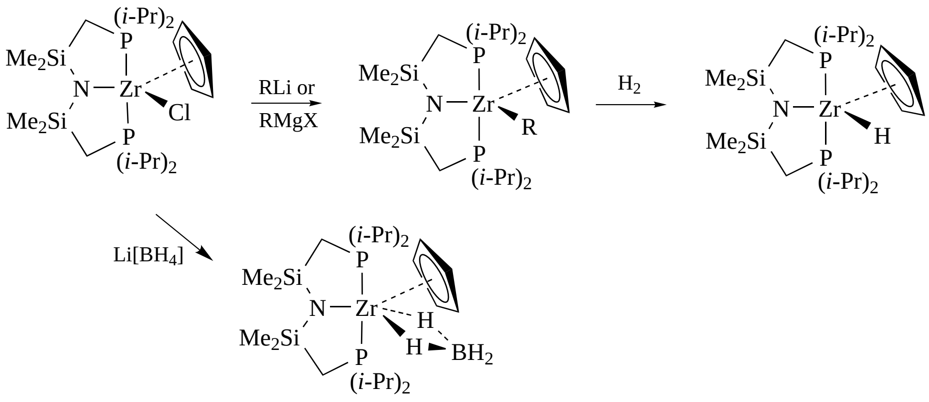
A monomeric hydride of a Zr(III) center supported by a cyclopentadienyl ligand and $N(SiMe_2CH_2P(i\text{-}Pr)_2)_2$ can be obtained. Metathesis reactions of the Zr(III) chloride complex with Me_3SiCH_2Li or MeMgBr give the corresponding alkyl derivatives. Reaction of these alkyl species with H_2 (1 atm) proceeds smoothly at room temperature to give $ZrH(\eta^5\text{-}C_5H_5)N(SiMe_2CH_2P(i\text{-}Pr)_2)_2$. The tetrahydroborate complex can also be obtained by reaction with $LiBH_4$ (Scheme 1).[20]

Reaction of the zirconium tetraamide complex $Zr(NMe_2)_4$ with silanes yields aminosilanes, H_2, and amide hydrides such as the unusual trinuclear complex $[(Me_2N)_3Zr(\mu\text{-}H)(\mu\text{-}NMe_2)]_2Zr$ (equation 13).[21]



(13)

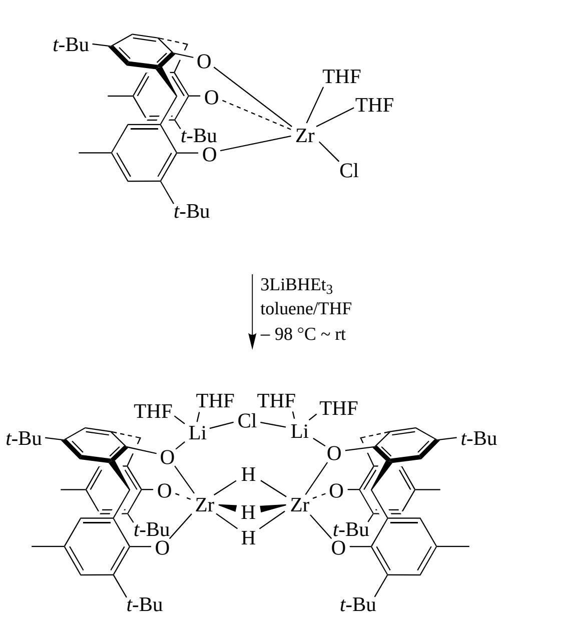
A zirconium complex of the *meso*-octaethylporphyrinogen ligand reacts with KH to yield a polynuclear hydride. When the reaction is performed in a 1:1 KH:Zr ratio, a dinuclear complex is observed. Using a 2:1 KH:Zr ratio under rigorously controlled reaction conditions leads to the formation of a polynuclear species. In the dinuclear complex, each Zr atom is



Scheme 1

η^5:η^1:η^5:η^1-bonded to the porphyrinogen ligand, while each potassium cation is η^5-bonded to two pyrrolyl rings to form a bent bis(cyclopentadienyl)-type fragment. The polynuclear complex contains the centrosymmetric unit $K_4Zr_4H_8$. Only four K^+ ions participate in the metal-hydride skeleton, while the other four are bonded to the porphyrinogen periphery (Scheme 2).[22]

A dimeric zirconium(IV) trihydride complex has been synthesized by reaction of $LiBHEt_3$ with the tridentate triaryloxide zirconium chloride complex $ZrCl(THF)_2$(*t*-Bu–L) (H_3(*t*-Bu–L) = 2,6-bis(4-*t*-butyl-6-methylsalicyl)-4-*t*-butylphenol) (equation 14). The solid-state structure shows each zirconium center adopts a trigonal prismatic structure with a Zr–Zr separation of 3.163(1) Å. In solution, the three resulting hydrides appear equivalent on the NMR timescale. Analogous reactivity was observed for the titanium conger. However, in the resulting titanium trihydride, the metals are assigned formal Ti(III) oxidation states.[23]



(14)

Sublimation of tetraneopentyl zirconium onto the surface of silica dehydroxylated at 500 °C results in the electrolytic cleavage of one Zr–C bond by a surface proton, with the formation of the tris neopentyl zirconium [Si]-O-Zr(CH_2CMe_3)$_3$ grafted species. Reaction of this supported Zr alkyl with hydrogen at 150 °C leads to the formation of a zirconium hydride. Interestingly, this reaction does not yield neopentane, but rather the formation of methane and ethane are observed. These products are in fact the result of the hydrogenolysis of evolved neopentane catalyzed by the silica-supported zirconium hydride.[24]

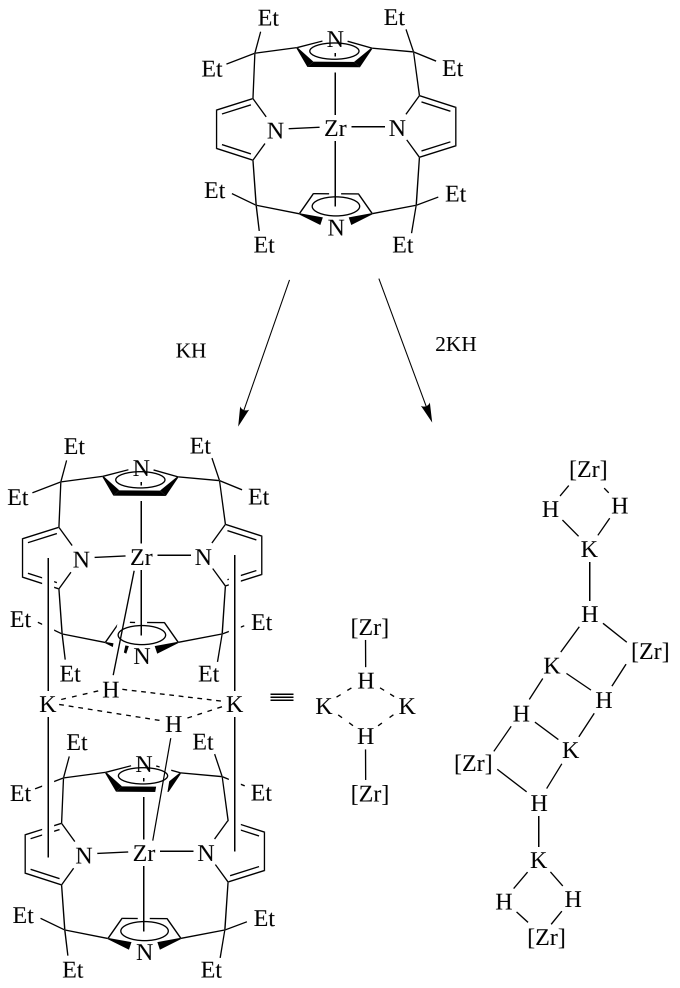
8.2 Halide Complexes

8.2.1 Ionic Complexes

Zirconium and hafnium tetrahalides form a variety of double halides with metal halides. The most widespread composition is Q_2MX_6 (Q = monovalent cation) but the QMX_5 complexes and fluoride complexes Q_3MF_7 and Q_4MF_8 are also documented. Q_2MX_6 chlorides and bromides consist of [MX_6] octahedra. The complex chloride anions $[MCl_5]^-$ and $[MCl_6]^-$ have been detected in molten MCl_4 (equation 15):

$$2MCl_4 \rightleftharpoons [MCl_3]^+[MCl_5]^- \rightleftharpoons [MCl_2]^+[MCl_6]^- \quad (15)$$

The structures of complex Zr and Hf fluorides depend on the nature of the cation. For Q_2MF_6 complexes, the following coordination polyhedra are known: an octahedron (Q = Rb), a square antiprism (Q = N_2H_6), and a dodecahedron with four bridging fluorine atoms (Q = K). Two structural types are described for Q_3MF_7 complexes: a pentagonal bipyramid (Q = Na) and a capped trigonal prism (Q = NH_4), like the NbF_7^{2-} anion (*see* ***Niobium & Tantalum: Inorganic & Coordination Chemistry***). The coordination polyhedron



Scheme 2

in Q_4MF_8 is a square antiprism, while, in the structure of $Cu_3[Zr_2F_{14}]\cdot 16H_2O$, two ZrF_8 square antiprisms share a common polyhedral edge. The dimeric anion in the complex $[Ph_3C]_2[Hf_2Cl_{10}]$ consists of edge-sharing octahedra.[25] Reaction of $ZrCl_4$ with $LiNPh_2$ affords two different THF adducts of $LiZrCl_5$, in the forms $[Li(THF)_4][ZrCl_5(THF)]$ and $[(THF)_3Li(\mu\text{-}Cl)ZrCl_4(THF)]$.[26]

8.2.2 Neutral Complexes

The tetrahalides of zirconium and hafnium are strong Lewis acids and form a variety of molecular complexes of composition MCl_4L_2, where L = ether, ester, amine, nitrile, phosphine (see below), and so on. All are monomeric and have a *cis* configuration (*see Isomer, Types of*). With diarsines (*see Arsine & As-donor Ligands*), eight-coordinate dodecahedral complexes $MCl_4(diars)_2$ are produced but the Hf complex, unlike that of Zr, precipitates only after a delay. Reaction of $MCl_4(THF)_2$ with tetradentate Schiff bases (*see Schiff Base*) yields pentagonal bipyramidal complexes $M(salen)Cl_2(THF)$, with trans chlorine atoms. When recrystallized from toluene they lose THF and transform into *cis* octahedral (*see Octahedral*) complexes.[27] $HfCl_4(THF)_2$ is an active catalyst for the esterification of carboxylic acids with alcohols and is more hydrolytically stable than $HfCl_4$. $ZrCl_4$ is also active, but inferior.[28]

8.3 Complexes with Oxygen Donor Ligands

Zirconium and hafnium show a greater preference for O-donors than does titanium.[29] Besides salts of oxygen acids, alkoxides of Zr and Hf and complexes with β-diketones and complexones (*see **Water & O-donor Ligands***) have been the most intensively studied. In nitrobenzene solution, MCl_4 forms adducts with two molecules of alcohol (such as $MCl_4(MeOH)_2$), ether or ester, but in a pure alcohol the equilibrium shown in equation (16) ($n = 1$ or 2) exists. Monomeric products of incomplete substitution having the composition $[HNMe_3]_2[ZrCl_4(OMe)(MeOH)]Cl$, with a linear Zr–O–Me bond, and also $(Et_2O)_2Li(\mu\text{-}Cl)_2Zr(tritox)_2$

have been isolated. The addition of a base, such as ammonia, shifts the equilibrium to the right and the alkoxides $M(OR)_4$ are produced quantitatively. Compounds with R = Me or *t*-Bu can be obtained by alcohol exchange with $M[O(i\text{-}Pr)]_4$, isopropanol being separated from the reaction mixture by distillation as an azeotrope with benzene. The best route for the preparation of these compounds is the exchange of $M[O(i\text{-}Pr)]_4$ with the appropriate ester (equation 17). The structure of $Zr[O(i\text{-}Pr)]_4$ in the solid state is a tetramer, with a Zr_4O_{16} core involving trigonal metaprismatic coordination of Zr, which persists in solution in hydrocarbon solvents.[30] $M(OR)_4$ compounds are colorless volatile solids or liquids, depending on the R group; their degree of association varies from 4 to 1.[31] For very bulky alkoxy groups like 2,6-substituted aryloxides, the substitution of the last chlorine atom in MCl_4 is difficult, and monomers such as $HfCl(OAr')_3$ are obtained. Zirconium methoxide, $Zr(OMe)_4$, is insoluble in MeOH or C_6H_6, while $Zr(OEt)_4$ has rather high solubility and sublimes at 120 °C at 10^{-4} mmHg. Stable *Tetrahedral* monomers, such as $M[OC(t\text{-}Bu)_3]_4$, have a vapor pressure of 650 Pa at 90 °C.

$$MCl_4 + nROH \rightleftharpoons M(OR)_nCl_{4-n} + nHCl \quad (16)$$

$$M(O\text{-}i\text{-}Pr)_4 + AcOR \rightleftharpoons M(OR)_4 + AcO\text{-}i\text{-}Pr \quad (17)$$

Metal alkoxide complexes with related alcohols are apparently edge-sharing bioctahedral dimers, on the evidence of the X-ray structure of the isopropyl complex. Some stable mixed alkoxides of the type $Q[M_3(OR)_9]$ (Q = Li, Na, K, NH_4, Ca/2) have been reported; they distill in vacuo without decomposition. The X-ray structures of several bimetallic alkoxides obtained by Caulton, $QZr_2[O(i\text{-}Pr)]_9$, Q = Li[HO(*i*-Pr)], K(DME), Ba[O(*i*-Pr)], show a similar triangular structure with two μ_3 and three μ-OR bridges.[32] The thallium salt of composition $Tl_2Zr(O^fR)_6$ obtained by the reaction shown in equation (18) has a distorted octahedral structure stabilized by six Tl:F contacts.[33]

$$ZrNp_4 + {}^fROH \xrightarrow{-4CMe_4} Zr(O^fR)_4 \xrightarrow{TlO^fR} Tl_2Zr(O^fR)_6 \quad (18)$$

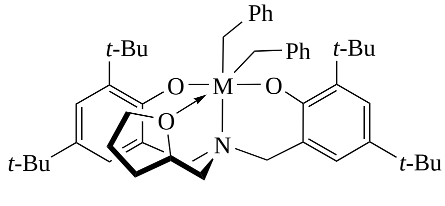
Oxo bridges are found in products of the partial hydrolysis of metal alkoxides. They noticeably stabilize polynuclear structures. In the complex $Zr_{13}O_8(OMe)_{36}$, the central ZrO_8 core is surrounded by 12 zirconium atoms, and the complex has a cubic symmetry. Tetrameric complexes, $Zr_3MO[O(i\text{-}Pr)]_{10}(acac)_n$ (M = Zr, Fe, Co), have a tetrahedral metal framework with a μ_4 oxygen atom.[34] Reaction of $KZr_2[O(i\text{-}Pr)]_9(DME)$ with two equivalents of KH generates an unusual complex $K_4Zr_2O[O(i\text{-}Pr)]_{10}$ containing a K_4Zr_2 octahedron with a μ_6-O^{2-} unit. This complex reacts with $CuCl_2$ in the presence of traces of water, yielding the polynuclear complex $Cu_4Zr_4O_3[O(i\text{-}Pr)]_{18}$ with a planar central Cu_4 moiety capped by two $Zr_2[O(i\text{-}Pr)]_8$ units and with a planar μ_4-O^{2-} ion.[35] These heterometallic alkoxides are considered the most suitable precursors for Sol–Gel synthesis of solids (*see* ***Sol–Gel Synthesis of Solids***) and chemical vapor deposition (*see Chemical Vapor Deposition*) technology. A rare example of five-coordinate Zr has been found in $(Ar'O)_2Zr[OCH(CH_2Ph)NC_5H_2PhCH(CH_2Ph)O]$, which is produced by carbonylation of $(Ar'O)_2ZrMe_2$ in the presence of pyridine in a 1:1 ratio; with a 1:2 ratio a more usual six-coordinate complex is obtained.[36]

Dihydric and polyhydric alcohols give very stable, apparently monomeric, complexes with zirconium and hafnium. Thus, the monomer $Li_2Zr(OSiPh_2OSiPh_2O)_3{\cdot}3py$ has been obtained by treatment of $ZrCl_4$ with the lithium salt of the disilanol.[37] The ability of hydrous zirconia to absorb pyrocatechols is used in medicine in the treatment of dermatitis. By analogy with their titanium counterparts, complexes of calixarenes (*see Calixarenes*), such as Q{4-*t*-butylcalix[8]arene[MO(*i*-Pr)]$_2$}, are believed to consist of a central dimeric $M(OR)_2M$ core with six-coordinate metal atoms.[38] The calixarene supported zirconium alkyl species [*p*-*t*-Bu-calix[4]-$(OMe)_2(O)_2ZrR_2$] react stepwise with carbon monoxide and isocyanides to give C–C formation products.[39]

β-Diketones form stable MA_4 complexes with six-membered chelate rings (equation 19). These complexes are used in separation of the elements by extraction from acid solutions. The stability constants of these complexes (*see* ***Stability Constants & their Determination***) are linearly dependent on the dissociation constant of the β-diketone. The best extracting agents are β-diketones with a trifluoro group, such as tta. The structures of the $M(acac)_4$ acetylacetonates (mp 194 °C for Zr and 188 °C for Hf) are square antiprismatic, and those of complexes of formula $M(acac)_3Cl$ are distorted pentagonal bipyramidal.

$$MOCl_2 + 4acacH + Na_2CO_3 \longrightarrow M(acac)_4 + 2NaCl + 2H_2O + CO_2 \quad (19)$$

Zirconium and hafnium complexes of an amine bis(phenolate) ligand with a THF side-arm donor have been shown to perform living polymerization of 1-hexene when activated with $B(C_6F_5)_3$.[40] The Zr catalysts (**1**) possess very high activities of 21 000 g $mmol^{-1}{}_{cat}$ h^{-1}. In neat olefin, the reaction is very exothermic and accompanied by various termination processes resulting in a higher polydispersity index than observed when the monomer is diluted in chlorobenzene.



M = Zr, Hf

(**1**)

8.4 Complexes with Nitrogen Donor Ligands

Addition of thiocyanate ions to chloride or perchlorate solutions of zirconium and hafnium yields complexes containing from one to eight isothiocyanate groups per metal atom. These systems are of interest because of the importance of thiocyanate complexes in the extraction and separation of the elements. IR spectroscopy indicates that M–N bonds are present in the violet (Zr) and pink (Hf) complexes $[NEt_4]_2[M(NCS)_6]$; analogous complexes have been obtained with alkali metal cations. In the presence of pyridine, the dodecahedral $Zr(bipy)_2(NCS)_4$ complex is produced (*see* ***Ammonia & N-donor Ligands***).

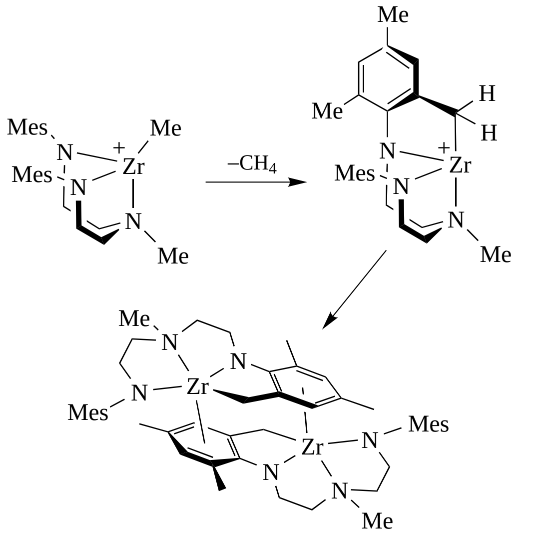
The amides of zirconium and hafnium, $M(NR_2)_4$, like the alkoxides, are associated. The degree of association depends on the nature of R.[41] $Zr(NMe_2)_4$ (mp 70 °C, bp 80 °C at 0.05 mmHg) in the solid state adopts the amide-bridged dimeric structure $Zr_2(\mu\text{-}NMe_2)_2(NMe_2)_6$.[42] A monomer–dimer equilibrium is established in solution but only the monomer exists in the gas phase. Gas-phase electron diffraction data indicate that the N atoms are coplanar, as a result of N to Zr p_π to d_π donation (*see p_π–d_π Bonding*).[43]

The ammonolysis of $(tritox)Zr(CH_2Ph)_3$ yields various polynuclear complexes, depending on the ratio of the reagents: $[(tritox)Zr]_6(\mu_6\text{-}N)(\mu_3\text{-}NH)(\mu\text{-}NH_2)_3$ (1:1), $[(tritox)Zr]_5(\mu_5\text{-}N)(\mu_3\text{-}NH)_4(\mu\text{-}NH_2)_4$ (1:1.75), and $[(tritox)Zr]_5(\mu_5\text{-}N)(\mu\text{-}NH_2)_{12}$ (1:2.6). The structures have been confirmed by NMR and X-ray analysis.[44] These polyamidonitriles can be considered as analogs of the known polyoxoanions, such as $(i\text{-}PrOY)_5(\mu_5\text{-}O)(\mu_3\text{-}O\text{-}i\text{-}Pr)_4(\mu\text{-}O\text{-}i\text{-}Pr)_4$.

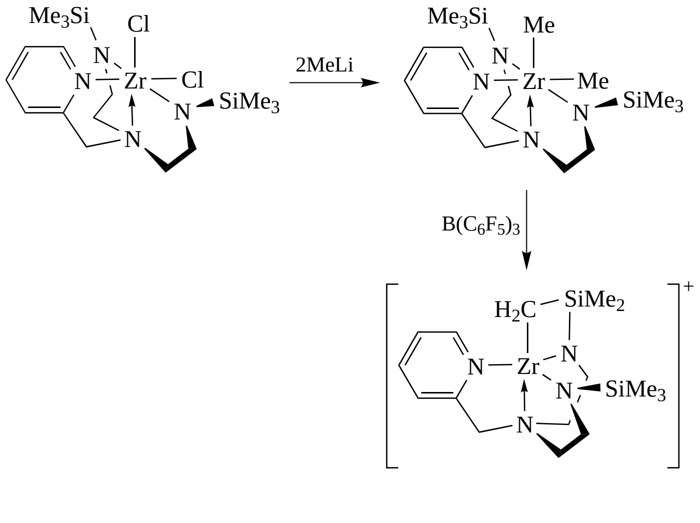
Several $ZrLCl_2(OR)$ complexes (R = alkyl or aryl) that contain the *Tripodal Ligand* tris(3,5-dimethylpyrazolyl)hydroborate, $HBpz'_3$, which is considered a formal isolobal analog of cyclopentadienide, have been obtained. In all of them the metal atom is six-coordinate, as in $CpZrCl_2(OR)$ complexes.[45]

The bis(porphyrinato) complexes of zirconium, $Zr(OEP)_2$ and $Zr(TPP)_2$, have a sandwich structure and have been obtained by treating $Zr(NEt_2)_4$ with the free porphyrins H_2OEP or H_2TPP (*see Porphyrin*). An X-ray analysis of $Zr(TPP)_2$ and its mono- and di-cations (as salts with the $SbCl_6^-$ anion) indicates a distorted square antiprismatic arrangement around Zr that contracts with increasing charge.[46]

There has recently been an explosion in the use of new multidentate anionic N-donor ligands for group 4 metals. The diamido-donor class of ligands where anionic amido groups flank a central neutral donor atom such as O, N, S, or P have been particularly well studied. Cationic organometallic catalysts based of Zr and Hf complexes of the dianionic $(RNCH_2CH_2)_2NMe$ ligand have shown very high activity for the living polymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***) of 1-hexene where R = 2,6-$Cl_2C_6H_3$. For R = Mes, activity



Scheme 3



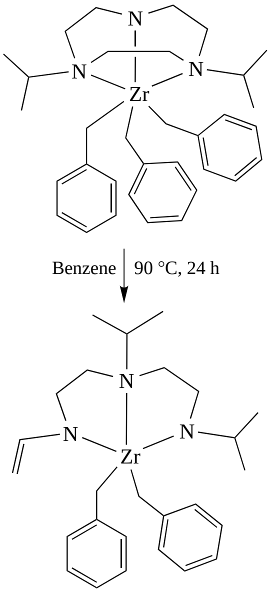
Scheme 4

is hindered by decomposition *via* mesityl methyl hydrogen abstraction. Dimerization of the cyclometallated cation occurs by coordination to an arene ring of another cation (Scheme 3).[47]

One or both chloride ligands in $ZrCl_2(N_2NN')$ can be substituted using organo-magnesium or -lithium reagents forming the mono- and dialkyl derivatives $Zr(CH_2Ph)Cl(N_2NN')$ and $ZrMe_2(N_2NN')$. Treatment of $ZrMe_2(N_2NN')$ with $B(C_6F_5)_3$ or $[CPh_3][B(C_6F_5)_4]$ leads to trimethylsilyl group C−H bond activation yielding a cyclometallated cation (Scheme 4).[48]

Hafnium alkyl complexes stabilized by the diamidopyridine ligand $(RNCH_2)_2C(CH_3)(2\text{-}C_5H_4N)^{2-}$ (R = Mes) (abbreviated $MesN_2py$) have also shown living polymerization activity of 1-hexene at temperatures below 10 °C. Activation of $Hf(i\text{-}Bu)_2(MesN_2py)$ with $[Ph_3C][B(C_6F_5)_4]$ gives the *i*-butyl substituted hafnium cation that is considerably more stable than that of the zirconium analog. Addition of 1-hexene causes quantitative polymerization without indication of β-hydride elimination over a period of 2−3 hours at 0 °C.[49]

The tribenzyl complex (i-Pr_2triazacyclononane)$Zr(CH_2Ph)_3$ eliminates toluene upon heating with concomitant ring opening of the ancillary macrocycle to yield $[CH_2{=}CHNCH_2CH_2N(i\text{-}Pr)CH_2CH_2N(i\text{-}Pr)]Zr(CH_2Ph)$ (equation 20).[50]



(20)

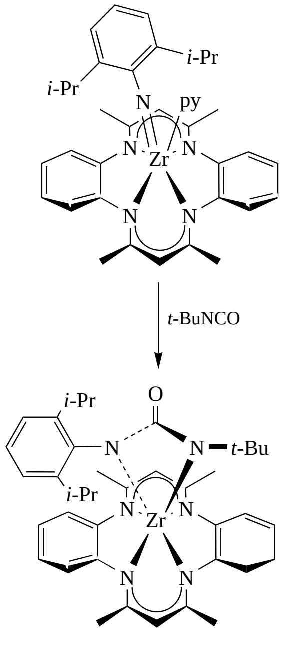
Group 4 metals in combination with alkali hydrides provide a remarkable method of chemical modification of porphyrinogens to give novel macrocycles (*see Macrocycle*) that cannot be prepared by classical organic methods. The reactivity of the zirconium hydride shown in Scheme 5 is demonstrated by the insertion reactions into the metal-hydride bond, for example, with terminal olefins, isocyanides, and alkynes. Particularly intriguing is the reaction of the oepg-zirconium-hydride species with CO. This formally converts a pyrrole ring of the oepg ligand into a pyridine fragment. The resulting modified ligand can be cleaved by hydrolysis. A subsequent transformation of the resulting pyridine tris(pyrrole) macrocycle using Hf in lieu of Zr leads to the doubly pyridine-modified, protonated ligand.[51]

Reactions of monochloro complexes of zirconium and hafnium stabilized by tripodal trianionic ligands (such as $MeC(CH_2NR)_3^{3-}$, $HC(SiMe_2NR)_3^{3-}$ and $MeSi(SiMe_2NR)_3^{3-}$) with the late transition metal organometallic complexes $K[CpM(CO)_2]$ (M = Fe, Ru) gives heterodinuclear complexes with unbridged metal−metal bonds. These heterobimetallic complexes react with, for example, methylisocyanide to yield insertion products (Scheme 6).[52]

Trinuclear complexes can be made if bis(amido) chelate ligands are used in place of the tripod ligands. The addition of two $CpM'(CO)_2$ units (M′ = Fe, Ru) can be carried out sequentially. However, mixed trinuclear complexes possessing Zr–Ru–Fe metal centers cannot be prepared this way (Scheme 7).[53]

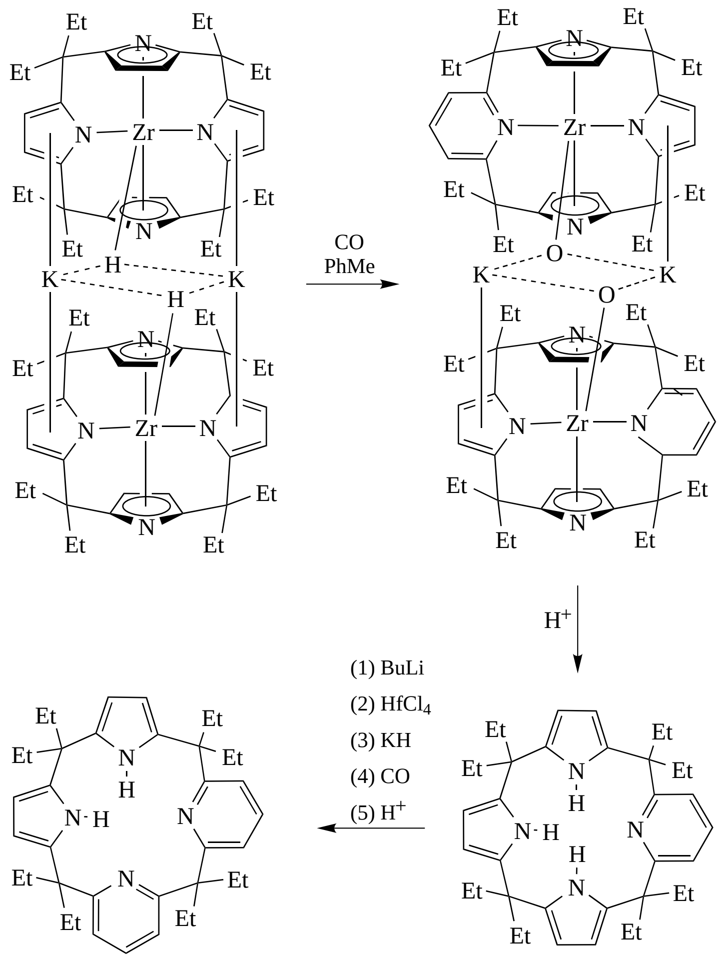
The activation of C–H bonds by d^0 metal centers can be investigated very effectively with complexes of the type $(t\text{-}Bu_3SiNH)_3ZrR$, where R is an alkyl or aryl group, as these compounds undergo reversible elimination of hydrocarbon. In these examples, concerted mechanisms involving R′–H bond interaction at d^0 metal imido complexes, either isolable or transient, give metathesis products via R–H elimination.[54,55]

The reactivity of zirconium imido complexes supported by a dibenzotetraaza[14]annulene (taa) macrocycle ligand toward a range of unsaturated substrates has been examined. Reaction with *t*-butyl isocyanate cleanly generated the cycloaddition product $Zr\{N(2,6\text{-}(i\text{-}Pr)_2C_6H_3)C(O)N(t\text{-}Bu)\}(Me_4taa)$ (equation 21).[56]



(21)

Group 4 imido chemistry (*see Imide Complexes*) is less well studied than that of the group 5−7 metals. An important reason for this is the change in reactivity of the imido ligand upon coordination to the more electropositive metals. The increased polarity of the M=NR unit in compounds



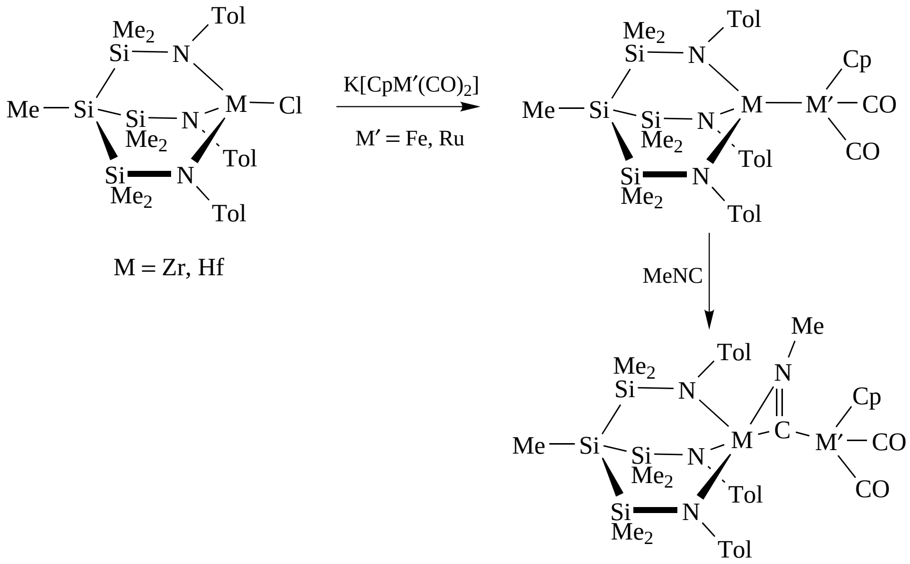
Scheme 5

of group 4 renders the imido ligand the preferential point of attack. One approach for stabilizing the imido unit is the protection of the greater part of the coordination sphere of the metal by a polydentate ligand that not only meets the electronic demand of the highly Lewis acidic early transition metal center but ideally allows the generation of low-coordinate imido species under controlled conditions.

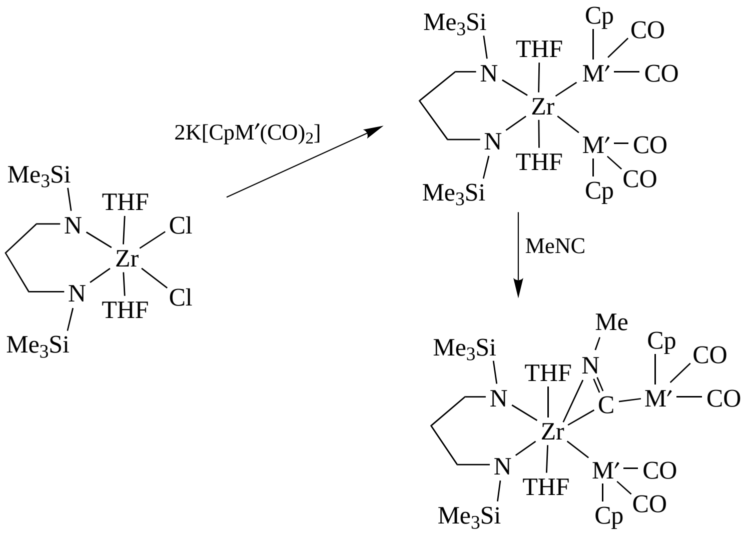
The number of titanium imido complexes characterized greatly outnumbers those of the heavier congeners, particularly for hafnium. Zirconium imides of a variety of diamido-based ligands have been prepared. A zirconium dialkyl complex supported by two alkyl guanidinate ligands reacts with aryl isocyanides to give the corresponding zirconium aryl imide species.[57] The relative instability of imides of zirconium as compared to titanium is apparent in complexes supported by 1,3,5-trialkyltriazacyclohexane (R′tach) and 1,4,7-triazacyclononane (R′tacn) ligands. Whereas crystalline aryl and alkyl imides of the form $TiCl_2(NR)(R'tach)$ and $TiCl_2(NR)(R'tacn)$ (R = *t*-Bu, 2,6-(*i*-Pr)$_2$C$_6$H$_3$, R′ = Me, *t*-Bu) can be readily obtained in excellent yield, the zirconium imide $ZrCl_2$(N-2,6-(*i*-Pr)$_2$C$_6$H$_3$)(Me$_3$tach) can only be prepared on an NMR tube scale.[58]

Treatment of *cis*-(ttp)$ZrCl_2$ (ttp = *meso*-tetra-*p*-tolylporphorynato dianion) with two equivalents of bulky lithium amide reagents, LiNHR (R = 2,4,6-Me$_3$C$_6$H$_2$, 2,4,6-*t*-Bu$_3$C$_6$H$_2$, 2,4,6-Ph$_3$C$_6$H$_2$, 2,6-*i*-Pr$_2$C$_6$H$_3$), in toluene resulted in the formation of terminal imido complexes. The 2,6-diisopropylphenyl derivative was most amenable to isolation and purification. The analogous Hf complex, (ttp)Hf(N-2,6-*i*-Pr$_2$C$_6$H$_3$), could be isolated by the same reaction. The solid-state crystal structures of the two compounds are isomorphous. The geometry about the metals is best described as distorted square pyramidal. Treatment of the Hf imide with excess aniline results in the formation of the bis(amido) complexes, (ttp)Hf(NHPh)$_2$ and (ttp)Hf(NHPh)(NH(2,6-*i*-Pr$_2$C$_6$H$_3$)).[59]

Chiral (*see Chiral*) nitrogen donor ligands have also been developed for enantioselective (*see Enantioselectivity*) catalysis in an effort to diversify this area of chemistry hitherto dominated by ansa-metallocene (*see Metallocene Complexes*) based ancillary groups. Using a diamino-biphenyl backbone, chiral multidentate ligands have been prepared and



Scheme 6



Scheme 7

coordinated to zirconium to give C_2 or other chiral species. Reaction of these amino ligands with $Zr(NMe_2)_4$ yields the metal complexes via protonolysis of two dimethylamido groups. Asymmetric variations of these ligands have also been prepared with different substituents at each amine (Figure 1).[60]

8.5 Dinitrogen Complexes

Coordination and organometallic complexes of zirconium and hafnium have in recent years shown a rich ability to form dinitrogen compounds (*see Dinitrogen & Dinitrogen Complexes*), as well as promoting reactivity at the dinitrogen center. Dinitrogen complexes of Zr and Hf are nearly always bimetallic with the coordinated N_2 fragment bridging the metals in either an end-on or side-on bonding mode. The bonding mode is strongly dependent on the ancillary ligands present. Reduction of $ZrCl_3(N(SiMe_2CH_2PR_2)_2)$ (abbreviated $ZrCl_3(PNP)$, R = *i*-Pr) with sodium amalgam yields the side-on bridging dinitrogen complex $(ZrCl(PNP))_2(\mu\text{-}\eta^2 : \eta^2\text{-}N_2)$. The resulting N_2 fragment possesses a highly elongated N–N bond

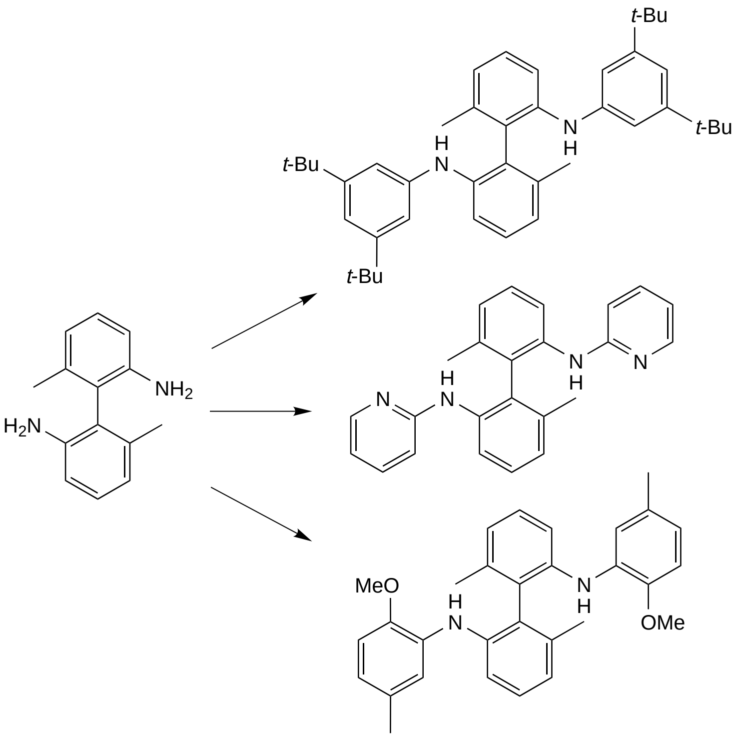


Figure 1 Chiral N-donor ligands used in asymmetric catalysis by Zr

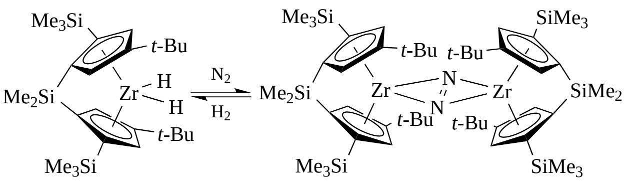
of 1.548(7) Å. Changing the chloride ligand to cyclopentadienyl alters the bonding mode of the dinitrogen unit generating an end-on bridging species $(ZrCp(PNP))_2(\mu\text{-}N_2)$ with a N−N distance of 1.301(3) Å. Replacement of chloride with another hard anionic ligand such as an alkoxide allows the side-on bonding mode of dinitrogen to be maintained. Interestingly, direct metathesis of the chloride-substituted dinitrogen complex with alkoxide or aryloxide transfer reagents results in product decomposition. However, the reduction of $ZrCl_2(OR')(PNP)$ ($R' = 2,6\text{-}Me_2C_6H_3$ or *t*-Bu) with sodium amalgam under N_2 gives the dinitrogen complex $(Zr(OR')(PNP))_2(\mu\text{-}\eta^2:\eta^2\text{-}N_2)$ with a N−N bond length of 1.528(7) Å (Scheme 8).[61]

A zirconium(IV) chloride complex of a macrocyclic ligand derived from the (PNP) system described above has been prepared. Reduction of $ZrCl_2(P_2N_2)$ (where $P_2N_2 = PhP(CH_2SiMe_2NSiMe_2CH_2)_2PPh$) with potassium graphite (KC_8) results in the formation of a dinuclear dinitrogen complex possessing a side-on N_2 unit with a N−N distance of 1.43(4) Å. Reaction of this dinitrogen complex with dihydrogen results in an unprecedented transformation to give a N−H unit and a bridging hydride, probably *via* heterolysis (*see Heterolytic Cleavage*) of the H–H bond. A similar process can be effected with primary silanes to generate silylhydrazido species with a bridging hydride. This transformation probably occurs in a similar manner to the addition of H_2, that is, through heterolytic activation of the H−Si bond (Scheme 9).[62]

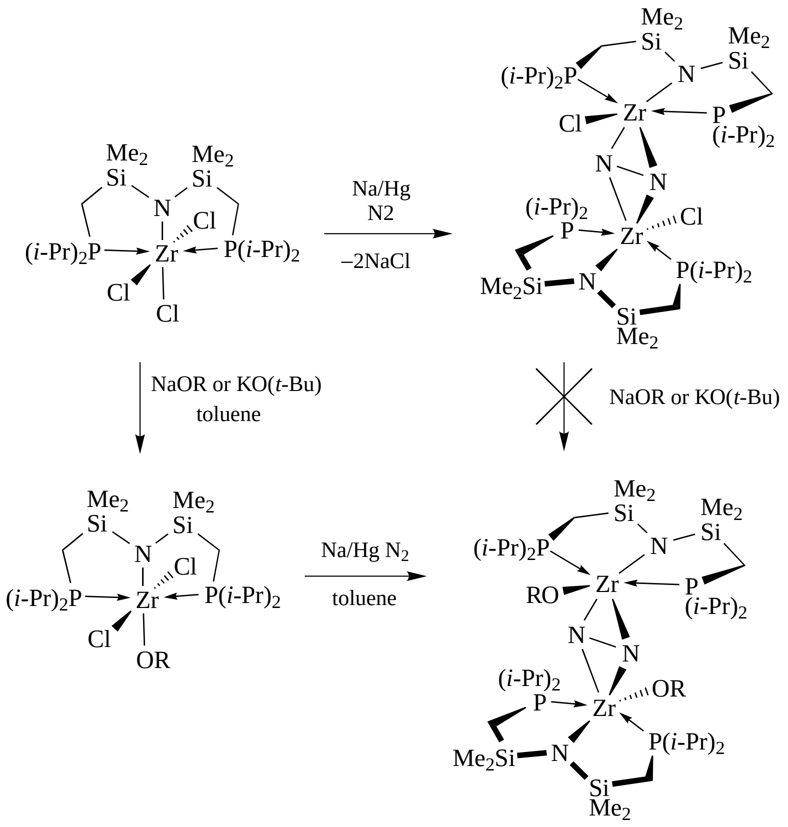
Zirconium hydride complexes have also exhibited dinitrogen activation. The chiral zirconocene dihydride eliminates dihydrogen spontaneously and in the presence of N_2 forms a dinuclear side-on bridged complex with a resulting N−N bond distance of 1.241(3) Å. The N_2 moiety in $Me_2Si(C_5H_2\text{-}2\text{-}SiMe_3\text{-}4\text{-}CMe_3)_2Zr_2(\mu\text{-}\eta^2:\eta^2\text{-}N_2)$, however, does become displaced upon exposure to PMe_3 to form the Zr(II) species $[rac\text{-}BpZr](PMe_3)_2$ (equation 22).[63]



(22)

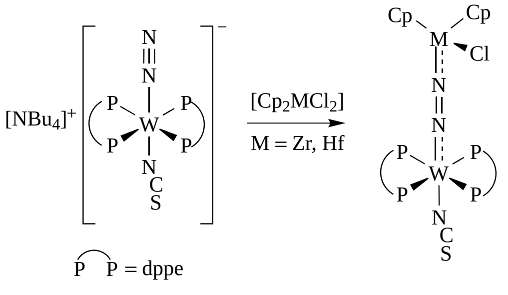
A related reaction, which yields a zirconocene dinitrogen complex possessing a side-on bound N_2 fragment, proceeds *via* alkane elimination from a zirconium alkyl hydride. Intramolecular C−H activation gives a cyclometallated hydride species, which upon exposure to an atmosphere of dinitrogen at − 35 °C results in a dinitrogen complex with a N−N bond length of 1.47(3) Å, shown in Scheme 10.[64]

Heterobimetallic dinitrogen complexes containing a group 4 transition metal have been prepared. Reaction of the anionic dinitrogen complex trans-$[NBu_4][W(NCS)(N_2)(dppe)_2]$ with Cp_2MCl_2 (M = Zr, Hf) or $Cp_2ZrClMe$ gives $W(NCS)(dppe)_2$



Scheme 8

(μ-N_2)MCp_2Cl or W(NCS)(dppe)$_2$(μ-N_2)$ZrCp_2Me$, respectively (equation 23).[65]



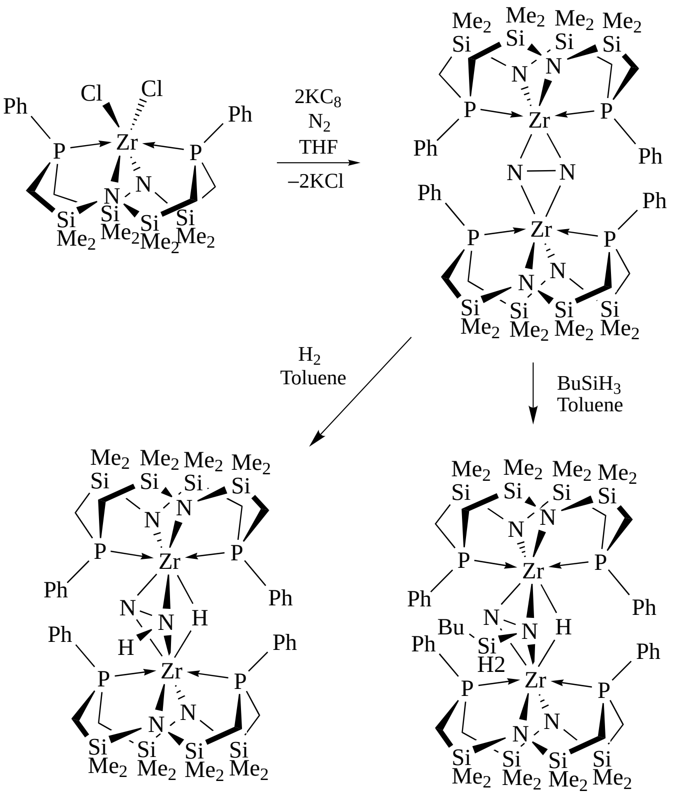
(23)

The products of reactions of laser-ablated zirconium and hafnium atoms with dinitrogen have also been examined and characterized by infrared spectroscopy. Density Functional (DFT) calculations were used to model the vibration bands arising from various metal-dinitrogen and -nitride fragments generated. Spectroscopic evidence suggests that dinuclear rhombic molecules with bridging nitrogen atoms are among the species observed, which provides evidence for the complete activation and bond cleavage of a dinitrogen molecule by two naked metal atoms. Also postulated was the presence of NMN-type dinitrides as well as side-on bound MN_2 and bis-η^2-bound $M(N_2)_2$ dinitrogen fragments.[66]

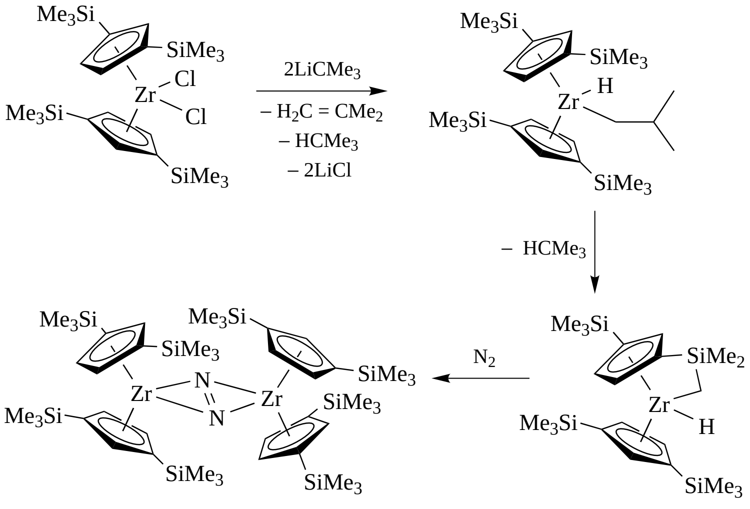
8.6 Complexes with Phosphorus and Sulfur Donor Ligands

Zr and Hf tetrachlorides form complexes of composition $MCl_4(POCl_3)$ and $MCl_4(POCl_3)_2$ with phosphoryl trichloride. These are used in the separation of the elements by distillation. The distillate has the composition $3MCl_4(POCl_3)_2$ and boils (1 atm) at 360 °C (Zr) and 355 °C (Hf). Phosphines react with zirconium halides in an appropriate solvent yielding monomeric adducts whose composition depends on the cone angle (*see Cone Angle*) of the ligand (*see **P-donor Ligands***). With PEt_3, PBu_3 (L) and bulky diphosphines dppe or dbpe (L−L) the six-coordinate ZrX_4L_2 and ZrX_4(L−L) complexes (X = Cl, Br) have been prepared, whereas with smaller chelating phosphines, such as dmpe, eight-coordinate complexes $ZrX_4(L{-}L)_2$ were obtained.[67] Although the structure of the latter is unknown, an analogy is implied with the dodecahedral ligand arrangement in the related complex $ZrMe_4(dmpe)_2$.

Zr–S bonds are rather weak. For example, zirconium, unlike other metals, does not form complexes with thioglycolic acid, whereas with glycolic acid the triglycolatozirconic acid derivatives $H_3[Zr(OH)(OCH_2CO_2)_3]$ are formed. Nevertheless, insertion (*see Insertion*) of CS_2 into a metal−nitrogen



Scheme 9



Scheme 10

bond gives a dithiocarbamate (*see Dithiocarbamate*) (equation 24).[68] In the dithiolate $[NMe_4]_2[Zr(S_2C_6H_4)_3]$, the coordination polyhedron is intermediate between a distorted trigonal prism and an octahedron.

$$Zr[N(i\text{-Pr})_2]_4 + CS_2 \longrightarrow Zr[S_2CN(i-Pr)_2]_4 \qquad (24)$$

Homoleptic anionic zirconium and hafnium phosphine complexes have recently been prepared using bisphosphinine ligands, which are phosphine analogs of the ubiquitous bipyridyl ligand. Structure determinations of the Li_3(solv)Cl salts were performed (solv = DME for M = Zr and THF for M = Hf) show the overall geometry around the metal center to be trigonal prismatic. Disruption of the aromaticity is

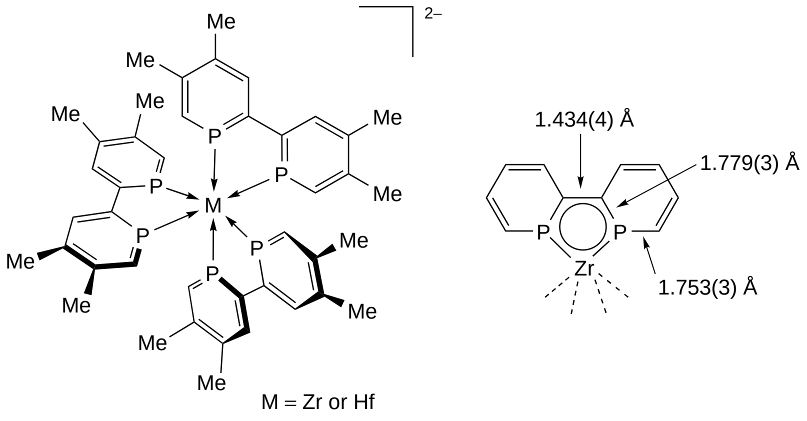


Figure 2 Homoleptic Zr and Hf bisphosphine complexes

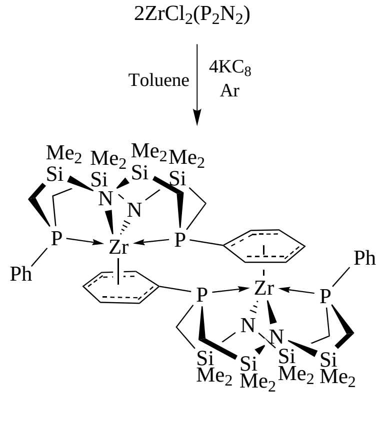
observed in each phosphinine subunit. It is suggested that the −2 oxidation state of the complex is only formal; the complex possesses a delocalized character that makes assignment of oxidation state difficult (Figure 2).[69]

8.7 Complexes with Mixed-Donor Ligands

A mononuclear imido complex of Zr has been prepared by reaction of LiNH(*t*-Bu) with $ZrCl_2(PhP(CH_2SiMe_2NSiMe_2CH_2)_2PPh)$ ($ZrCl_2(P_2N_2)$) followed by addition of MeLi. In the formation of Zr(N-*t*-Bu)(P_2N_2), there was no evidence that the putative Zr(NH(*t*-Bu))Me(P_2N_2) was stable with respect to alkane elimination.[70]

During the preparation of dark blue $(Zr(P_2N_2))_2(\mu\text{-}\eta^2:\eta^2\text{-}N_2)$, a small amount (<5%) of a yellow crystalline by-product was sometimes observed. A Pasteur separation of a few crystals of this material allowed analysis by X-ray crystallography and showed that this by-product does not contain dinitrogen; instead, a phosphorus-phenyl group on one $Zr(P_2N_2)$ unit is bound to the zirconium center of another $Zr(P_2N_2)$ fragment. When this reduction is performed in the absence of N_2 (either under argon or in vacuum), good yields of the dimer were obtained (equation 25).[71]



(25)

The reaction of one equivalent of $LiN(SiMe_2CH_2PR_2)_2$ (R = Me, Ph) with MCl_4 yields the six-coordinate $MCl_3(N(SiMe_2CH_2PR_2)_2)$ complexes with meridional (Zr) or facial (Hf) geometries. The same reaction with two equivalents of the lithium salt generates chiral distorted octahedral $MCl_2(N(SiMe_2CH_2PR_2)_2)_2$ complexes with two bidentate hybrid ligands that are inert to nucleophilic attack.[72]

Mixed-donor variations of the diamido-amine ligands, which are discussed above, have been prepared where the central neutral donor atom is a P, O, or S atom. The group 4 chemistry of these coordination complexes has been primarily directed at polymerization catalysis and small molecule activation. The various NON, NPN, and NSN ligands studied include (RN-*ortho*-$C_6H_4)_2D^{2-}$ (D = O, S) and $(RNCH_2CH_2)_2D^{2-}$ (D = O, P) type systems that have shown a tremendous range of reactivity toward, for example, olefin polymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***) and dinitrogen complex formation. The ligands may bind either meridionally (*mer*) or facially (*fac*) (Figure 3).[73–76]

Addition of two equivalents of MeMgCl or MeLi to $ZrCl_2(N(CH_2SiMe_2N\text{-}t\text{-}Bu)_2)$ yields a dimeric product with two zirconium centers bridged by two imido groups. Although addition of one equivalent of MeLi to the dichloride precursor gives $ZrCl(Me)(N(CH_2SiMe_2N\text{-}t\text{-}Bu)_2)$ in good yield, attempts to replace the second chloride result in ligand degradation by a proposed electron transfer to zirconium followed by elimination of a *t*-Bu radical (Scheme 11).[77]

The desire for new nonmetallocene-based single-site polyolefin catalysts has lead to the use of high-throughput screening techniques to achieve faster identification of catalytically active systems and allow a much broader range of catalyst candidates and conditions to be evaluated. Particularly in the case of highly modifiable ligand systems, that is, those where the donor substituents and donor atoms themselves may be modified, this approach allows for even small variations in electronic and steric properties to be probed. These high-throughput approaches require an efficient method of attaching

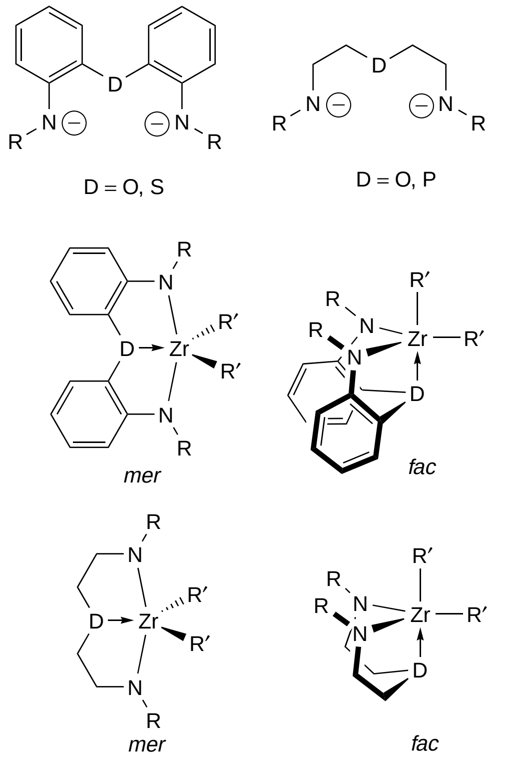


Figure 3 Hybrid diamido-donor ligands

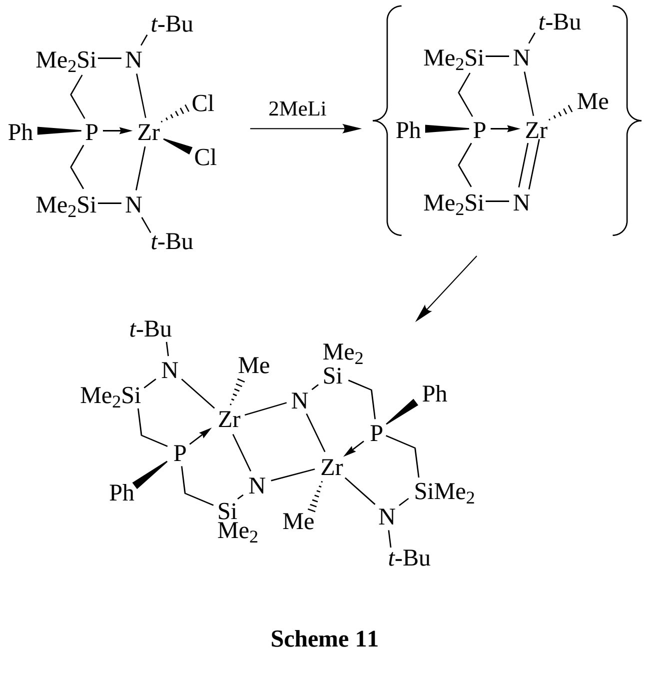

Scheme 11

a ligand to the metal. The most useful approach has been to capitalize on the labile nature of M–C bonds and their susceptibility to elimination by protio ligand derivatives. $M(CH_2Ph)_4$ (M = Zr and Hf) complexes can be used in the preparation of catalyst candidates by reaction with ligands that possess acidic protons, as in the protonated forms of the ligands discussed above.[78]

9 LOWER OXIDATION STATES

9.1 Inorganic Compounds

Low oxidation states are not characteristic of zirconium and hafnium. There is no aqueous chemistry of the metals in oxidation state ≤ III, except for the unstable orange aqua ion $[Zr(H_2O)_6]^{3+}$, which is analogous to the stable violet $[Ti(H_2O)_6]^{3+}$ ion. Inorganic compounds of M^{III}, M^{II}, and M^{I} have been studied mainly as halides and chalcogenides, M_2X_3 and MX (X = S, Se, Te). Chalcogenides of the trivalent metals were obtained by the direct reaction of the elements at 800 °C. Some distinction between Zr and Hf is displayed in the structure of M_2S_3: cubic for Zr and hexagonal for Hf. The compounds are stable toward both hot water and air.

The halides MX_3 and MX_2 are intensely colored (from blue-black to olive-green) solids. Trihalides with nonstoichiometric phases MX_x ($x = 2.94-3.03$ for Cl and 2.83–3.43 for I) are known for all halides (except HfF_3); they are obtained by the reduction of the related tetrahalide with the metal (equation 26), or with aluminum in a molten MCl_4–$AlCl_3$ mixture. The reaction shown in equation 26 is carried out under elevated pressure to prevent disproportionation (*see Disproportionation*). Zirconium is reduced more readily than hafnium, so that in the mixture $ZrCl_4$/$HfCl_4$/Zr, only $ZrCl_3$ is detected. The trihalides MX_3 are rather strong reducing agents. Their vigorous reaction with water is accompanied by oxidation of the metal and evolution of hydrogen; they remove potassium from KNH_2 in liquid ammonia (equation 27).

$$Zr + 3ZrCl_4 \longrightarrow 4ZrCl_3 \qquad (26)$$

$$ZrBr_3 + KNH_2 \xrightarrow{NH_3(l)} K + ZrBr_3NH_2 \qquad (27)$$

On heating, the trihalides MX_3 disproportionate, yielding related dihalides. Further heating produces the subchlorides MCl for X = Cl and the metal for X = Br. HfCl may be also obtained by the electrolysis of molten hafnium chlorides with a zirconium anode. ZrX and HfX (X = Cl, Br) have layered (MMCl=ClMMCl=Cl) structures[79] and are better lubricants than graphite in the temperature range 400–1000 °C. ZrCl and ZrBr phases can be intercalated (*see* ***Intercalation Chemistry***) with oxygen, carbon, nitrogen, and hydrogen, forming $ZrXO_x$, ZrXH, and $ZrXY_{0.5}$ (Y = H, C, N) phases. In the first two of these, oxygen and hydrogen atoms occupy tetrahedral interstices between double zirconium layers, whereas in the last named, interstitial atoms are localized in octahedral holes.[80]

In the phases of composition Zr_5Sb_3Z, obtained either by arc melting, vapor-phase transport, or metal flux methods,

the interstitial atom Z (C, O, Al, Si, P, etc.) occupies all the zirconium trigonal antiprism sites in the Zr_5Sb_3 host structure.[81]

9.2 Coordination Compounds

Reduction of $ZrCl_4$ by sodium amalgam in the presence of phosphines yields dinuclear Zr^{III} complexes of composition $[(PR_3)_2ZrCl_2(\mu\text{-Cl})]_2$, containing Zr–Zr bonds (CN 7).[82] Complexes with the PMe_3 ligand have also been obtained via photolysis of $ZrNp_2Cl_2(PMe_3)_2$. The first analogous hafnium complex with an Hf−Hf bond (3.099 Å), $Hf_2Cl_6(dippe)_2$, has been obtained by the reduction of $HfCl_4$ with Na/K alloy in the presence of the phosphine.[83] Recently, iodide analogs $[(PR_3)_2ZrI_2(\mu\text{-I})]_2$ and complexes with the substituted pyridine bppy have also been prepared. The zirconium complex of a multidentate phosphido ligand, $Zr_2Cl_3[P(CH_2CH_2PMe_2)_2]_3$, has been isolated; it has two bridging phosphorus atoms and one chlorine atom, and an eight-coordinate metal atom.[84] The metal−metal distance in such complexes is rather long and lies within the range 3.1−3.4 Å (*see* ***Dinuclear Organometallic Cluster Complexes***).

Triangular zirconium mixed-valence complexes stabilized by arenes, $[Zr_3(\mu\text{-Cl})_6(\eta^6\text{-}C_6Me_6)_3]^{n+}$ ($n = 1, 2$) (*see Arene Complexes*), have been isolated as salts with the $[Al_2Cl_7]^-$ anion (equation 28).[85] Arenes also stabilize divalent hafnium in the complexes $(\mu\text{-}\eta^{12}\text{-}C_6H_5R)[HfI_2(PMe_2Ph)_2]_2$ (R = H, Me), which have a piano stool structure (*see Piano Stool Structure*).[86]

$$9ZrCl_4 + 9C_6Me_6 + 4Al + 8AlCl_3 \longrightarrow 3[Zr_3Cl_6(C_6Me_6)_3][Al_2Cl_7]_2 \quad (28)$$

The most exciting feature of low-valent zirconium and hafnium complexes is their ability to coordinate small unsaturated molecules. Thus reduction of the monomeric complex $ZrCl_3(N(SiMe_2CH_2P(i\text{-}Pr)_2)_2)$ by Na/Hg under N_2 yields deep blue crystals of dimeric $\{ZrCl(N(SiMe_2CH_2P(i\text{-}Pr)_2)_2)\}_2(\mu\text{-}N_2)$[87] (*see Dinitrogen & Dinitrogen Complexes*); also dimers $M_2X_6(PEt_3)_4$ (M = Zr, Hf; X = Cl, Br) directly react with ethylene under mild conditions to produce metal−alkene complexes (*see Alkene Complexes*) $M_2X_6(PEt_3)_4(\eta^2\text{-}C_2H_4)$.[88] In both complexes, the bridging molecules (dinitrogen or ethylene) lie perpendicular to the M−M axis, forming a planar MX_2M moiety. The N−N distance (1.548 Å) is longer than that in hydrazine (1.47 Å), and the C−C distances (>1.5 Å) are close to those of ordinary C−C bonds. This is evidence of the highly reduced state of dinitrogen and ethylene in these complexes. The oxidative addition of pivalonitrile to the Zr−Zr bond yields the complex $[ZrCl_2(bppy)_2]_2(\mu\text{-Cl})[\mu\text{-}\eta^2\text{-NC}(t\text{-Bu})]$ with a Zr−Zr distance of 3.55 Å (compared with 3.14 Å for a Zr−Zr single bond).[89]

A few examples of zerovalent zirconium and hafnium complexes are known. The reduction of MCl_4 with lithium in the presence of a diamine (bipy, phen) gives air-sensitive, monomeric, diamagnetic $M(L{-}L)_4$ complexes.[90] Carbonyl complexes of Zr^0 and Hf^0 have been reported (equation 29) that are stabilized by the tripodal phosphine ligand, $(trmpe)M(CO)_4$, and by a triamine, $(ttacn)M(CO)_4$. These are obtained by the reduction of MCl_4 with potassium naphthalenide in the presence of a ligand.[91] Further reduction in the presence of macrocyclic ethers (only for Zr) or of cryptands (*see Crown Ethers*; *Cryptands & Cryptates*) yields complexes of zirconium and hafnium in oxidation state −II having the formula $[KL]_2[M(CO)_6]$ (L = 15-crown-5 for zirconium, cryptand [2.2.2] for both metals). The existence of the octahedral $M(CO)_6{}^{2-}$ anion has been confirmed for zirconium by ^{91}Zr NMR studies and by X-ray analysis (Zr−C = 2.210 Å, Hf−C = 2.178 Å).[92]

$$MCl_4(THF)_2 + trmpe + 4KC_{10}H_8 + 4CO \xrightarrow{\text{DME, } -70\,^{\circ}\text{C}} (trmpe)M(CO)_4 + 4KCl + 4C_{10}H_8 + 2THF \quad (29)$$

9.3 Clusters

Heating $[(PMe_2Ph)_2ZrCl_2(\mu\text{-Cl})]_2$ leads to the formation of a $Zr_6Cl_{12}(PMe_2Ph)_6$ cluster consisting of an octahedral zirconium skeleton stabilized by edge-bridging chlorides and terminal phosphines.[93] For inorganic Zr_6Cl_{12} cluster phases of the formula $Q_m[Zr_6(Z)Cl_{12}]Cl_n$, an interstitial atom is required in all cases for the stabilization of the Zr_6 cluster (*see* ***Electronic Structure of Clusters***). A large family of these phases with Z = H, Be, B, C, N, and even Mn and Fe has been obtained via both solid state and nonaqueous reactions.[94] High-temperature reactions have been used to produce Zr_5Sb_3Z phases containing an interstitial atom (Z = C, O, Al, Si, P, S, etc.) in the centers of all zirconium trigonal antiprism sites in the Zr_5Sb_3 host (see Section 9.1).[81]

1 INTRODUCTION

Since the discovery of the first organometallic complexes (*see Organometallic Complexes*) Cp_2TiBr_2 and Cp_2ZrBr_2 by Wilkinson in 1953, the literature on this subject has reflected the astonishing extension of the organometallic chemistry of the group 4 transition metals (*see Transition Metals*). This article focuses on modern organometallic chemistry of zirconium and hafnium, while the organotitanium complexes (*see* ***Titanium: Organometallic Chemistry***) appear elsewhere in this encyclopedia.

During the last decade, more than a thousand papers have been published (as during the preceding 40 years) dealing with several thousands of Zr and Hf compounds, largely dominated by organozirconium complexes. In fact, Zr occurs in the lithosphere to the extent of 0.022%. Although it is much less abundant than titanium (0.63%), it is roughly as abundant as carbon. Despite some technical difficulties in the production of pure Zr compounds (due to the presence of about 2% of Hf in the minerals), it is one of the less expensive transition metals. Hf is more difficult to obtain, and commercially available reagents usually also contain some traces of Zr. Very pure derivatives can be obtained by distillation and ion-exchange techniques (*see Ion Exchange*).

Because the ionic radii of the metals are similar (Zr = 0.79 Å, Hf = 0.78 Å), as are the covalent radii (Zr = 1.55 Å, Hf = 1.54 Å) (*see Covalent Radii*), their complexes often exhibit a close similarity in their behavior and molecular structure. However, several well-characterized Zr complexes have no counterparts in the Hf series, which always appear the less reactive in accordance with bond dissociation enthalpy measurements (*see Enthalpy*).

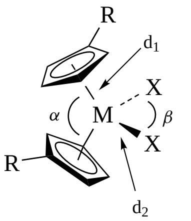
Most of the stable complexes have d^0 structure (*see d^n Configuration*) and formally count as having 16 valence electrons surrounding the metal, with an empty d orbital (*see d-Orbitals*) being responsible for the observed reactivity. This number is less than required by the 18-electron rule (*see Eighteen Electron Compounds*) as related to the stability of transition metal complexes. So, for some Zr or Hf organometallics, stabilization is achieved by completing the electronic configuration to 18 electrons, by coordinating an additional neutral ligand (such as a solvent or phosphane molecule) or by reacting with some unsaturated molecules to form zirconocene-ate complexes. The coordination number of the metal for Zr complexes ranges from 4 to 8. For Hf complexes with the same ligands, it is often smaller. A typical example of this effect is the structure of Cp_4Zr, which is consistent with the presence of three pentahapto and one monohapto Cp ligands (*see Hapticity*), while the structure of the Hf analog contains two pentahapto and two monohapto Cp rings. The most common oxidation state (*see Oxidation Number*) for Zr and Hf complexes is +4, as suggested by their electronic configuration (Zr: [Kr] $4d^25s^2$; Hf: [Xe] $5d^26s^2$). But a significant number of examples with the lower value +2 are known, such as $Cp_2Zr(CO)_2$ or

$Cp_2Zr(PMe_3)_2$. Some complexes, as alkene- and alkyne-$ZrCp_2$ structures can be considered as Zr^{II} complexes, but also as zirconacyclopropanes and zirconacyclopropenes respectively, in which Zr is the +4 oxidation state. They can be represented as resonance hybrids (**1**) and (**2**). On the contrary, Zr^{III} and Zr^{I} compounds are rarer and displayed few synthetically useful transformations.

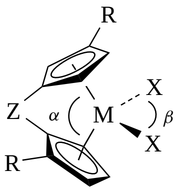
(**1**) (**2**)

Cationic zirconocene complexes are well-known very reactive species with interesting applications owing to their Lewis acidic character (*see Lewis Acids & Bases*). In particular, they are often involved into various catalytic processes including Ziegler-Natta type polymerizations (*see Ziegler–Natta Catalysts*).

The crystal structure of the 16-electron d^0 species (*see Bent Metallocenes*) such as $(RCp)_2MX_2$ (**3**), is a distorted tetrahedron, each Cp ligand (*see Cyclopentadienyl*) occupying a single coordination position. Owing to the steric demand of the Cp ligand, the angle α is larger (and consequently β is smaller) than for a regular tetrahedron. Typically, α and β lie in the range 128–133° and 94–97° respectively, depending on the nature of R and X. In case of *ansa* metallocenes containing a bridge with at least two atoms, the distortion of the tetrahedron is similar. On the contrary, it is more pronounced in *ansa* metallocenes (*see Bridging Ligand*) with a monoatomic bridge (**4**) and largely depends on the nature of Z ($\alpha = 116$–129°; $\beta = 97$–101°). In every case, the Cp ligands can be staggered, eclipsed, or intermediate. Apparently, there is no relation between the relative conformation of the rings and the nature of the α-ligands. Substituents in the two Cp rings are generally opposed to each other in the favored conformation, thus minimizing steric and electronic interactions, but some exceptions have been noted. The distance d_1 lies in the range 2.10–2.32 Å (with an Hf–Cp bond slightly shorter (0.01–0.03 Å) than Zr–Cp bond), whereas d_2 is more largely dependant on the identity of the metal and the X groups.



(**3**)

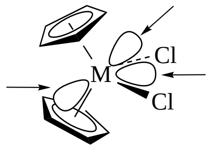


Z = B, C, Si, Ge, P

(**4**)

Spectroscopic techniques are very useful techniques to characterize the group 4 metallocenes (*see Metallocene Complexes*). ^{1}H NMR is a very convenient method for studying the diamagnetic d^0 complexes (*see Diamagnetism*), for which the proton resonances of the organic ligands generally appear in the range 0–10 ppm downfield from the Me_4Si reference. Exceptions are found, especially for hydrido ligands, where resonances appear at higher field. ^{13}C and ^{31}P NMR are also valuable tools for establishing structures, but ^{91}Zr NMR seems limited to simple and very symmetrical complexes. EPR spectroscopy (*see Electron Paramagnetic Resonance*) affords suitable information about paramagnetic M^{III} complexes (*see Paramagnetism*). Infrared spectra (*see Infrared Spectroscopy*) are typical: for example, dicarbonyl complexes exhibit two strong metal-carbonyl stretching bands with frequencies in the range 1980–1840 cm^{-1}. A normal isotopic pattern is generally detected in mass spectrometry (*see Mass Spectrometry*). Photoelectron spectroscopy (UV) has been used to determine the electronic and conformational structures of these molecules.

Although there are many different types of M^{IV} and M^{II} compounds, roughly 75–80% of the currently known well-characterized organozirconiums or organohafniums are cyclopentadienyl derivatives. In these 16-electron d^0 M^{IV} complexes (**5**), one valence-shell empty orbital is available for coordination. They are therefore fundamentally Lewis acidic and certainly, most of their reactions are governed by interaction of the empty metal orbital with electron donors. Probably for the same reason, apart from the dihalides and a few other compounds, Zr and Hf complexes are air- and moisture-sensitive. They require handling in an inert atmosphere, using, for example, the Schlenk tube technique (*see Schlenk Tube*) or a glove box.



The available coordination sites are indicated by the arrows

(**5**)

Although organozirconium and hafnium compounds are not as well known as Grignard reagents (*see Grignard Reagents*), it seems that the time is apt for synthetic chemists to fully enter the world of that chemistry. Very reactive cationic zirconocenes, often *in situ*-generated from neutral complexes, are very useful catalysts in different fields of chemistry, particularly in stereospecific polymerization process, even in industry. According to the structure of the M^{IV} complexes, the empty Zr or Hf orbital may interact with any proximal electrons, including n electron lone-pair, π electrons, or σ electrons. Such interactions may be intermolecular or intramolecular. These processes, which explain the astonishing development of the synthetical applications of organozirconiums, include σ and π complexations, hydrozirconation (*see Hydrozirconation*) and carbozirconation (*see

Carbometalation), oxidative addition (*see Oxidative Addition*) and reductive elimination (*see Reductive Elimination*), σ-bond metathesis (*see σ-Bond Metathesis*), and migratory insertion (*see Migratory Insertion*).

An overall review of these most important topics is developed below. This article is not an exhaustive review; it deals only with the main actual aspects of Zr and Hf chemistry, complementary to those developed in the first edition of the Encyclopedia of Inorganic Chemistry.[1] For more specific details, readers should consult the references mentioned within the articles cited.

2 CYCLOPENTADIENYL COMPLEXES OF Zr AND Hf

Unquestionably, group 4 complexes containing one or two Cp ligands are the most important and the most versatile reagents that find use in catalytic and stoichiometric reactions.

The most widely used approach for coordination of Cp, as well as the many variations of this ligand, requires use of lithium, sodium, and magnesium (or sometimes thallium or potassium) salts of the ligand anion. They can be obtained by direct reaction of the metal or some organometallic reagents on a suitable cyclopentadiene monomer. Another way for synthesizing substituted Cp ligands is the reduction or alkylation of a parent fulvene at the exocyclic carbon atom. But disadvantages of these procedures include the need to prepare moisture- and air-sensitive ligand anions. So, some alternative methods circumvent these difficulties. In this area, reaction of trimethylsilyl- or stannyl-substituted cyclopentadienyls with transition metal halides is a useful procedure.[1] Some more recent reports[2] are related to the use of neutral reagents for the preparation of racemic bis indenyl and bis cyclopentadienyl group 4 complexes. In parallel, the reaction of group 4 homoleptic compounds (*see Homoleptic Compound*) with fulvene derivatives gives rise to mono or bis cyclopentadienyl compounds (Scheme 1). Coordination of the *cis*-diene to the metal should encourage transfer of the metal ligands to the exocyclic carbon giving functionalized Cp complexes.[3]

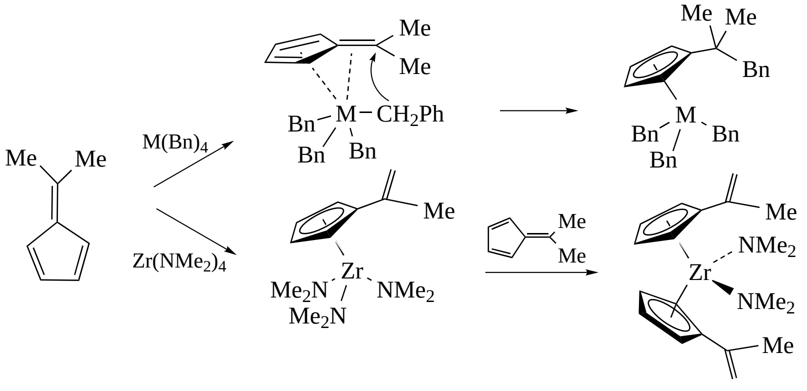
Amine elimination process can be used starting from cyclopentadiene derivatives to produce in good yield *ansa* metallocenes.

2.1 Bis Cyclopentadienyls of Zr^{IV} and Hf^{IV} $[(\eta^5\text{-L})(\eta^5\text{-L}')MXY]$

2.1.1 *Dihalides and Related Complexes*

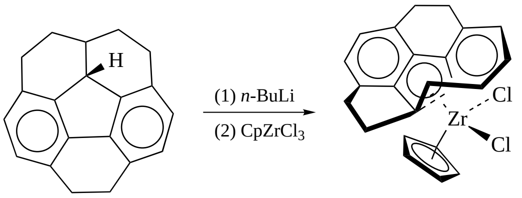
These complexes, which are readily synthesized by transmetalation (*see Transmetalation*) from the appropriate Cp metal and MX_4 ($L = L'$) or (η^5-L)MX_3 ($L \neq L'$), represent a large family of quite always air-stable compounds. The bromides and iodides are also obtained from chlorine exchange reactions with the appropriate boron trihalide. The fluorides can be obtained by metathesis (*see Metathesis*) of chlorides derivatives with Me_3SnF. With only one equivalent of tin reagent per mole of dichloride, partial fluorination occurs affording mixed halide metallocenes. The fluorides are also prepared by chloride/fluoride, by chloride/NMe_2 followed by NMe_2/fluoride exchange, and by oxidative addition (*see Oxidative Addition*).[4]

Of course, complexes containing unsubstituted Cp ligands were the first to be prepared, but to date a great variety of certainly many thousands of complexes have been prepared by different very efficient ways. Substituents are consistent with various carbon or main group functionalities. For example, the structures are very different to Zr complexes of the sterically demanding pentaphenylcyclopentadienyl,[5] bis fluorenyl derivatives[6] or very exciting Zr complex containing a corrannulene-based ligand (equation 1).[7] This bowl-shaped ligand has two sides because of the curvature of the molecule: an *endo* (concave) and an *exo* (convex) side (*see Exo & Endo Substituents*). The Zr atom was determined to be found at the



Scheme 1

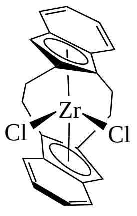
exo side of the bowl.



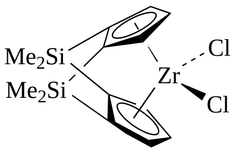
(1)

The stereoselective complexation (*see Stereochemistry*) of the heterotopic faces of Cp ligands can be realized. For example, starting from the isodicyclopentadienyl anion and MCl_4 or (η^5-L)MCl_3, the results clearly indicate the temperature dependence in the stereo differentiation of the two heteropic sides of the anion.[1]

Special attention must be given to the *ansa* organometallics. The bridge linking the two Cp ligands can be very short (B, CR_2, SiR_2, GeR_2, NR, PR, etc.), or longer ($(CH_2)_n$, cyclic derivatives, siloxy chains, etc.). Even, the doubly bridged complexes (**6**) and (**7**) can be prepared.[8,9] An interannular bridge restricts the free rotation of the Cp ligands about the Cp–metal axes with respect to each other changing the dihedral angle between the two Cp ligands.

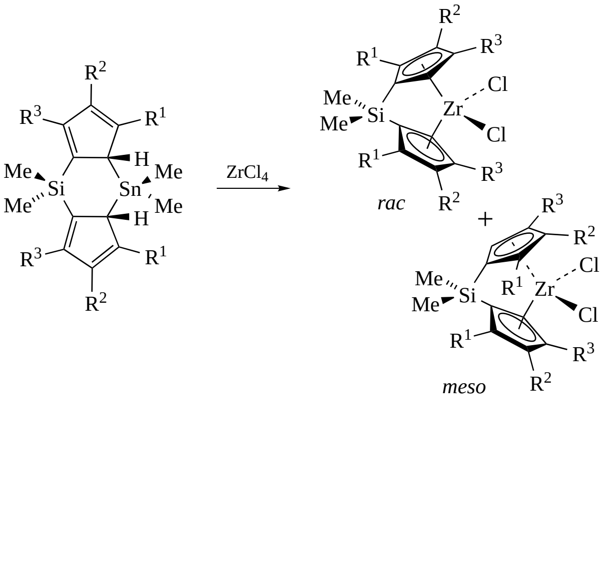


(**6**)



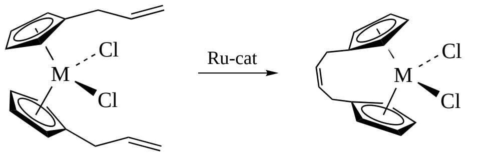
(**7**)

Of course, the nature of the bridge allows varying degrees of stereorigidity and accessibility to the coordination site of the molecule. Some additional ways can be used to prepare *ansa* metallocenes. For example, it is possible to use silastannatetrahydro-s-indacenes as Cp transfer agents for producing silanediyl-bridged zirconocene complexes (equation 2).[10]



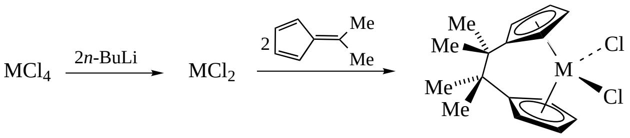
(2)

It is also possible to generate the bridge in a second step by ring-closing metathesis reaction (*see Metathesis*) using the Grubb's catalyst $RuCl_2(=CHPh)(PCy)_3$. *Ansa* metallocenes can be isolated in good conditions by this way (equation 3).[11] The method was extended to diastereoselective kinetic resolution of *meso*- and *dl*-isomeric mixtures and showed excellent selectivity.



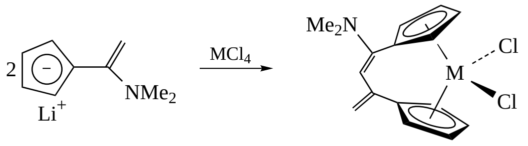
(3)

Another reaction can be used to generate a two-carbon bridge between the Cp ligands.[12] In tetrahydrofuran (THF), the reaction of $ZrCl_4$ with two equivalents of *n*-BuLi, begun at −78 °C and completed at 25 °C, results in a black suspension of $ZrCl_2$ and LiCl, which reacts with fulvenes to provide a high yield of *ansa* zirconocene dichloride (equation 4).



(4)

This reaction can operate starting from a lot of fulvenes. Some allyl-bridged metallocenes can be synthesized by an unusual intramolecular $HNMe_2$ elimination and a fulvene coupling (equation 5).[13]



(5)

Different procedures can be used to obtain racemic or even optically active *ansa* metallocenes of great interest for applications in asymmetric reactions (*see Asymmetric Unit*) or polymerization processes (*see Polymer*). For example, reaction of $C_2H_4(Ind)_2Mg(thf)_2$ with zirconium biphenolate complexes gave directly the pure diastereomers.[14] In the more classical metalation of bis indenyl ligands, a good choice of the starting material and the metallic salt can change dramatically the *dl*/*meso* proportion.[15] Starting from the bis anion and $ZrCl_4$, a 1/1 mixture was obtained. On the contrary, pure *dl* racemate can be obtained with amine elimination process.

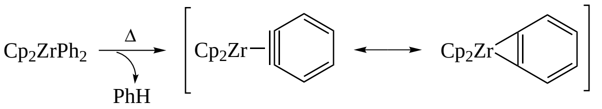
For the preparation of enantiomerically pure ebthi zirconium derivatives, an efficient procedure using optically pure binol can be used starting from racemic mixture.[16]

2.1.2 Dialkyls, Diarys, and Related Complexes

These important compounds with regards to their reactivity are obtained by transmetalation (*see Transmetalation*) between the appropriate metallocene dichloride (*see Metallocene Complexes*) and an alkyl- or aryl-lithium reagent. Dialkyl and diaryl zirconium complexes are very moisture-sensitive, degrading to form μ-oxo species (see Section 5).

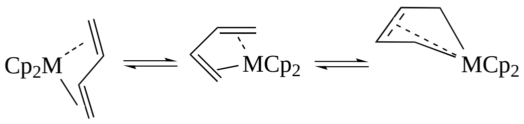
Dimethylzirconocene is thermally stable and can be sublimated *in vacuum*. Its photolysis yields methane together with transient zirconocene species, which can be trapped with several types of electron-donating ligands including dienes, phosphanes, and CO (see Section 2.3). Same behavior is observed for diarylzirconocenes with formation of biaryl products.

Thermolysis of diarylzirconocenes readily affords arynezirconocene complexes (equation 6). These species are best described as metallacyclopropenes, and are versatile reagents in organic synthesis. When $(Cp^*)_2ZrPh_2$ or $(t\text{-}BuCp)_2ZrPh_2$ are heated at 80 °C, cyclometallated complexes (*see Cyclometalation*) are formed by hydrogen transfer from a methyl group to the coordinated benzyne ring.[1]



(6)

Other complexes of great interest are the η^4-conjugated diene metallocenes.[1] They are conveniently prepared by the one-pot reaction of the photochemically induced metallocene with the diene at low temperature. Alternative routes include the treatment of the metallocene dichloride with a conjugated diene dianion equivalent or the coupling of alkenyl ligands in the coordination sphere of the metal. The resulting systems show unusual behavior. For example, buta-1,3-diene directly leads to the *s-trans* complex (**8**), which can be thermally equilibrated into the *s-cis* isomer (**9**). This form exhibits a substantial metallacyclopentene character and is best described as a d^2 metal^{IV} (σ^2,π)-type complex (**10**), as shown by X-ray crystal analysis. On the other hand, the *s-trans* isomer should be formally regarded as a real d^2 metal^{II}-alkene π-complex.



(**8**) (**9**) (**10**)

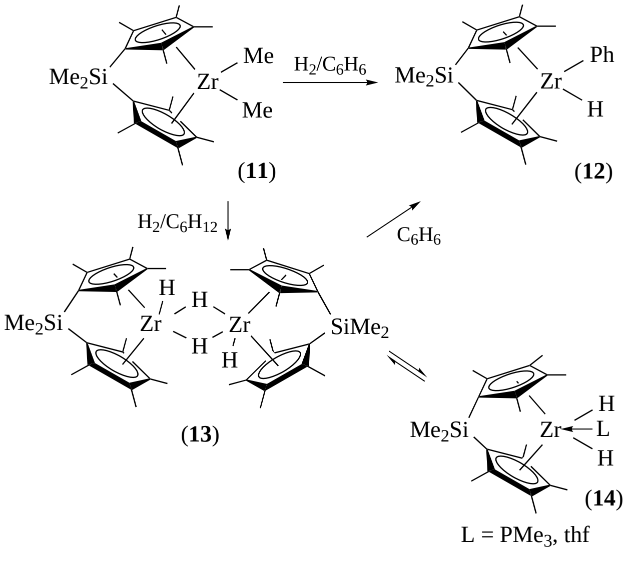
2.1.3 Hydrides and Related Complexes

Hydrides (*see Hydrides*) or aluminio- and borio-hydrides of Zr and Hf are important intermediates in catalytic processes and organic synthesis. The metal–hydrogen bond can be formed by the reduction of a dihalide metallocene with $LiAlH_4$ or $LiHAl(Ot\text{-}Bu)_3$. An efficient reaction which can be used, in particular, for several substituted Cp systems is the hydrogenolysis of the corresponding dimethyl complexes.[17] In some cases, these reactions can proceed under mild conditions (1 atm H_2, 25 °C). The molecularity of these hydride species was dependent on the substituents on the Cp rings. Monomeric compounds were found for hindered systems while dimeric systems containing hydrogen bridges were obtained for less steric crowded systems.

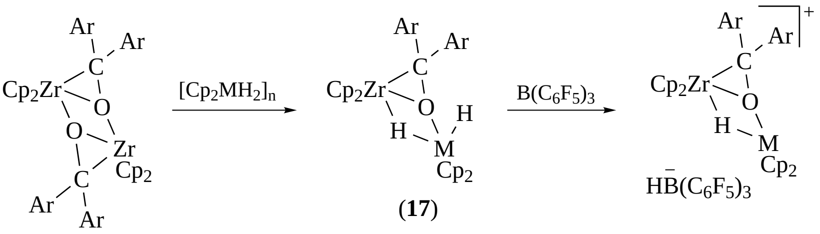
As a proof of the *ansa* effect, an interesting difference between the *ansa* complex (**11**) and traditional metallocenes can be observed (Scheme 2). Attempts to prepare the *ansa* zirconocene analog of $Cp^*_2ZrH_2$ lead instead to C–H bond activation of benzene to hydride complex (**12**). Performing the reaction in cyclohexane gave the dihydride bridged dimer (**13**) which reacts with benzene to give (**12**) or can be converted to the monomeric derivative (**14**) upon addition of a donor ligand. Compound (**13**) readily reacts with $(CH_2{=}CH_2)_2Mg$ and gives the first structurally characterized zirconocene ethylene-hydride $[\{Me_2Si(C_5Me_4)_2\}Zr(\eta^2\text{-}C_2H_4)H]_2Mg$. This complex might be considered as a model for intermediates in catalytic olefin hydrogenation processes (*see Hydrogenation*) and polymerization. The unique reactivity observed with these *ansa* systems is ascribed to the increased electrophilicity (*see Electrophile*) of their metal center.

Treatment of Cp_2ZrCl_2 with $LiAlH_4$ and then H_3GaNMe_3 or reaction of the preformed hydride Cp_2ZrH_2 with H_3AlNMe_3 affords the heterobimetallic complex (**15**).[18] Boron-containing heterobimetallic complexes (**16**) can be prepared by reaction of metallocene dichlorides with the cyclic hydroborate anion $[H_2BC_5H_{10}]^-$,[19] then reduction of M–Cl bond with LiH.

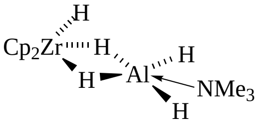
Dihydrides metallocenes can react with (η^2-diarylketone) zirconocene dimers to yield dimetallic compounds (**17**).[20] These systems contain a dimetallabicyclic framework in which



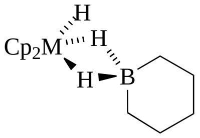
Scheme 2



Scheme 3



(15)

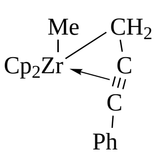


(16)

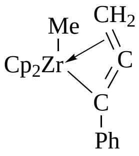
the two metal centers are bridged by the oxygen atom of the η^2-diarylketone ligand and a μ-hydride ligand. The remaining hydride ligand is oriented *trans* to the μ-H moiety of the MCp_2 unit. Treatment of these complexes with $B(C_6F_5)_3$ results in the selective abstraction of the terminal hydride ligand to form dimetallic cation complexes (Scheme 3).

2.1.4 *Mono Alkyls and Related Complexes*

Halogeno(alkyl)metallocenes are generally obtained from the halides by transmetalations (*see Transmetalation*) with careful control of the stoichiometry and experimental conditions.[1] The cleavage using $PbCl_2$ of a Zr–C bond from a dialkyl complex, hydrozirconation (*see Hydrozirconation*) of unsaturated molecules and scrambling reactions (*see Disproportionation*) between dichlorides and dialkyls have also been employed to prepare compounds of this class. They exhibit a rich reactivity by substitution of the chloride moiety. Thus, the reaction of $Cp_2Zr(Me)Cl$ with $PhC{\equiv}CCH_2MgBr$ affords an η^3-propargyl/allenyl zirconocene.[21] The complex can be described as two resonance forms in which the allenyl representation (**19**) is more important than the propargyl form (**18**).



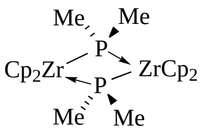
(**18**)



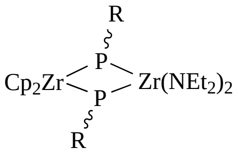
(**19**)

2.1.5 *Phosphido Ligands-containing Complexes*

Owing to their potentialities in coordination chemistry and catalysis, the chemistry of complexes incorporating Zr–P bonds presents an increasing development.[22] Compounds can be synthesized by halide metathesis (*see Metathesis*) from lithium phosphanides and the corresponding dihalogeno or halogeno(methyl)metallocene. In addition, electron-rich lithium phosphanides can reduce Zr^{IV}, affording Zr^{III} dimer (**20**). Others strategies are based on oxidative addition (*see Oxidative Addition*) of P–H bonds to zirconocenes. An efficient synthesis of the phosphanidozirconium complex (**21**) is the treatment of $Cp_2Zr(PHR)_2$ ($R = Me_2(i\text{-}PrMe_2C)Si$) with $Zr(NEt_2)_4$.[23]

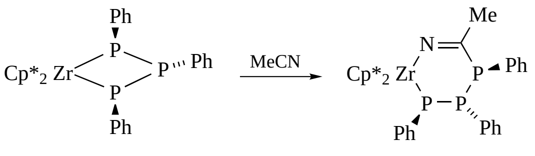


(**20**)



(**21**)

Beside classical Zr–P bond cleavage with the release of the corresponding phosphane, ketones, aldehydes, nitriles, isonitriles, and epoxides have been inserted into the Zr–P bonds of four- or five-membered phosphazirconacycles leading to ring expansion. For example, the equation (7) shows the insertion of acetonitrile in a triphosphanato complex affording an unsymmetrical six-membered ring complex.[22]



(7)

Finally, the main application of zirconium phosphanido complexes is to use them as metalloligands for coordination with the late transition metals to form phosphorus-bridged early–late heterobimetallic complexes.

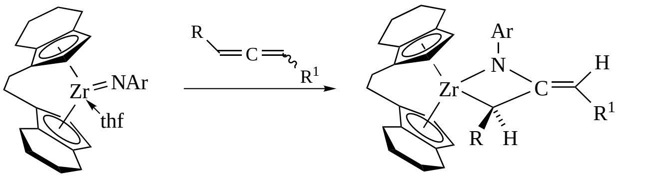
2.1.6 *Complexes Containing an M=E Bond (E = N, P, O, S, Se, Te)*

Early transition metal complexes that contain doubly bonded ligands have been developed in view to synthetical applications. Imido, phosphinidene, and chalcogenido

complexes are the most commonly used.[24] They exhibit high reactivity with small unsaturated molecules owing to the nucleophilicity of the main group element combined with high electrophilicity of the metal center. Additionnaly, they have been proposed as the catalytic agents in many organic transformations.

Imido zirconocenes (*see Imide Complexes*) are synthesized from thermolysis of $Cp_2Zr(Me)NHR$. They react with a wide variety of organic substrates (alkynes, imines, azides, carbodiimides, ketones) to yield [2 + 2] cycloaddition products (Scheme 4) (*see Metallacycle*).[25]

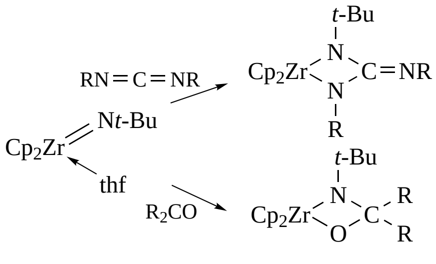
Enantioselective chemistry (*see Enantioselectivity*) has been also developed with imido complexes.[26] The stereospecific reaction of *rac*-(ebthi)(thf)Zr=NAr with racemic symmetrically or unsymmetrically 1,3-disubstituted allenes (1,3-diphenylallene, 3,4-heptadiene, 4,5-nonadiene or 1,2-cyclononadiene) provides at room temperature a single diastereoisomeric azazirconacycle (equation 8). In certain cases, this system allows conversion of an allene racemate into a mixture enriched in one enantiomer.



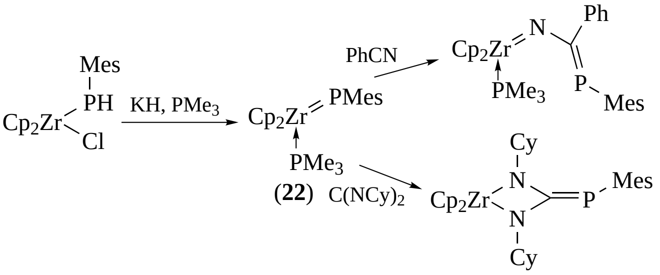
(8)

Different procedures were developed for the obtention of Zr phosphinidene complexes. The first stable complex was obtained *via* the loss of phosphane from an intermediate bis phosphanido complex. Other routes were sought to more readily gain access to these unsaturated complexes. Thus, the addition of a base to a primary phosphanido complex is another opportunity to obtain such complexes.[22] Benzonitrile and dicyclohexylcarbodiimide react with the phosphinidene complex (**22**) by insertion into the Zr=P bond, or by cycloaddition and subsequent rearrangement (Scheme 5).

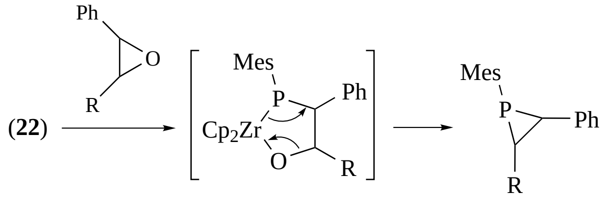
Starting from the phosphinidene complex (**22**) and ketones, the double-bond metathesis reaction provides access to a phosphaalkene and the zirconocene oxide $(Cp_2ZrO)_n$. A similar situation is also observed in the reaction with epoxides to give the corresponding phosphiranes (Scheme 6).[22]



Scheme 4



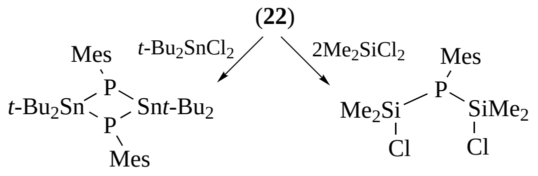
Scheme 5



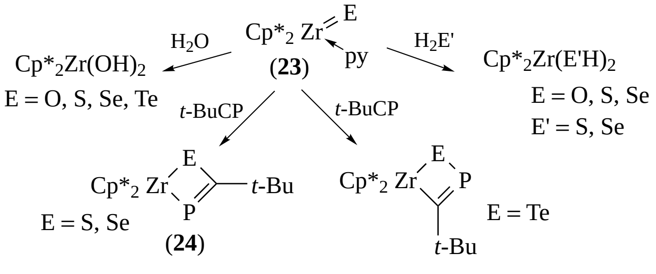
Scheme 6

Phosphinidene-group transfer reaction to main group elements can also be achieved starting, for example, from Me_2SiCl_2 or t-Bu_2SnCl_2 (Scheme 7).[22]

Terminal chalcogenido zirconium complexes (**23**) are conveniently synthesized by the reactions of dicarbonylzirconocene with either N_2O or the elemental chalcogens (S, Se, Te) (*see Chalcogens*) in the presence of pyridine. The Zr=E bond in these complexes is highly reactive and leads to a variety of 1,2-addition and cycloaddition reactions (Scheme 8).[27,28]



Scheme 7

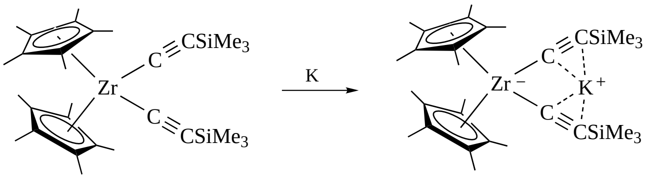


Scheme 8

The four-membered ring Zr systems (**24**) can undergo further ring expansion reactions with other chalcogenides, nitriles, and isonitriles (Scheme 9).[28]

2.2 Bis Cyclopentadienyl Complexes of Zr^{III} and Hf^{III}

In contrast to Zr^{IV} complexes, monomeric Zr^{III} complexes are scarcely reported, most of the evidence being drawn by EPR spectra of Zr^{IV} derivatives reduced electrochemically or by chemical agents.[29] Some of them have been structurally characterized, however, such as the zirconocene^{III} diacetylide complex of the tweezer type in equation (9).[30]



(9)

2.3 Bis Cyclopentadienyl Complexes of Zr^{II} and Hf^{II}

Despite the efforts expended in the synthesis and characterization of 14-electron zirconocenes and hafnocenes, no true monomeric M^{II} complexes have been isolated. Cp_2Zr and Cp_2Hf are transient species with a d^2 configuration. Similarly to titanocene (*see Titanocene*), they possess one electron lone-pair and two vacant orbitals, affording a reactivity comparable to that of carbenes. Consequently, these complexes can be trapped by electron-donating neutral ligands giving, for example, dicarbonyl compounds with CO.[1] Those fragments are able to react with a great number of unsaturated molecules to form a variety of metallacycles. Some of them give with other substrates organic, heterocyclic, or organometallic useful chemical reactions.

Cp_2M^{II} fragments were initially generated by reducing Cp_2MCl_2 and related Cp_2M^{IV} derivatives with $Mg/HgCl_2$, Na/naphtalene and Na/Hg.[31] For use Cp_2M^{II} species in organic synthesis applications, the crucial point is to find ligands that sufficiently stabilize the metallocene fragment, but that can be quantitatively released under mild conditions to generate the unstable and very active core complex. Two main ways have been developed which fill these requirements, as described in the following.

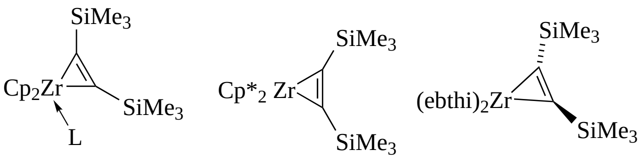
2.3.1 1-Butene Zirconocene

Zirconocene dichloride with two equivalents of *n*-BuLi has been shown to generate Cp_2Zr(1-butene) (zirconocene equivalent also called Negishi's reagent) by a β-H abstraction (*see β-Hydride Elimination*) of dibutylzirconocene (Scheme 10).[1,31] Treatment of Cp_2ZrCl_2 with two equivalents of *t*-BuLi provides also a Cp_2Zr equivalent. Conversion of dialkylzirconocenes into the corresponding zirconacyclopropanes has been shown to be a nondissociative concerted process. Consequently, free Cp_2Zr is not generated at any time.

In the presence of π compounds, alkyne- or alkene-Cp_2Zr derivatives (eventually stabilized by complexation with trimethylphosphane) have been obtained. The potentialities of these reagents in synthetic chemistry will be developed in the Section 7.

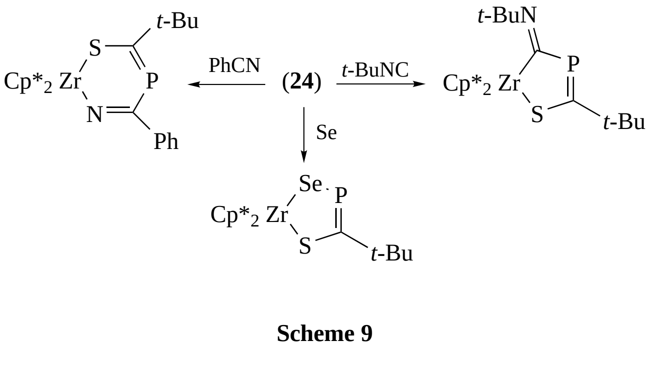
2.3.2 Bis(Trimethylsilyl)Acetylene Complexes

Among the other potentially useful Cp_2Zr equivalents, the most important are stable and well-defined bis(trimethylsilyl)acetylene complexes (**25–28**).[32,33]

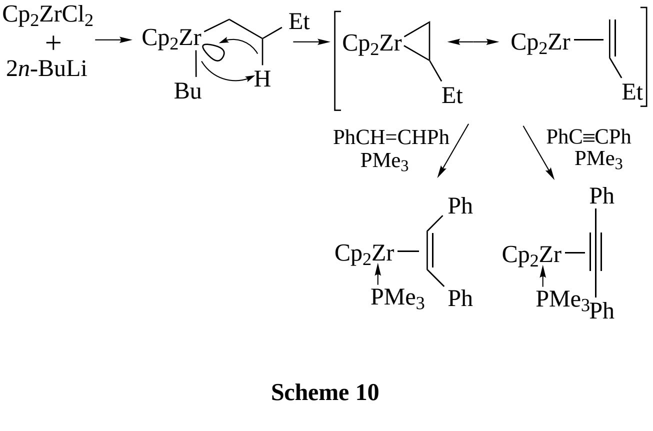


(**25**) L = thf (**27**) (**28**)
(**26**) L = py

From their resonance forms, these complexes have been considered as acetylenic π-complexes (M^{II}) or as metallacyclopropenes (M^{IV}) which led to coupling reactions



Scheme 9

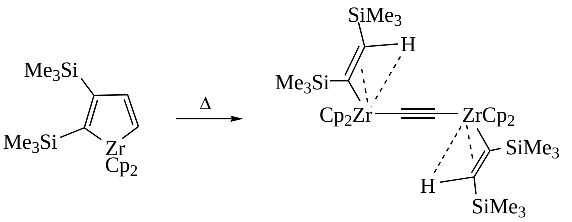


Scheme 10

of the alkyne (insertion into the metallacyclopropene) or to a substitution of the alkyne by a given substrate. Their behavior is, in all cases, best explained by the easy release of the silyl-substituted alkyne. In Zr chemistry, it seems that this result was obtained by an associative mechanism, while for titanium complexes, the substitution can also proceeds *via* a free titanocene (dissociative mechanism). The complexes (**25–28**) are able to react with many unsaturated molecules affording very original structures.

2.3.3 Reaction of Zirconocene Equivalents with Mono or Polyalkynes

The reaction of (**26**) with acetylene at low temperature gives rise to a five-membered zirconacycle that upon warming generates a dimeric complex with a bridging diacetylide group and an agostic (*see Agostic Bonding*) 1-alkenyl ligand (equation 10).[31]

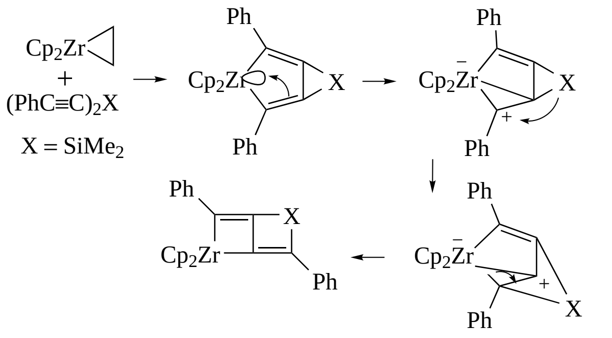


(10)

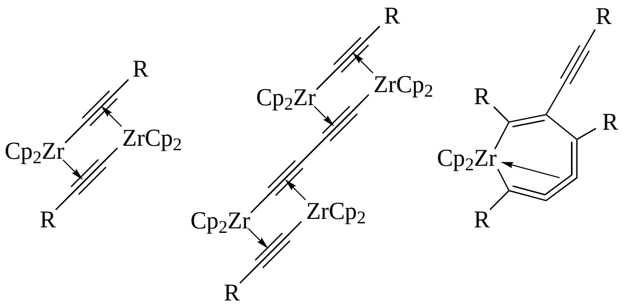
With not conjugated diynes of general formula RC≡CXC≡CR, a structural diversity is observed depending on the nature of the spacer X. Coordination or *exo–exo* coupling reactions affording metallacyclopentadienes are observed.[31] In addition, polymers, cyclodimers, cyclotrimers, cyclotetramers, and macrocycles[34] (*see Macrocycle*) that contain the metallacyclopentadiene unit have been obtained starting, for example, from $Me_3SiC{\equiv}C(C_6H_4)_nC{\equiv}CSiMe_3$ ($n = 1–4$), $Me_3SiC{\equiv}CC_6H_4(C_5H_3N)_2C_6H_4C{\equiv}CSiMe_3$, and $Me_3SiC{\equiv}C(C_5H_3N)_2C{\equiv}CSiMe_3$. Bis(alkynyl)silanes give access to an annelated zirconacyclobutene-silacyclobutene complex (Scheme 11).[35] The mechanism of the reaction might be rationalized by an initial coupling of the diyne to the zirconocene and a subsequent rearrangement of the intermediate complex *via* a zwitterionic zirconocene-ate (*see Ate Complexes*).

Depending on the nature of the Cp ligands, the metal, the stoichiometry, and the reaction conditions, very different complexes have been obtained by treatment of (**25–28**) with 1,3-butadiynes.[31] For instance, the formation of (**29**) and (**30**) results of cleavage of the C–C bond of the alkynes. The coupling of two alkyne units in the coordination sphere of the metal gives (**31**).[32]

Original metallacyclocumulenes were obtained from a 1:1 stoichiometric reaction between dialkyne and zirconocene (equation 11).[36] The unusual molecular structure of the five-membered zirconacycle (**32**) shows an almost planar arrangement containing three carbon–carbon double bonds.

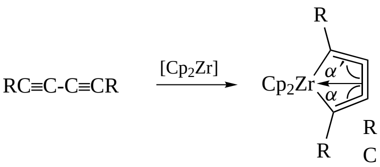


Scheme 11



(**29**) (**30**) (**31**)

The central one is longer than the two others; this elongation has been ascribed to the intramolecular interaction of this bond with the metal center.

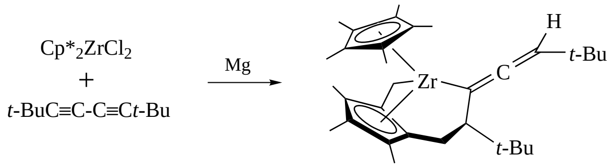


(**32**)

R = *t*-Bu:
C = C : 1.28, 1.31 and 1.29 Å
$\alpha = 150.0°$, $\alpha' = 147.2°$

(11)

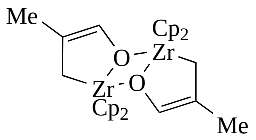
In the Cp* series, the same structure has been obtained using the same procedure but as well, by irradiation of $Cp{*}_2Zr(\sigma\text{-}C{\equiv}CR)_2$. In the case of 2,2,7,7-tetramethyl-3,5-octadiyne, the activation of the methyl groups of a Cp* ligand and C–C coupling with the diyne have been observed (equation 12).[37]



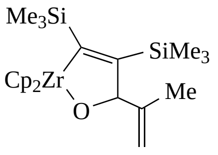
(12)

2.3.4 Reaction of Zirconocene Equivalents with Hetero Unsaturated Compounds

The reactions of complex (**25**) with carbonyl compounds show a strong dependence on the substituents leading to the substitution or elimination of the silyl-substituted acetylene or the insertion into the Zr–C bond.[31] Moreover, the reaction of methacrolein with (**25**) depends strongly of the solvent used: in hexane elimination of bis(trimethylsilyl)acetylene leads to the formation of dimer (**33**) while in THF insertion with the formation of zirconacycle (**34**) is observed.

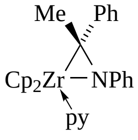


(**33**)

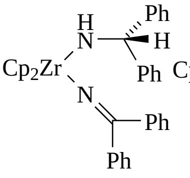


(**34**)

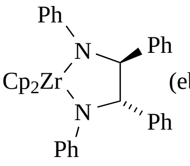
Various phenyl-substituted imines react with (**26**) in a manner that depends on the substituents present but in all cases, elimination of the alkyne is observed.[31] The imine PhN=CMePh affords the η^2-complex (**35**). On the contrary, with the ketimine $HN{=}CPh_2$, complex (**36**) is generated by hydrogen transfer. Two molecules of the aldimine PhN=CHPh are coupled to give a five-membered diamido complex (**37**). An unusual reaction with 2-vinylpyridine takes place starting from (**26**) or (**28**). Monoazadienes (**38**) are formed, in which the aromaticity of the pyridine ring has been lost.



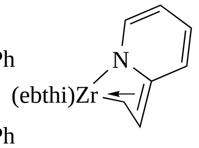
(**35**)



(**36**)



(**37**)

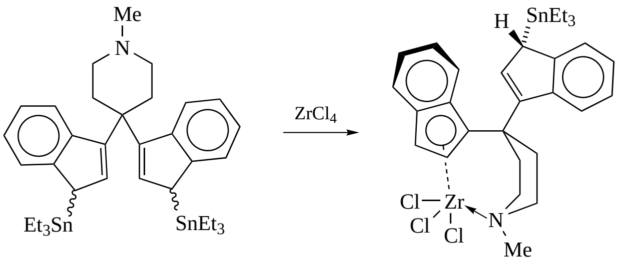


(**38**)

2.4 Mono Cyclopentadienyl Complexes of Zr^{IV} and Hf^{IV}

Mono Cp metallocenes are interesting as starting materials for the synthesis of mixed ring systems. The most efficient access to $CpMCl_3$ compounds is the radical cleavage of a Cp–M bond from Cp_2MCl_2 under irradiation. Thus the reaction of Cp_2ZrCl_2 with one equivalent of bromine yields the useful precursor $CpZrCl_2Br$.[38] Transmetalation from main group or alkali metal complexes is another widely used method.[1] Additionally, DME complexes of $CpMCl_3$ can be generated by ligand exchange reactions in good yields (*see Ligand Substitution*).[1]

Unusual nitrogen-stabilized Zr trichloride complex bearing pendant ligand (*see Pendant Groups*) can be obtained by reaction of zirconium tetrachloride on a 1:1 *rac*/*meso* distannyl Cp derivative (equation 13).[39]



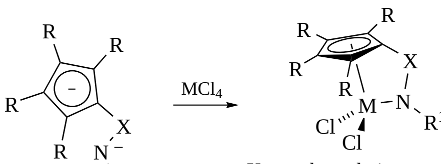
(13)

In general, the solubility of solvent-free complexes is very low. However, coordination of Zr with donor solvents gives more soluble compounds. Depending on the extent of the steric effect of the pentahapto ligand, solvent mono or bis adducts are obtained. However stronger electron-donating molecules such as phosphanes do not form adducts, according to the Lewis acidity of the metal.

2.5 Constrained-geometry (CG) Complexes

In homogeneous polymerization catalysis (*see Kaminsky Catalysts*), constrained-geometry (CG) catalysts differ from bis Cp metallocenes in their ability to readily incorporate α-olefins in copolymerization with ethylene. This ability is due to the open nature of the catalyst active site.

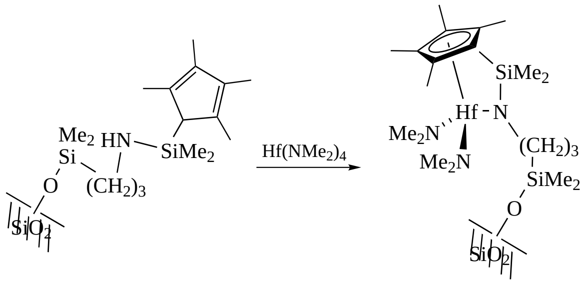
A method of preparation of CG complexes involves the metathetical reaction of the dilithio salt of $[(C_5R_4)X(NR^1)]^{2-}$ with an appropriate metal halide (equation 14). Nitrogen can be replaced by phosphorus atom.



X = carbon chain
or heteroatom fragment (Si, Ge…)

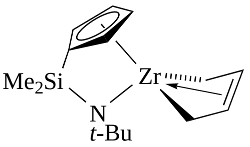
(14)

Amine elimination reaction developed for metallocenes is another method (see Section 2). Immobilized CG complexes can be prepared by this way to form heterogeneous phase systems (*see Heterogenized Catalyst*) (equation 15).[40]



(15)

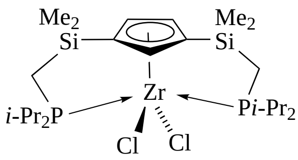
Independently of the interest of the CG complexes in polymerization catalysis, similar reactivity to that of metallocenes can be observed. For instance, the metathetical reaction of $[(C_5H_4)SiMe_2(Nt\text{-}Bu)]ZrCl_2$ with $[Mg(C_4H_6)(thf)_2]_n$ affords the Zr-butadiene complex (**39**).[41]



(**39**)

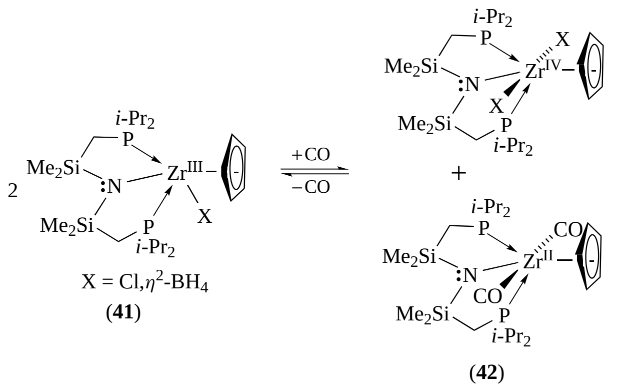
2.6 Mono Cyclopentadienyl Complexes with Low-valent Zr and Hf (M^{III}, M^{II}, and M^0)

Very few complexes of general formula (η^5-L)ZrXY have been characterized by EPR spectroscopy and even less have been isolated. They are generated by Na naphtalenide reduction, by UV irradiation of the appropriate metallocene, or by electroreduction of dialkyls. They can be stabilized by phosphane donors hold by the Cp rings (**40**).[42]



(**40**)

Addition of carbon monoxide to the Zr^{III} complex (**41**) stabilized by a tridentate ligand (*see Tridentate Ligand*) gives rise to an equal mixture of two diamagnetic products among which the rare mono Cp dicarbonyl Zr^{II} complex (**42**) (equation 16).[43]



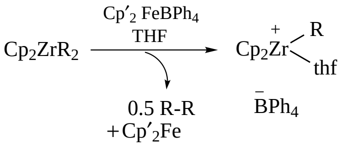
(16)

The metal^0 anionic salt, $CpM(CO)_4^-$ is reported as the result of the alkali metal naphtalenide reduction of the trichloride precursor in the presence of carbon monoxide.[44] Zr^0 and Hf^0 complexes containing α-bonded ligands, without Cp, are also known.[1]

2.7 Cationic Complexes

The chemistry of cationic d^0 16-electron $Cp_2MR(L)^+$ complexes, and d^0 14-electron $Cp_2M(R)^+$ has been largely developed, in particular, because these species can perform Ziegler-type alkene polymerizations (*see Ziegler–Natta Catalysts*) and can also be used as reagents in other organometallic syntheses. Usually, the zirconocene precursors are neutral complexes that first need *in situ*-activation before displaying cationic reactivity. Different general reactions for preparing cationic complexes have been developed.

The Lewis acid $B(C_6F_5)_3$ (*see Lewis Acids & Bases*), as well as the trityl salt $[Ph_3C][B(C_6F_5)_4]$, can abstract a methyl group from Cp_2ZrMe_2 and related zirconocenes to form $[Cp_2ZrMe]^+$.[31] A single-electron oxidation of dialkylzirconocenes with a ferricinium or a silver salt induces the formation of a cationic zirconocene (equation 17).[31]

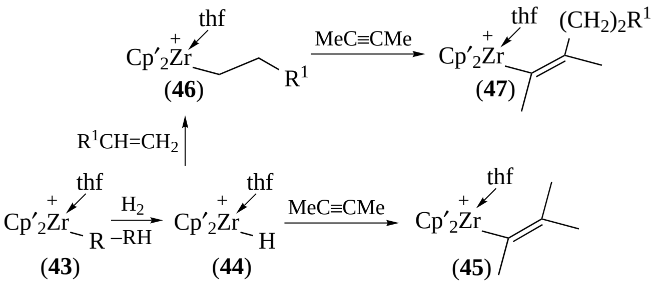


(17)

Finally, the methylaluminoxane (MAO) $[Al(Me)O]_n$ can be involved in several ways in the generation of a cationic zirconocene species. It can serve as a methylation agent (conversion of Zr–Cl to Zr–Me), and as a Lewis acid in abstracting methyl groups. In the generation of polymerization catalysts from Cp_2ZrCl_2 and MAO, the active species has the supposed composition $[Cp_2ZrMe]^+$ $[Me\text{–}MAO]^-$.[45]

The structure of some cationic zirconocenes has been determined by spectroscopic methods and by X-ray crystallography (*see X-ray Crystallography*). None of these cations is ever completely free; they are either coordinated by an additional ligand (typically a solvent molecule), or they interact with their counterions.

The solvent-stabilized cations $[Cp'_2ZrR(solvent)]^+$ shows typical reactivity patterns (Scheme 12). Hydrogenolysis of the



Scheme 12

starting cationic species (**43**) results in the formation of the hydride (**44**) which undergoes insertion of an alkyne or an alkene unit to yield (**45**) or (**46**) respectively. Moreover, the alkylzirconocene (**46**) can insert an alkyne to give an alkenyl zirconocene cation (**47**) (see Section 7.2). All these species can be isolated as complex salts with the counterion BPh_4^-. Hydride (**44**) is also a catalyst for ethene polymerization.[31]

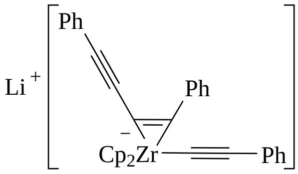
Complexes of the general formula Cp_2ZrY_2 (Y = nonnucleophilic counterion) can be prepared by halide abstraction from Cp_2ZrCl_2 with AgY. The case of $Cp_2Zr(OTf)_2(thf)$ serves as a typical example.[46] Whereas it has been shown by X-ray structure determination that this is a neutral complex with covalently bound triflates, even a weak donor (e.g. solvent, substrate) will cause ionization in solution.

2.8 18-Electron Complexes

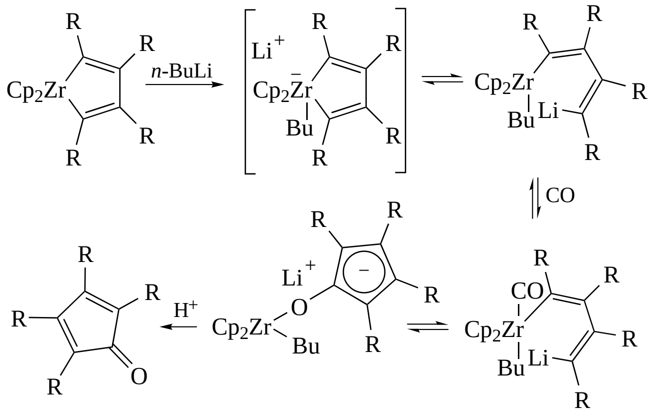
2.8.1 Anionic Complexes

Group 4 metallocenes being 16-electron derivatives, have an empty orbital that can undergo organometallate species formation. Thus, the electronegativity of Zr being greater than that of Li, intermediate formation of zirconate species can explain the reactivity of zirconacyclopentadienes with *n*-BuLi (Scheme 13).[31]

The anionic Zr^{II} intermediate (**48**) can also be involved in the photoassisted coupling reaction of alkynyl moieties.[47]



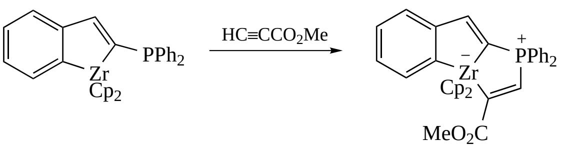
(**48**)



Scheme 13

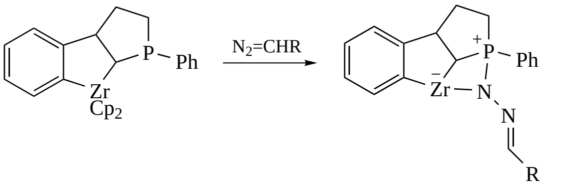
2.8.2 Zwitterionic Metallocenes

Organozirconates. Zwitterionic zirconocene-ate (*see Ate Complexes*) intermediates have been evoked to explain some reaction mechanisms (see Section 2.3.3). In fact, electron transfer from an organic ligand to 16-electron metal center permits the generation of a carbocationic center which can, then, undergoes isomerization and rearrangement characteristic of carbocations.[48] It is now possible to isolate and characterize stable zwitterionic phosphonium zirconate complexes (equation 18).[49]



(18)

Similar reactions can be performed starting from various heteroallenes (CO_2, CS_2, RN=C=NR, RN=C=S, RN=C=O) giving stable monomeric five-coordinated anionic complexes. Addition of diazoalkane to phosphanozirconocenes leads to stable N-metal phosphazines (equation 19).

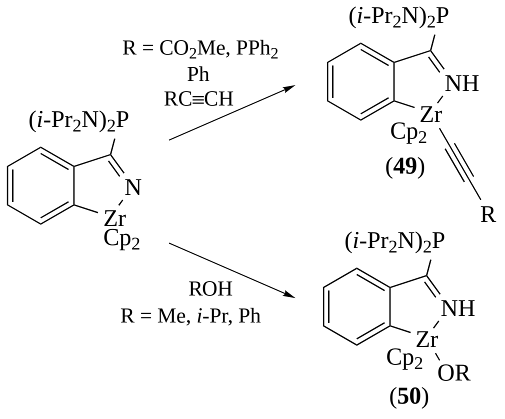


(19)

The formation of zirconate species can be performed even on the surface of dendritic systems, inducing the formation of multizwitterionic species.[50]

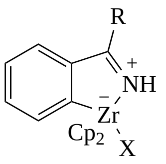
Some azazirconacyclopentene-substituted phosphanes activate the X–H bonds (X = C, O, N, P, S) of different reagents (Scheme 14).[51]

This is due to the combination of two factors:



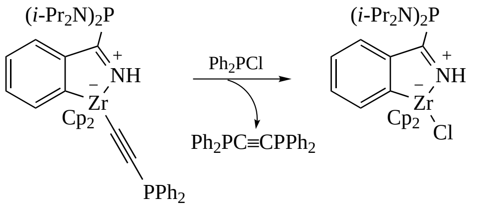
Scheme 14

– the presence of the phosphorus lone-pair in (**49**) or (**50**) increases the basicity of the cyclic imino nitrogen atom through delocalization along the P–C=N unit.
– the existence of a dative zirconium–nitrogen bond in (**49**) or (**50**) stabilizes the metal at 18 valence electrons. Thus, these structures can be described as betaines (**51**).



(**51**)

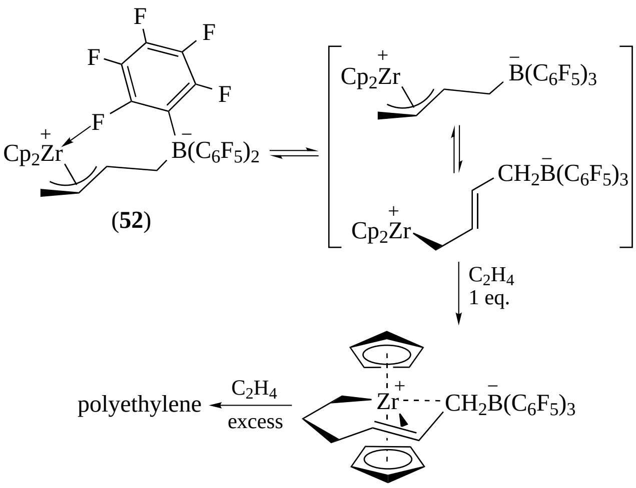
The resulting Zr–X bonds can be readily cleaved as shown by the reaction with diphenylchlorophosphane (equation 20).[51]



(20)

Zirconocene Boron-betaine. An interesting concept that can be applied to the synthesis of single-component metallocene Ziegler catalyst consists to covalently bind an anionic counterpart to the cationic framework.[52] The counterion can be attached either to an alkyl group linked to the metal or to one of the Cp ring.

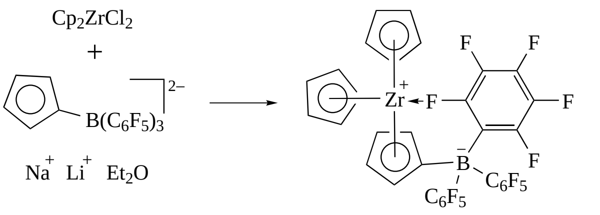
Compounds of the first type can be obtained starting from butadiene zirconocene (with or without an *ansa* bridge). In the formation of (**52**), a pronounced property of cationic center is its ability to bind fluoride. The chemistry of these compounds reveals two important features (Scheme 15). First, through reaction of (**52**) with one equivalent of ethylene, a mono insertion product has been characterized. This requires that the next insertion is much slower and implies therefore that at early stages of the polymerization the charges remain in close proximity. Secondly, this type of zwitterions (*see Zwitterion*) is short-lived under catalytic conditions; after several insertions, terminaison occurs to produce a conventional nonzwitterionic active site.



Scheme 15

Starting from half-sandwich zirconium 1,3-diene complexes and boron(trispentafluorophenyl) affords a way for synthesizing a triple-decker sandwich (*see Triple-decker Sandwich*) featuring an *ansa* borole-allyl ligand.[53] Other typical examples of zwitterionic complexes can be obtained starting from bis propynyl zirconocene and tris(pentafluorophenyl)borane.[54] When $B(C_6F_5)_3$ abstracts an alkynyl group from the bis acetylide (**53**), the borate alkyne inserts into the remaining Zr bond yielding zirconocene boron-betaine (**54**), which further reacts with two equivalents of isonitrile (Scheme 16).

Zwitterionic structures with a borate anion covalently attached to a cyclopentadienyl donor can be obtained by a number of synthetic approaches. In the known compounds, the means by which the borate is tethered to the ring has a significant impact on the properties of the zwitterions. In particular, the length of the tether connecting the ring with the borate is crucial for the stability and intramolecular ion–ion contacts. For example tris cyclopentadienyl zirconium betaine complex in which boron atom is directly bonded to Cp can be generated from boron substituted cyclopentadienyl anion (equation 21).[55]

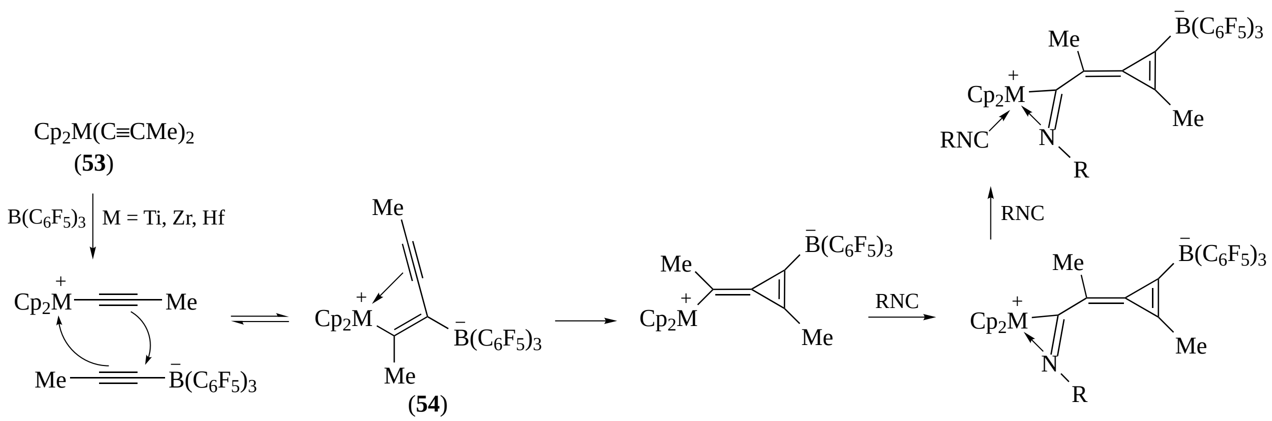


(21)

Most of zirconocene boron-betaines are single-component mediators of olefin polymerization and at least rival conventional catalysts with respect to productivity.

3 UNUSUAL COORDINATION GEOMETRIES AT CARBON STABILIZED BY GROUP 4 METALLOCENES

Independently of the classical four-coordinate tetrahedral, three-coordinate trigonal planar, or two-coordinate linear geometries at carbon (*see Coordination Geometries*), group

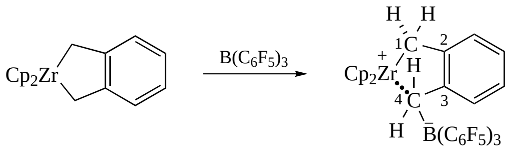


Scheme 16

4 metallocenes offer the opportunity to stabilize other unusual carbon geometries of extraordinary stability.[56] In these complexes, the Cp_2M units may serve as strong σ-donors (*see σ-Donor*) and σ-or π-acceptors. The assistance of the metal system can be obtained by two different ways: internal ion pairing (*see Ion Pairing*) and three-center-two-electron bonds.

3.1 Metal–carbon Ion Pair

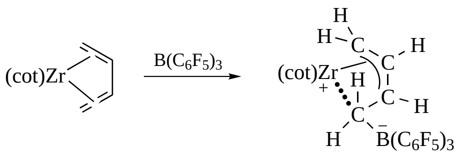
When a 2-zirconaindane system is treated with one equivalent of the strong organometallic Lewis acid $B(C_6F_5)_3$ selective addition to one of the two methylene groups takes place (equation 22). The X-ray crystal structure of the obtained product (**55**) reveals the formation of a new ring system, which displays a strong internal ion pair interaction. The C4–B bond is strong (1.682(3) Å). The carbon atom C4 exhibits an ion pair interaction with the Zr center (bond lengths: C4–Zr 2.593(3) Å, C1−Zr 2.264(3) Å; angles C3–C4–B 119.1(3)°, Zr···C4–B 155.3(2)°, Zr···C4–C3 85.4 (2)°, Zr–C1–C2 93.5(2)°).[56]



(22)

(**55**)

A similar complex was obtained by treatment of (*s-cis*-η^4-butadiene)(cot)zirconium with tris(pentafluorophenyl)borane (equation 23). As for (**55**), the complex (**56**) shows an internal Zr–C ion pair and gives rise to a five-membered metallacycle.[56]

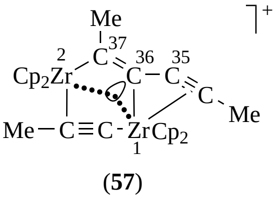


(23)

(**56**)

3.2 Planar-tetracoordinate Carbon

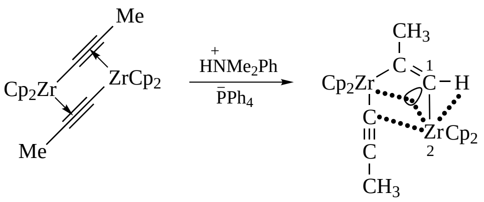
The formation of planar-tetracoordinate carbon is an unusual situation that can be obtained, for instance, by treatment of the *in situ*-generated $[Cp_2Zr–C{\equiv}C–CH_3]^+$ with one equivalent of starting bis(propynyl)zirconocene.[56] In homodimetallic system (**57**), C36 is a planar-tetracoordinate carbon atom. In fact, it is a part of a C=C double bond (C37−C36 1.317(8) Å). C36 is also connected to the acetylene carbon atom C35 by a Csp−Csp$^2\sigma$-bond (C36−C35 1.401(8) Å) and exhibits an unsymmetrical three-center-two-electron interaction with the adjacent Zr atom (C36−Zr1 2.435(6) Å; C36−Zr2 2.530(5) Å). The central core of three atoms around C36 is coplanar. An activation barrier of $\Delta G^{\neq}_{rearr}(190\,K) = 9.5 \pm 0.5\,kcal\,mol^{-1}$ was determined by studying the dynamic feature of (**57**).



(**57**)

Most of the known examples of complexes incorporating a planar-tetracoordinate carbon contain alkyl, aryl, or even bulky substituents on the carbon center.[57] However, recently a

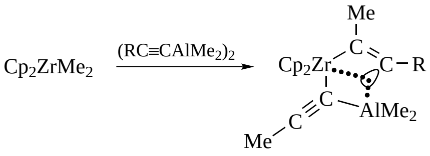
way was found to prepare such compounds bearing hydrogen at this carbon atom.[58] A typical example was obtained by treatment of a dimeric zirconocene complex with the Brönsted acid *N*,*N*-dimethylanilinium tetraphenylborate (equation 24). Moreover, in homodinuclear complex (**58**), the low $^{13}C-^{1}H$ coupling constant (99 Hz) indicates an agnostic (*see Agostic Bonding*) CH···Zr2 interaction.



(24)

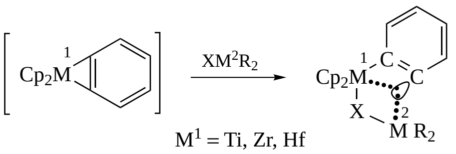
(**58**)

The formation of complexes containing planar-tetracoordinate carbon atoms is even more favorable by combination of group 4 metallocene and main group compound. A typical preparation involves reaction of dimethylzirconocene with the dimethylaluminium(phenylacetylide) dimer (equation 25).[57]



(25)

The group 4 benzynemetallocenes combined with boron, aluminum, and gallium building blocks were successfully employed in the stabilization of planar-tetracoordinate carbon compounds (equation 26).[56]

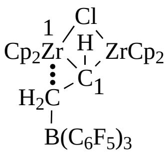


(26)

M^1 = Ti, Zr, Hf
M^2 = B, Al, Ga
X = H, alkyl

3.3 Stable C_{2v}–methane Derivative

A stable organometallic C_{2v}–methane derivative (**59**) was obtained starting from the (*μ*-vinyl)bis(zirconocene) complex with tris(pentafluorophenyl) borane.[59]

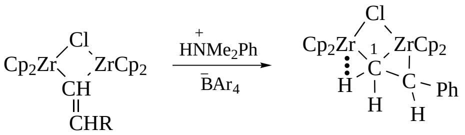


(**59**)

The $Cp_2Zr1\cdots C2H_2$–B interaction is probably electrostatic. It corresponds to an internal ion pair situation (Zr1–C2 2.600(3) Å, C1–C2–B 119.2(2)° and Zr1–C2–B 155.0(2)°) analogous of the complexes described previously (see Section 3.1). It seems that this distorted C_{2v}–methane-like coordination geometry is ca. 5 kcal mol^{-1} less stable than ideal tetrahedral geometry. Certainly the gain of energy afforded by the ion pair formation is responsible for the stability of homodinuclear complex (**59**).

3.4 Distorted Square-pyramidal Hypercoordinated Carbon Compounds

Protonation of (*μ*-alkenyl)bis(zirconocene) complexes under nonnucleophilic conditions takes a different regiochemical course than the $B(C_6F_5)_3$ addition (equation 27).[60] The X-ray crystal structure of (**60**) is consistent with distorted square-pyramidal pentacoordinated geometry at the central atom C1.



(27)

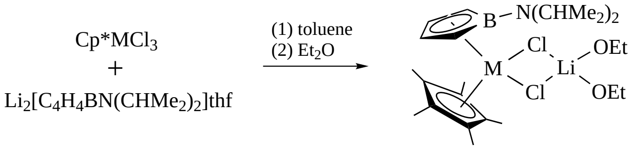
(**60**)

4 OTHER ANIONIC *π*-LIGANDS COMPLEXES

A variety of Zr and Hf complexes containing ligands that are isoelectronic to Cp have been developed for the purpose of creating analogs of classical metallocenes. The new ligands which might confer different properties on the derived metal complexes are essentially based on heterocyclic anions with elements of groups 13 to 16.

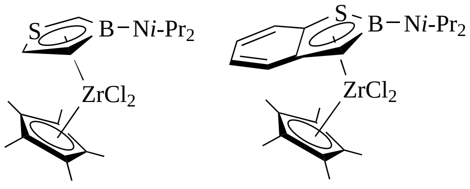
Substitution of a uninegative 6*π* electron Cp ligand with a dianionic 6*π* electron ligand provides a way to prepare metallocene analogs bearing an additional negative charge relative to the corresponding metallocenes. This is the case with aminoborole zirconate and hafnate that are isoelectronic to neutral metallocenes Cp_2MCl_2 (equation 28). These 16-electron derivatives represent an unusual class of molecules having both Lewis acidic and Lewis basic sites (*see Lewis Acids & Bases*) held in relatively close proximity. Aminoborollides were also used in the synthesis of neutral alkyl complexes of the type $Cp^*[C_4H_4BN(CHMe_2)_2]MR$ that are isoelectronic to metallocenium cations $[Cp_2MR]^+$.[61] These 14-electron compounds exhibit a rich reactivity and potentially

useful applications in catalysis.



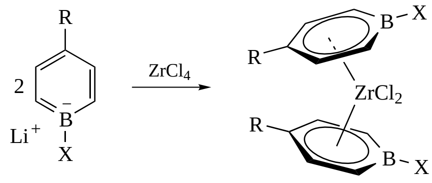
(28)

Other boron-containing ligands like 1,2- and 1,3-thiaborollides or 1,2-benzothiaborollide can also give rise to various metallocenes (**61, 62**) analogous to cyclopentadienyl or indenyl ones.



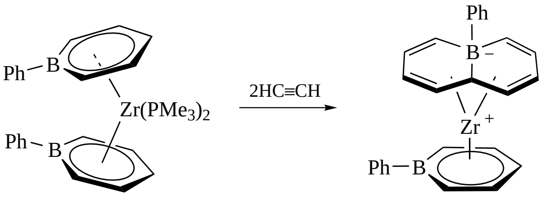
(**61**) (**62**)

Monoanionic boratabenzene ligands are isoelectronic to cyclopentadienide anion and can be used to synthesize Zr^{IV} equivalent metallocenes (equation 29). A more congested complex of 9-phenyl-9-borata-anthracene (*C*1-symmetry) was obtained by a similar way.[62] Mono and bis boratabenzene complexes can also be prepared by reaction of a neutral boratabenzene-PMe_3 adduct with tetrabenzyl zirconium or hafnium.[63] Boratabenzene *ansa* metallocenes with CH_2–CH_2 or $Si(CH_3)_2$ bridges[64] as well as Cp-boratabenzene mixed complexes[65] or CG complexes were synthesized.



(29)

The coordination mode of those boron-containing ligands is quite different of the one of Cp rings. In 1,2-thiaborole systems, the zirconium atom is slip-distorted away from boron atom and the ligand is very close to η^4-coordination. The boratabenzene ring approached a η^5-coordination with the metal being much closer to the five ring carbon atoms than to the boron atom. In bridged structures by boron atoms, the boratabenzene ligand can be η^6-bonded to the metal center. The coordination mode also differs in oxidation state of the metal. The aminoboratabenzene is η^5-coordinated to the central metal in $(C_4H_4BN\textit{i}\text{-}Pr_2)_2ZrCl_2$ and η^6-bonded in $(C_4H_4BN\textit{i}\text{-}Pr_2)_2Zr(PMe_3)_2$. The reaction of the boratabenzene Zr^{II} complex with ethyne involves an unprecedented ring annelation to afford the complex (**63**), which contains a novel boron-containing ligand (equation 30).[66]

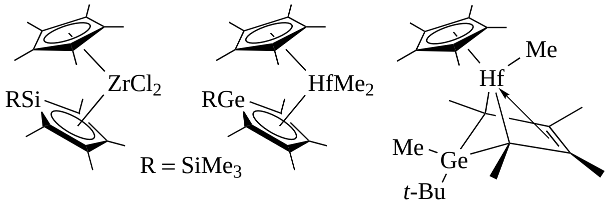


(30)

(**63**)

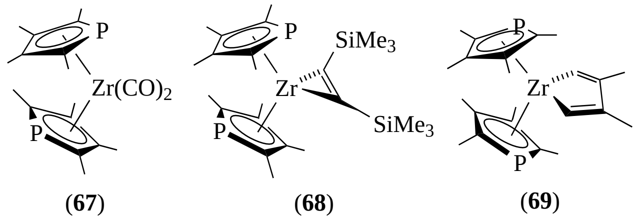
Another class of compounds whose ligation chemistry has been found to parallel that of Cp are the 7,8-C_2B_9- and 2,3-C_2B_4-carborane dianions. Like Cp, they are donor ligands in which six electrons are delocalized in π-type orbitals around a five-membered ring. The reaction of these carborane ligands with the appropriate metal reagent results in several mixed-ligand sandwich and full- and half-sandwich complexes of zirconium and hafnium.[67]

Neutral silolyl and germolyl metallocenes (**64–65**) have been prepared. The η^4-germole complex of Hf (**66**), resulting from a migration of a methyl group from Hf to Ge can be characterized during the course of these studies.[68]



(**64**) (**65**) (**66**)

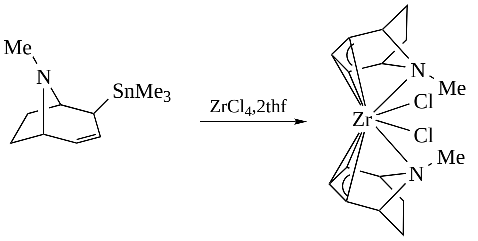
Phospholyl anions are also isoelectronic to Cp ligands, and these species readily complex Zr^{IV}.[1] A reduction reaction of $(C_4Me_4P)_2ZrCl_2$ by magnesium in THF gives transient diphosphazirconocene species which can be trapped by CO, bis trimethylsilyl acetylene, or 2-butyne to yield the corresponding dicarbonyl (**67**), zirconacyclopropene (**68**), and zirconacyclopentadiene (**69**).[69]



(**67**) (**68**) (**69**)

The cyclic π ligand derived from tropine in which an allyl group is completed with nitrogen as a two-electron donor atom leads to the synthesis of bis tropidinyl zirconium dichloride

(equation 31).[70]



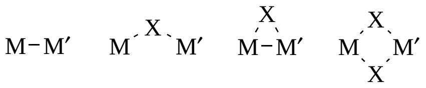
(31)

Complexes containing an open chain are also metallocenes analogs. For instance, pentadienyl anions (*see Pentadienyl Ligand*) form open metallocenes with transition metals as efficiently as do cyclopentadienyls.[1] Half-open metallocenes can be obtained in a similar way starting from $CpZrCl_2Br$ (Scheme 17).[38]

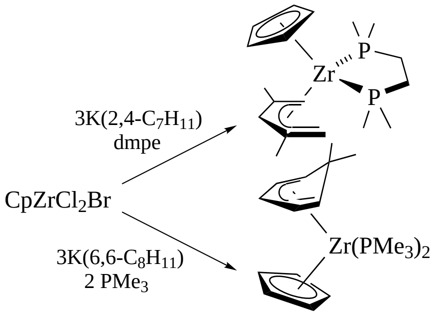
5 DINUCLEAR COMPLEXES

Dinuclear transition metal complexes (*see Dinuclear*) in which two reactive metal centers are maintained in close proximity have been largely studied owing to the opportunity provided to observe a synergism effect. In many cases, interest has focused on complexes containing early (electron deficient) and late (electron rich) transition metals in different oxidation states in which such interactions are more probable. They can combine the Lewis acidity of the early metals and the known ability of the late metals to activate small molecules.[71]

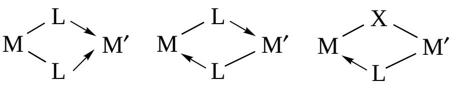
Except for some specific arrangements, homo and hetero dinuclear complexes can be classified within the seven main groups (**70–76**) in which for some of them one of the organometallic moieties can be viewed as a metalloligand for the other part.



(**70**) (**71**) (**72**) (**73**)



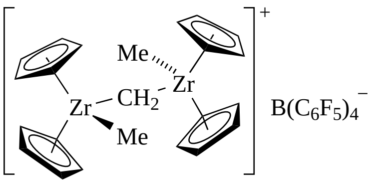
Scheme 17



(**74**) (**75**) (**76**)

A few stable metal–metal bonded complexes (**70**) have been described. They are synthesized by reaction of a zirconium dichloride complex with an organometallate of iron or ruthenium[72,73] (see following section). CO_2 and CS_2 insertion into the polar metal–metal bond affords hetero dinuclear complexes of the second family (**71**) (Scheme 18).[73]

The μ-oxo complexes are representative complexes of the (**71**) group. They are readily prepared by the smooth hydrolysis of most metallocenes.[1] Arrangement (**71**) is also present in the methyl-bridged homo dinuclear species (**77**) formed by reaction of methylzirconocene cation with Cp_2ZrMe_2.

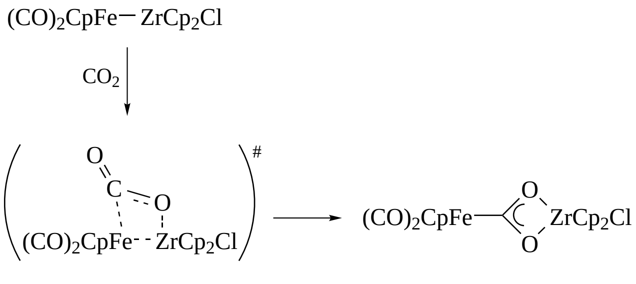


(**77**)

Dimeric association (**71**) can be obtained by an acid-base reaction between alkyl zirconocene and a terminal alkynyl ruthenium complex (equation 32). Surprisingly, the same reaction was observed with an iron acetylide opposed to Schwartz's reagent (*see Schwartz's Reagent*) (equation 33).[74]

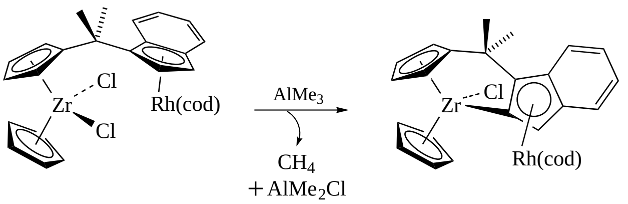
$$(PMe_3)_2CpRuC{\equiv}CH + Cp_2Zr(Me)Cl \xrightarrow{-CH_4} (PMe_3)_2CpRuC{\equiv}CZrCp_2Cl \quad (32)$$

$$(dppe)CpFeC{\equiv}CH + Cp_2Zr(H)Cl \xrightarrow{-H_2} (dppe)CpFeC{\equiv}CZrCp_2Cl \quad (33)$$



Scheme 18

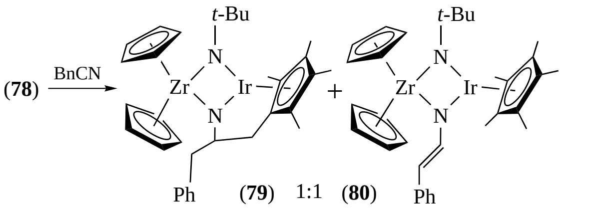
Another early–late bimetallic complex related to the (**71**) group can be prepared by connecting the two Cp rings by a carbon bridge. Its reaction with an excess of $AlMe_3$ affords a doubly bridged hetero bimetallic complex (equation 34).[75]



(34)

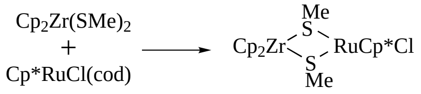
The complex (**78**) containing a zirconium–iridium bond and an imido bridge is the rare example of type (**72**) (Scheme 19). This early–late bimetallic compound contains two electronically unsaturated transition metals (Zr $= 16e^-$, Ir $= 16e^-$) which can make the structure interesting for testing the cooperative effect. Indeed, its reactivity with a variety of carbon-heteraoatom bonds results in cleavage of the metal–metal bond involving both metal centers. For instance incorporation of carbon dioxide produces a metallacyclopentane with a bridging metallacycle ester moiety.[76]

With various nitriles, two different hetero dinuclear complexes with arrangement (**73**) are obtained (equation 35). The formation of the cyclometalated species (**79**) involves a hydrogen transfer from a Cp* methyl group to the electrophilic carbon center of the nitrile in an intermediate fulvene complex. Kinetic results indicate that a second molecule of nitrile catalyzes the conversion of this fulvene intermediate into (**80**).[76]



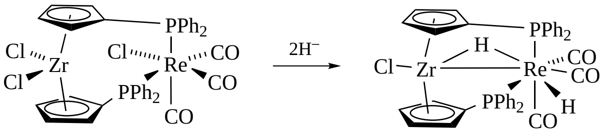
(35)

Many other examples of complexes of group (**73**) have been described. In particular, four-membered homo or hetero bimetallacyclic compounds can be obtained by simple way (equation 36).[76,77] In $Cp_2Zr(\mu\text{-SMe})_2RuCp^*Cl$, the four atoms of the ZrS_2Ru core lie in a plane, the two methyl groups on the sulfur atoms being in *syn* conformation in solid state. On the contrary, in complex $Cp_2Zr(\mu\text{-N}t\text{-Bu})_2IrCp^*$, the four-membered Ir–Zr–N_2 ring is puckered (fold angle 17.6°), and the nitrogen atoms are planar, indicating π-donation to the formally electronically unsaturated Ir and Zr centers. The Zr–Ir distance is 0.3 Å longer than Zr–Ir single bonds, indicating that there is little direct Zr–Ir interaction. A homobimetallic eight-membered ring complex $[Cp_2Zr(\mu\text{-}O_2BPh)]_2$ can be generated by reaction of dimethylzirconocene with phenylboronic anhydride.[78] In this dimer, the metal centers are positioned above and below the approximate plane defined by the boron and oxygen atoms, generating a chair like conformation within the heterometallacycle.



(36)

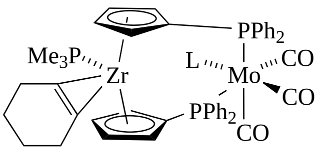
When the arrangement (**74**) is present in early–late transition metal complexes, the bridging ligand can be a substituent of the Cp ligands. For example, hetero bimetallic complex (**81**) is obtained starting from $(Ph_2PCp)_2MCl_2$ and $Re(CO)_5Cl$. The second metal fragment is anchored through the phosphane substituents on the Cp ring.[79] Substitution reactions are very difficult on complex (**81**). Only, careful addition of a stoichiometric amount of $LiAlH_4$ produced a small quantity of a particular dihydride (equation 37).



(**81**)

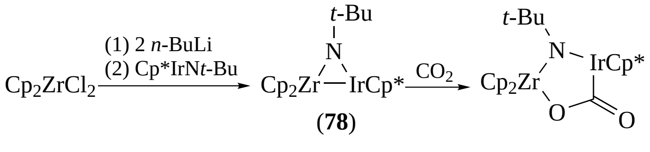
(37)

Even, $C_5H_4PPh_2$-bridged Zr^{II}–Mo^0 complexes (**82**) can be obtained upon treatment of $[Cl(Me)Zr(\mu\text{-}C_5H_4PPh_2)_2Mo(CO)_3L]$ (L = CO, PMe_3) with cyclohexenyllithium and trimethylphosphane.



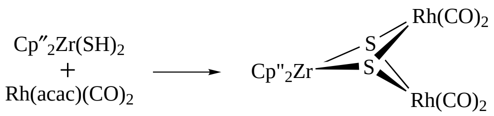
(**82**)

Chiral C_2-symmetric early–late complexes can be obtained *via* similar complexation starting from bis phosphinoenolato zirconocene.[80] Assembly of phenyl-substituted phospha-metallocene and $[(binap)Rh(cod)]^+$ leads also to a chiral hetero dinuclear complex. The unprecedented thermal room temperature isomerization of Zr derivative was exploited to achieve its dynamic resolution producing enantiopure bimetallic *ansa* metallocene.[81]



Scheme 19

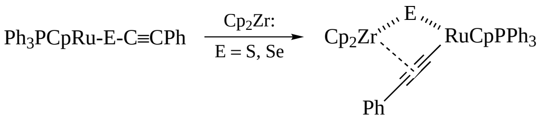
The twofold deprotonation of a hydrosulfide zirconocene with the appropriate rhodium compound results in the clean formation of d^0-d^8 trinuclear complex (equation 38).[82]



Cp″ = 1,3-disubstituted Cp (38)

Dimeric associations (**75**) are typical of some low oxidation state and coordinatively unsaturated complexes that spontaneously exhibit a tendency to completely fill the valence electronic shell around the metal. Dinuclear dihydride $[(C_5H_4Me)_2ZrH(\mu\text{-}H)]_2$, for which the two metallocene-H units are joined by two Zr–H–Zr (two-electron-three-center bonds) are examples of this family.[1]

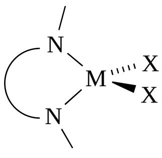
Alkynylchalcogenato ruthenium^{II} complexes react with zirconocene to give rise to heterobimetallic early–late dissymmetrically bridged complexes of family (**76**) (equation 39).[83] In those specific complexes, the two metal centers are linked by μ-chalcogenido and μ-σ, π-alkynyl moieties. The acetylenic bridge is unsymmetrical because the terminal carbon of alkynyl is σ-bonded to ruthenium, while zirconium interacts with both alkynyl carbons in a side-on fashion.



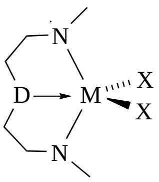
(39)

6 COMPLEXES OF Zr^{IV} AND Hf^{IV} LACKING π-LIGANDS

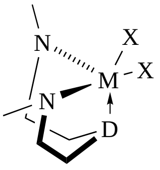
Beside the historical dominance of metallocenes and other cyclopentadienyl-based complexes, nonmetallocene complexes of group 4 have recently been the subject of renewed interest owing to the fact that new ligand environments might result in novel patterns of reactivity. Several bi, tri, or tetradentate ligands (*see Bidentate Ligand*; *Tridentate Ligand*; *Tetradentate Ligand*) have been employed to build early transition metal complexes. Except for some specific arrangements, such systems can be classified within the following families (**83**) to (**90**).



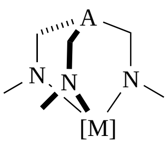
(**83**)



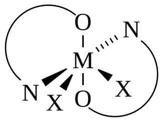
(**84**)



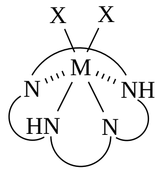
(**85**)



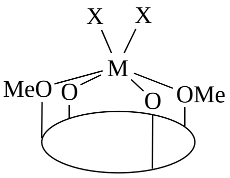
(**86**)



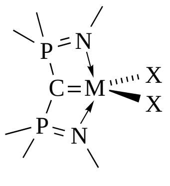
(**87**)



(**88**)



(**89**)

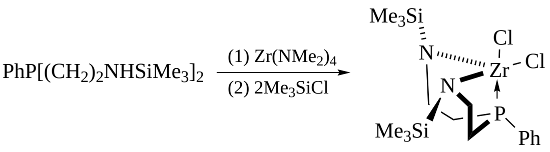


(**90**)

X = Cl, CH_2Ph
D = donor atom
(N, P)
A = carbon or
boron atom
or carbocycle

The 1,1′-ferrocenediyl-bridged ligand system $Fe[(C_5H_4)NPh]_2$ give access to redox-active chelate complexes of the type (**83**).[84]

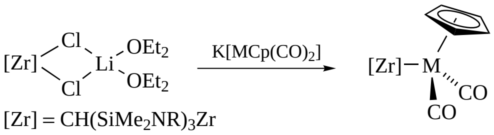
One of the issues surrounding group 4 complexes of the type (**84**) or (**85**), which have a central donor atom and arms between the donor and the two nitrogen atoms, is that the geometries *mer* (like (**84**)) or *fac* (like (**85**)) mainly influence the reactivity of the metal center. By using phosphorus atom as the donor, it is possible to force the geometry to be *fac*, in order to finely adjust the steric hindrance for catalytic applications (equation 40).[85]



(40)

C_3-symmetrical tripodal ligands have been used to obtain amido complexes of family (**86**). If chiral substituents are present in the ligand periphery, some stereo discrimination is observed in the reaction with several chiral ketones and aldehydes.[86] On the other hand, such systems can generate early–late heterobimetallics with metal–metal bonds (equation 41). Reaction of (**91**) with MeNC as well as the heteroallenes CO_2, CS_2, RNCO and RNCS led to insertion into the polar metal–metal bond.[72] Tris (pyrazolyl)borate (*see Tris(pyrazolyl)borates*) Zr and Hf complexes are other interesting examples of the type (**86**). In combination with MAO, they give promising results in ethylene and ethylene/hexene polymerizations. Substitution of these sterically crowded ligands allows adjustements of the environment of the active site to the

monomer.[87]



(41)

[Zr] = CH(SiMe$_2$NR)$_3$Zr
M = Fe, Ru

(**91**)

Bis 8-quinolinato metal complexes are representative examples of distorted octahedral structures of the type (**87**). It was noted that these systems bear a topological resemblance to the chiral, octahedral, active metal sites that have been proposed for supported Ziegler-Natta catalysts, and are interesting for modeling catalytic properties. Similar comportment has been observed with diamine bis (phenolate) ligands.[88]

Tetraazamacrocycles ancillary ligands including porphyrins have been used to prepare numerous group 4 organometallic complexes (**88**). These ligands are formally 12-electron donors to metal centers. Cationic tropocoronand group 4 organometallic complexes were found to generate differences in the Lewis acidity of the metal in comparison with their metallocene analogues. Thus, the use of tropocoronand ligands influences both the insertion chemistry and the structural properties of the resulting complexes.[89]

Similar behavior is observed for calix[4]arene (*see Calixarenes*) complexes of the type (**89**).[90] Moreover, the oxygen donor atoms are particularly appropriate for the oxophilic early transition metals. A rich chemistry has been developed with complexes containing zirconium–carbon bonds. In this area, aryne zirconocene compounds can be thermally generated and isolated without trimethylphosphane additional coordination. Zirconium-butadiene chemistry has been explored as well and constitutes a source of zirconium^{II} complexes.

Complexes of type (**90**) represent a new class of zirconium hydrocarbyl derivatives in which a strong metal carbene interaction in a pincer ligand structure is formed.[91] The crystal structure of such complexes shows a short metal carbon link common to two fused four-membered rings which are almost coplanar.

7 NEUTRAL ORGANOZIRCONIUM COMPLEXES IN ORGANIC AND ORGANOMETALLIC SYNTHESIS

For some years, organozirconium complexes are among the most useful reagents in organic, heterocyclic, and organometallic synthesis.[31] The success of organozirconium reagents in synthesis can be explained in terms of chemo, regio (*see Regioselectivity*), diastereo, and enantioselectivity (*see Enantioselectivity*). These compounds are generally able to discriminate between similar functionalities that differ only slightly in their steric and/or electronic environment.

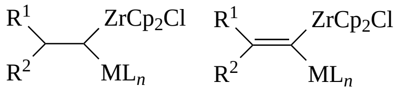
7.1 Hydrozirconation

The availability of the Schwartz's reagent Cp$_2$Zr(H)Cl (*see Schwartz's Reagent*) and its versatile behavior explain its extensive use in organic chemistry.[1] The scope of hydrozirconation (*see Hydrozirconation*) with respect to both substrate structure and chemoselectivity lies somewhere between those of hydroboration (*see Hydroboration*) and hydroalumination.

7.1.1 Hydrozirconation and Subsequent Quenching

The clean *cis* addition of the Schwartz's reagent across an alkyne affords a good way to functionalize alkenes. Starting from an alkyne bearing a methyl group, which has been known to favor placement of the zirconium species at the least hindered site, provides extremely valuable access to natural products after hydrozirconation (*see Hydrozirconation*), I$_2$ quenching and subsequent Stille coupling with vinylstannane (e.g. *reveromycin B*).[92]

Hydrozirconation is a useful way to produce *gem* metallozirconocenes of general formula (**92**) and (**93**), which are interesting reagents in organic synthesis.



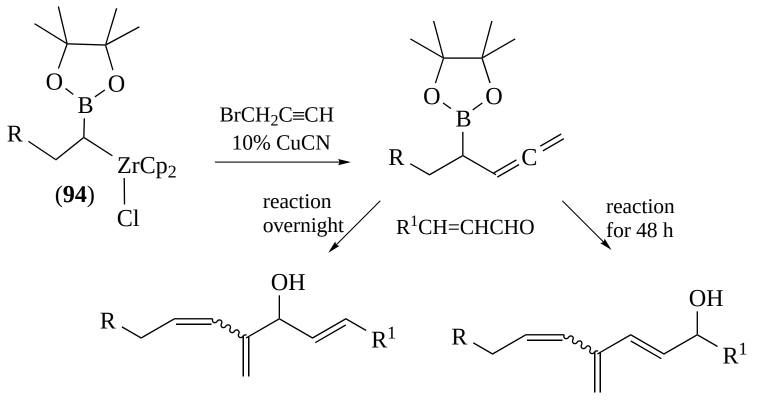
(**92**) (**93**)

M = Al, B, Li, Ga, Sn, Zn, Zr

In fact, cleavage of the carbon–zirconium bond occurs classically with various electrophiles (*see Electrophile*), generally under mild conditions. In addition, the other carbon–metal bond in *gem* metallozirconocenes undergoes a broad range of transformations. The different reactivities of the carbon–metal and carbon–zirconium bonds are the results of the difference of electronegativity of the two metal centers and the two different bond polarities.

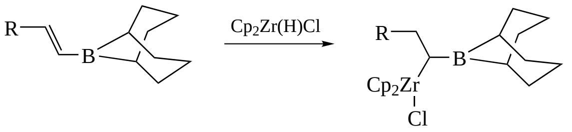
Aluminiozirconocene complexes can be obtained by the addition of an organoaluminium hydride to an alkenylzirconium complex or by the addition of the Schwartz's reagent to an alkenylaluminium derivative.[31] Hydrozirconation of phenyl(trimethylsilyl) acetylene gives the corresponding alkenylzirconocene chloride, that generates by treatment with AlMe$_3$ a stable complex with a planar-tetracoordinate carbon atom (see Section 3).[31] Similar Zr/Al and Zr/Ga structures can also be obtained by trapping a transient μ-alkyne complex with a Lewis acidic main group organometallic. Benzynezirconocene can also give rise to such complexes by treatment with trimethylgallium.[31]

Gem boriozirconocene alkanes can be prepared by either hydrozirconation of alkenylboranes or hydroboration of



Scheme 20

alkenylzirconium compounds (equation 42).[31] However, these compounds proved to be unstable.

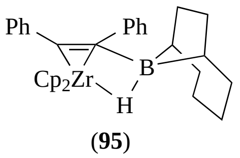


(42)

Boronates are more stable since they are stabilized owing to the donor effect of oxygen lone-pairs to the empty orbital of the boron. The two different carbon–metal bonds afford particular reactivity. For example, addition of propargylbromide on (**94**) in presence of a catalytic amount of copper^{I} cyanide undergoes a carbon–carbon bond formation with exclusive cleavage of the C–Zr bond. The subsequent borylallene, by treatment with α,β-unsaturated aldehydes, affords two trienes, depending on the reaction conditions (Scheme 20).

Other classical reactions such as halogenation or amination with zirconium and boron compounds respectively are possible starting from 1,1-boriozirconocene complexes.

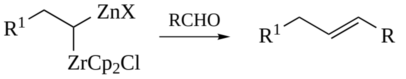
In boriozirconocene alkenes, the chemistry of Csp^2–Zr and Csp^2–B bonds differ considerably and this feature allows a sequential route to substituted alkenes.[93] Furthermore, cleavage of the two types of bonds generally occurs with retention of geometry. On the other hand, heating of alkynezirconocene complexes with 9-BBN, to 80–90 °C, affords a bimetallic complex (**95**) showing a planar-tetracoordinate carbon and an *iso*-BBN structure.



(**95**)

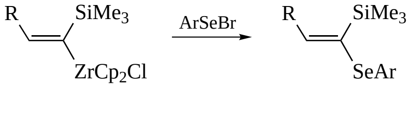
The addition of $Cp_2Zr(H)Cl$ to trialkylstannylacetylenes leads to 1,1-stanniozirconocenes that formally represent stereodefined 1,1-dianion equivalents.[31] Starting from this compound and according to the difference of exchange rate Sn/Br and Zr/Br, it is possible to generate with complete stereocontrol (*see Stereochemistry*) bromoiodoalkenes. Combination of Zr-promoted bicyclization and properties of 1,1-stanniozirconocenes offers opportunities to synthesize some natural products.[31]

Addition of $Cp_2Zr(H)Cl$ to an alkenylzinc halide affords relatively unstable 1,1-bimetallics of Zn and Zr. Addition of an aldehyde or a ketone is a general way to synthesize (*E*)-alkenes. Remarkably, the hydrozirconation can be applied to functionalized alkenylzinc reagents bearing an ester, chloride or cyano functionality (equation 43).[31]



(43)

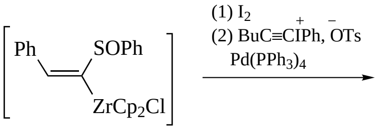
1,1-siliciozirconocene can be converted as well by quenching with arylselenylbromide to an array of vinylselenides which may be further transformed into chain-elongated materials (equation 44).[31] In these products the selenide and the silane groups can be substituted: the aryl selenide by copper-catalyzed couplings with Grignard reagents, and the silicon by displacement with electrophiles. Analogous procedures using disulfide or sulfonyl chloride as quenching agent give rise to vinyl sulfides and sulfones.[31]



(44)

An overview of the hydrozirconation of alkynyl sulfones reveals many variations in the regiochemistry. Starting from arylacetylenic sulfoxides, the hydrozirconation classically takes place in a *cis* fashion, with zirconium in the α-position

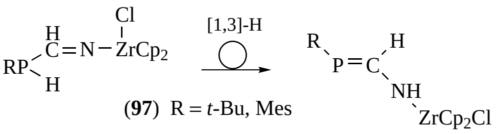
(equation 45).[31]



(45)

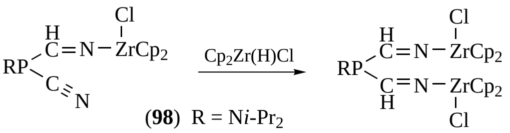
Hydrozirconation can be applied to heteroatomic systems affording original compounds. In this way, cyanophosphanes react cleanly with the Schwartz's reagent, the metal being linked to the more electronegative atom of the double bond. Quenching with many main group electrophiles affords a large variety of *C*-phosphanyl-*N*-phosphanyl or *N*-boranylimines (**96**) (Scheme 21).

Treatment of dicyanophosphanes with one equivalent of the Schwartz's reagent leads to a substitution that gives the stable hydrocyanophosphanes.[94] Further addition of one equivalent of $Cp_2Zr(H)Cl$ to the latter ones affords the primary phosphane R–PH_2 (R=Me) or the aldimino secondary phosphane (**97**). At room temperature, a [1,3]-H sigmatropic rearrangement is observed for (**97**), giving a *N*-zirconated phosphaalkene (equation 46).



(46)

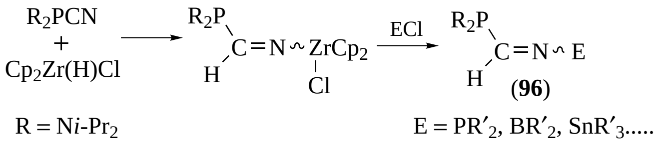
Dicyanophosphane (R = N*i*-Pr_2) undergoes a true hydrozirconation reaction with the formation of the aldiminocyanophosphane (**98**) and of a dihydrozirconated compound after further addition of one equivalent of $Cp_2Zr(H)Cl$ (equation 47).[94]



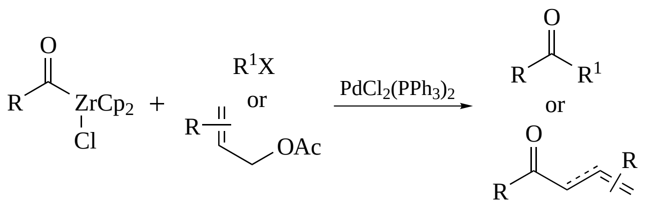
(47)

7.1.2 Ring-forming and Ring-opening Reactions

The Schwartz's reagent (*see Schwartz's Reagent*) allows ring formation from substrates possessing both oxirane and alkene functionalities (equation 48).[31] Based on *in situ* NMR analyses, it has been shown that the mechanism proceeds by

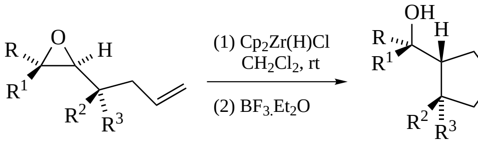


Scheme 21



Scheme 22

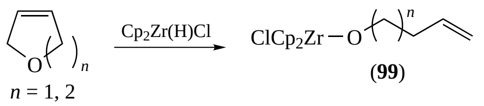
clean inversion at the reacting oxirane center. No reaction takes place in the absence of the Lewis acid.



(48)

Hydrozirconation (*see Hydrozirconation*) of phosphaimines, phosphaalkenes, or bis(imino)phosphorane takes place with the formation of various three- or four-membered phosphazirconacycles.[31]

Ring-opening reactions of oxygen heterocycles such as dihydrofuran or dihydropyran are initiated by Schwartz's reagent. The nature of the resulting complex depends on the stoichiometry of the reaction. With one equivalent of $Cp_2Zr(H)Cl$, the linear derivative (**99**) is obtained by migration of the Cp_2ZrCl fragment initiated by the oxophilicity of Zr (equation 49). The action of two equivalents of $Cp_2Zr(H)Cl$ leads directly to a dihydrozirconated complex, precursor of phosphinito-phosphane by a Zr/P exchange.[95]



(49)

7.1.3 Acyl Zirconocenes

Acylzirconocene chlorides are easily accessible in a one-pot procedure through the hydrozirconation (*see Hydrozirconation*) of alkene or alkyne derivatives with the Schwartz's reagent and subsequent migratory insertion (*see Migratory Insertion*) of carbon monoxide into the alkyl- or alkenyl–zirconium bond. The stability of the acylzirconocene chlorides is remarkable at room temperature, and consequently allows many applications in organic synthesis.

Classically, the acylzirconocene chlorides can be converted into aldehydes, carboxylic acids, esters, and acyl halides. Recently, the usefulness of acylzirconocenes has been extended. In fact, these unmasked acyl anions directly add to aldehydes and imines affording α-hydroxy or α-amino ketones, respectively.[31] The reaction of acylzirconocene chlorides with imines also proceeds under Brønsted acid-catalyzed conditions, even with aqueous acids.[31]

Several palladium-catalyzed processes have also been developed for carbon–carbon bond formation based on acyl zirconocenes. Both alkylations and acylations occurred, the best results being obtained with allylic acetates as coupling partners. Selective additions to α,β-enones can be achieved starting from acylzirconocene chlorides with cyclohexanone in the presence of a palladium catalyst. Even more, the regioselectivity (*see Regioselectivity*) can be very easily controlled by the choice of the catalytic system ($Pd(OAc)_2$,$BF_3{\cdot}Et_2O$ for 1,4-addition and $PdCl_2(PPh_3)_2$ for 1,2-one). An enantioselective (*see Enantioselectivity*) version of the 1,2-addition has been recently developed using (*R*)–MOP ligand in place of triphenylphosphane (66% ee).[31] α,β-ynones can also react with acylzirconocene chlorides affording easily cyclopentenone derivatives.[96]

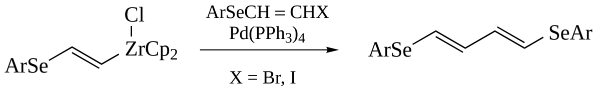
Metal catalyzed cross-coupling reactions with acylzirconocene chlorides and various organic halides or acetates can give rise to unsymmetrical ketones or a mixture of β,γ- and α,β-unsaturated ketones (Scheme 22). The advantage of the use of a Cu^{I} catalyst instead of a Pd catalyst is to avoid the undesirable formation of α,β-unsaturated ketone.[31]

7.1.4 *Allylic Zirconocenes*

Allylic zirconocenes, generated by hydrozirconation (*see Hydrozirconation*) of allenic systems, react with terminal alkynes when activated with MAO to regioselectively afford 1,4-dienes.[31] The same MAO catalyzed process, applied to haloalkynes, leads to excellent yields of the 1,4-enyne (**100**) (Scheme 23).[97]

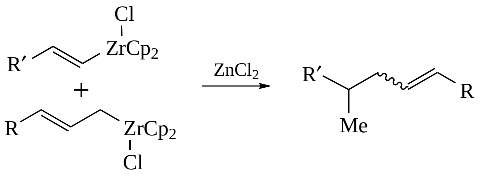
7.1.5 *Cross-coupling Reactions*

Combination of hydrozirconation (*see Hydrozirconation*) process with other catalyzed reactions represents a great interest in the synthesis of polyenic natural products. The synthesis of the backbone of the antibiotic *Lissoclinolide* can be realized by hydrozirconation with *i*-$BuZrCp_2Cl$ and subsequent Pd-catalyzed coupling (*see Coupling*) of the fragments.[98] Similar cross-coupling reactions of vinylzirconocenes can give rise very smoothly to a variety of vinyl selenide containing materials, which can be further transformed into stereodefined butadienes (equation 50).[99]



(50)

Treatment of alkyl or alkenylzirconium with Cu^{I} or Zn^{II} salts *via* stoichiometric or catalytic processes provides new possibilities for improving coupling reactions of these species. For example, cross-coupling reactions of alkylzirconocenes to unsaturated oxazolidinones take place in the presence of $CuBr{\cdot}SMe_2$. Hydrozirconation-transmetalation of terminal alkynes can be effective using Me_2Zn at low temperatures in toluene, the resulting zinc species being able to react with aldehydes to produce racemic allylic alcohols. Even more, a nonracemic version of this reaction has been developed with excellent levels of enantioselectivity (*see Enantioselectivity*).[100] Another combination of hydrozirconation and zinc mediated reactions can produce reductive coupling of allenes and alkynes affording finally an α-adduct *via* a zinca-Claisen rearrangement (equation 51).[31]

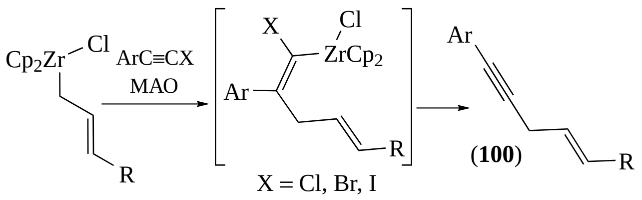


(51)

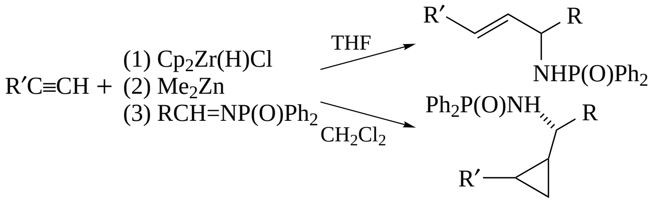
On the other hand, hydrozirconation-transmetalation to zinc, when carried out in THF, can be used to prepare allylic amines. When carried out in CH_2Cl_2, however, a different reaction pathway is followed (Scheme 24).[101] Even more, with a different order of introduction of the reagents, it is possible to obtain diastereoselectively homoallylic amines instead of the expected aminocyclopropanes.[31]

7.2 Carbozirconation

Migratory insertion (*see Migratory Insertion*) and carbozirconation (*see Carbometalation*) represent two C–C bond formation processes in which Zr–C bonds directly participate. The synthetic scope of migratory insertion in organozirconium



Scheme 23



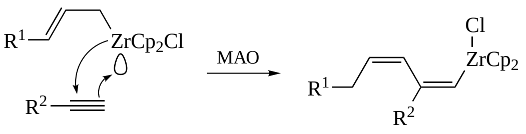
Scheme 24

chemistry is quite limited to the use of carbon monoxide (*see CO Insertion*. Carbozirconation requires dipolar (and mostly bimetallic) activation and/or very reactive small-ring zirconacycles, especially three-membered ones that can undergo cyclic carbozirconation. These reactions can be either stoichiometric or catalytic in Zr.

7.2.1 Stoichiometric Acyclic Carbozirconation

Activation or ate complexation are necessary to obtain acyclic carbozirconation. In fact, no reaction was observed between chloromethylzirconocene and *n*-propylacetylene. On the contrary, carbozirconation occurred starting from aluminated alkyne (Scheme 25).

The reaction of allylzirconocene with alkynes in presence of MAO, which begin with an ate complexation (*see Ate Complexes*) of the alkyne, appears to be mechanistically closely related to the above example (equation 52).[31]



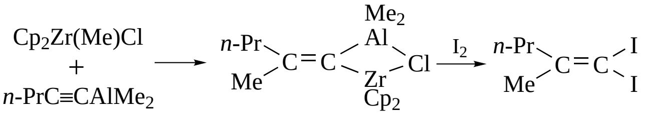
(52)

7.2.2 Stoichiometric Cyclic Carbozirconation

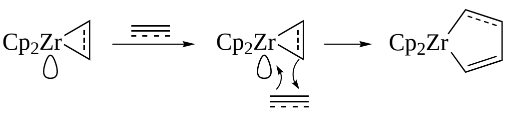
Three-membered zirconacycles (zirconacyclopropanes and zirconacyclopropenes) undergo ring expansion through cyclic carbozirconation (*see Carbometalation*) (Scheme 26).

The enyne bicyclization-carbonylation tandem reaction is of great interest to synthesize various organic compounds. Possible mechanisms have been proposed as follows (Scheme 27).

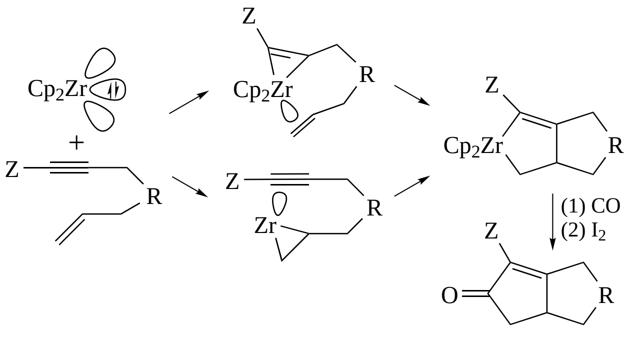
The subsequent development of $Cp_2Zr(n\text{-}Bu)_2$, which reacts as a Cp_2Zr equivalent, has been the beginning of an interesting organic chemistry, including natural products.[102] A 14-electron species like Cp_2Zr (see Section 2.3) has almost no chance to exist freely, and the equivalents of zirconocene are 16- or even 18-electron species. This has been rationalized by



Scheme 25



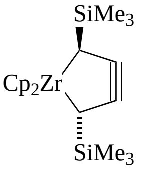
Scheme 26



Scheme 27

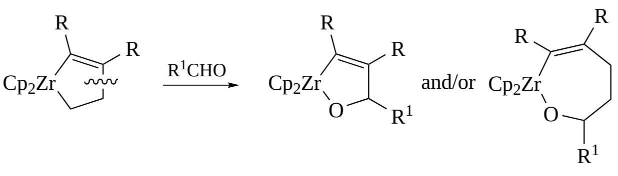
formation of three-membered zirconacycles before subsequent reaction. Three different protocols have been developed: i) by reaction with π-compounds of *in situ*-generated dialkylzirconocenes, ii) by β-H abstraction without the use of π-compounds, and iii) by using bis(trimethylsilyl)acetylene as a labile π-ligand.

Interestingly, high regioselectivity (*see Regioselectivity*) and stereoselectivity (*see Stereoselectivity*) have been observed in the reaction of zirconocene equivalents and unsaturated molecules. Thus, alkyl substituents prefer to be β to Zr, whereas aryl and alkenyl ones prefer to be α to Zr. In cases where there are two carbon-bound substituents, they usually prefer to be trans to one another, presumably to minimize steric interactions like in the 1-zirconacyclopent-3-yne (**101**), the first metallocyclopentyne complex.[103]



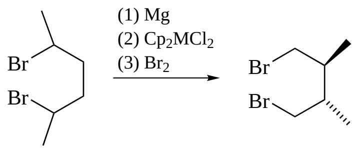
(**101**)

One important aspect of the Cp_2Zr-promoted cyclization that is now well-established is the ready reversibility through decarbozirconation, presumably involving an interaction between the empty Zr-orbital and the $C\beta$ –$C\beta'$ bond of the five-membered zirconacycle and subsequent displacement of ethylene (equation 53).[31] Reaction of 2-azadienes on zirconocene affords *via* a retro-Brook rearrangement interesting azaoxazirconacycles.[104]



(53)

Interesting consequence of the reversibility of the carbozirconation (*see Carbometalation*) process includes stereo and regioselectivity backbone rearrangement (equation 54).[31]



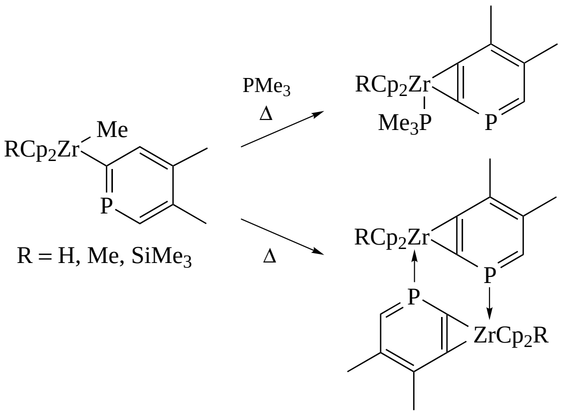
(54)

Another pathway to generate reactive three-membered zirconacycles and zirconaheterocycles is the thermolysis of diphenylzirconocene or related complexes. Many different structures with or without heteroatoms are readily obtained. These strongly constrained compounds are very reactive towards a large variety of polar or nonpolar species.

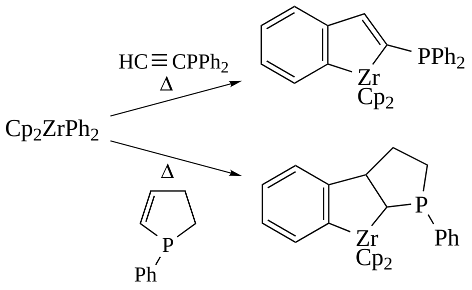
Similar to the benzynezirconocene, cyclohexyne, cyclopentyne, alkyne, alkene, cycloalkene zirconocenes, and related species insert various substrates such as alkynes, alkenes, aldehydes, ketones, nitriles or phosphaalkynes. They lead in general five-membered zirconacycles, which can be converted by transmetalation or exchange reactions into fused-ring aromatic or heterocyclic compounds.[1] The extension of this chemistry to heterobenzyne complexes can be realized, for instance, in phosphinine compounds.[105] Consequently, under mild conditions, η^2-phosphabenzyne-zirconocene complexes are formed and can be isolated either as PMe_3 adducts or as dimers when the elimination reaction is carried out without added phosphane (Scheme 28).

With dissymmetrical alkynes or alkenes, very clean reactions are often obtained by regiospecific processes (*see Regioselectivity*).[1] For example, the use of phosphorus unsaturated reagents afford the opportunity to generate various mono or diphosphanes and related species (Scheme 29).[106,107]

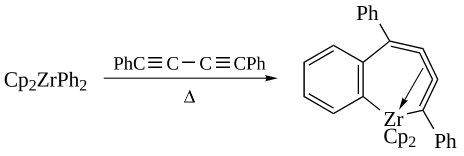
By reaction with buta-1,3-diyne, an unusual complex of a distorted cyclocumulene can be generated (equation 55).[108] This structure is stabilized by coordination of the central double bond of the seven-membered ring to the electronically unsaturated zirconium atom.



Scheme 28



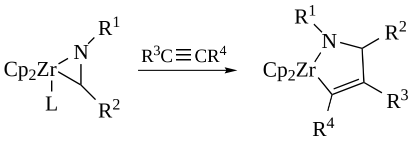
Scheme 29



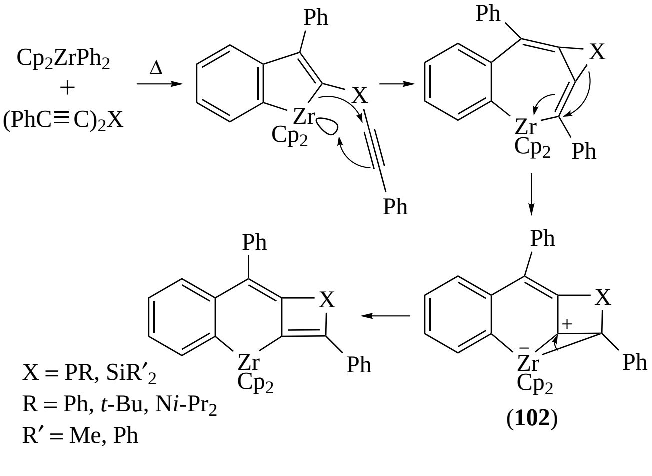
(55)

When the two alkynyl functions are separated by a silyl or a phosphano group, an interesting rearrangement takes place giving rise to tricyclic species (Scheme 30).[109] This skeletal rearrangement proceeds *via* intermediate zwitterionic zirconate (**102**). The empty orbital and electrophilicity of Zr are probably the reasons that lead to zwitterionic species containing zirconates and carbocationic centers.

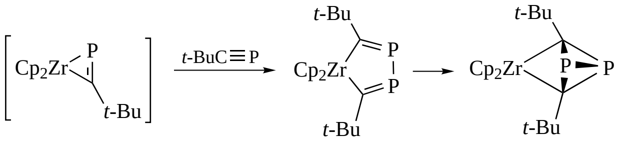
Many zirconaheterocyclic complexes containing oxygen, nitrogen, phosphorus, chalcogens or silicon atoms can be generated by similar ways and offer also interesting reactivity (equations 56–58).[1,110,111]



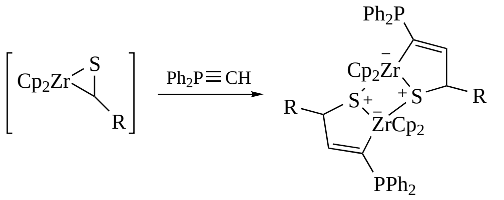
(56)



Scheme 30



(57)



(58)

Even cationic azazirconacycles such as $[Cp_2Zr(\eta^2$-picolyl).thf$]^+$ that are isoelectronic (*see Isoelectronic*) to the neutral Zr-benzyne complex exhibit similar insertion reactions (*see Insertion*).[1]

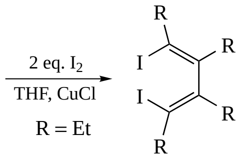
7.2.3 Synthetical Applications of Zircona-cycles and -Heterocycles

As previously demonstrated, zirconacycles can be prepared by coupling (*see Coupling*) a low-valent metal complex and one or two molecules of unsaturated compound. Most of them are very useful starting materials for synthetical applications. Several processes can be employed to transform the metallacycles (*see Metallacycle*) into a variety of organic compounds.

Hydrolysis. Hydrolysis of zirconacyclopentadienes (**103**) with inorganic acid (*see Acids & Acidity*) provides, in a stereocontrolled manner, 1,2,3,4-tetrasubstituted dienes.[31] Protonolysis with weak organic acids such as ethanol gives monoprotonated dienylzirconocene, which can be reacted with electrophiles to yield pentasubstituted diene derivative (Scheme 31).[31] In the same way, β,γ unsaturated amines are obtained by cleavage of Zr–C and Zr–N bonds of azazirconacycles.

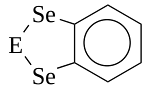
Halogenolysis. Halogenolysis of zirconacyclopenta dienes (**103**) affords 1,4-dihalodienes. Whereas the iodination of zirconacyclopentadienes in THF with 2 equivalents of I_2 affords mainly the monoiodinated diene, the diiodo diene is the major product in CH_2Cl_2. Iodination carried out in THF in the presence of two equivalents of CuCl undergoes diiodination in 95% yield (equation 59).[31]

(**103**)



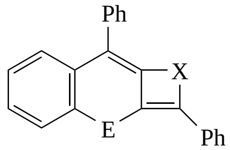
(59)

σ-Bond Metathesis Including Transmetalation. All the complexes that can be obtained through benzynezirconocene and related species can react with different electrophiles affording carbo or heterocycles *via* replacement of zirconium moiety by other carbo or heteroatomic species or by transmetalation reactions (*see Transmetalation*). Reactions of zirconacyclopentadienes with dihalides electrophiles derived from elements of groups 13 to 16 afford heterocyclic systems in good yield.[1] A four-center mechanism involving the availability of an empty orbital on each metal atom is usually proposed as being required for this transformation. In the reported examples, the Cp_2Zr moiety is converted into the very stable Cp_2ZrX_2. The driving force of the heteroatom transfer is presumably the high halophilicity of Zr. This reaction was extended to a lot of zirconacycles and leads original heterocycles (**104–107**).[1,107,109,110] In the particular case of silicon exchange, it is hardly possible to exchange Zr with Si by using R_2SiCl_2. It is difficult with $SiBr_4$, but easy with H_2SiCl_2.[31] Steric constraints reasons have been given to explain these difficulties.



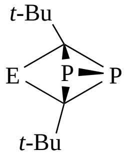
E = $SnMe_2$

(**104**)



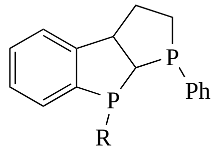
X = PPh, $SiMe_2$
E = AsPh, SbPh

(**105**)



E = BPh, PCl

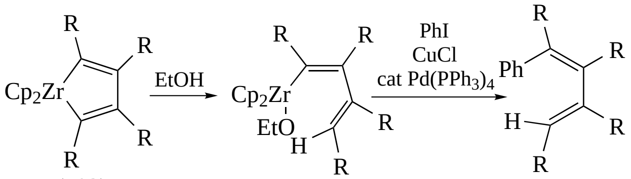
(**106**)



R = Ph, Me, *t*-Bu, N*i*Pr_2

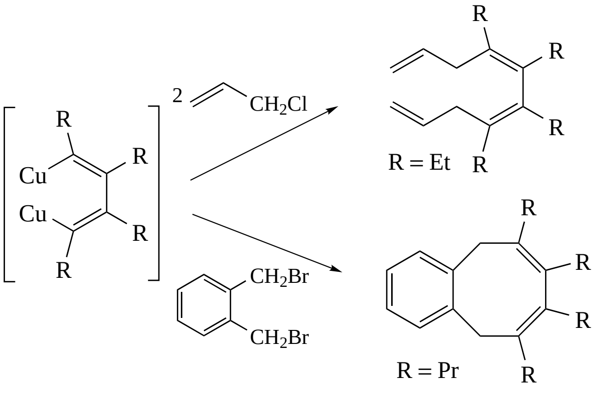
(**107**)

Transmetalation to Cu, Ni, or Zn is sometimes necessary to release the organic compounds. For instance, treatment of zirconacyclopentadiene with CuCl generates an unstable dicopper complex, which can couple in situ with allyl, benzyl, aryl, thienyl, alkynyl, and alkenyl halides (Scheme 32).[31]



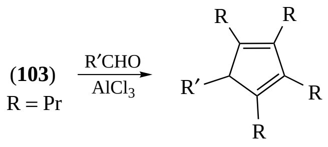
(**103**) R = Et

Scheme 31



Scheme 32

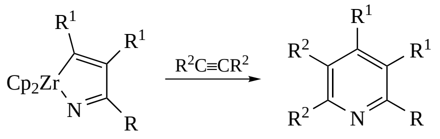
Reactions of zirconacyclopentadienes with aldehydes in the presence of $AlCl_3$ afford cyclopentadiene derivatives (equation 60). Aluminacyclopentadiene might be an intermediate in this reaction.[112]



(60)

Addition reactions to Carbon–carbon multiple bonds. 1,1-additions of metallacyclopentadienes to carbon–carbon triple bonds are rare but some interesting examples are described. Particularly, addition of propynoate to zirconacyclopentadienes gives cyclopentadiene derivatives without any transmetalation to other metal.[31] Benzene derivatives can be obtained in high yields *via* reaction of dimethylacetylenedicarboxylate with zirconacyclopentadienes according to a 1,2-addition (Scheme 33).[31]

Starting from azazirconacyclopentadienes, pyridine derivatives can be obtained in the presence of $NiCl_2(PPh_3)_2$ (equation 61).[113]



(61)

In a similar way to the above examples, the addition of zirconacyclopentadienes to methylmaleate gives cyclohexadiene derivatives. It is noteworthy that the two ester groups are *cis* in the starting material and *trans* to one another in the product.[31]

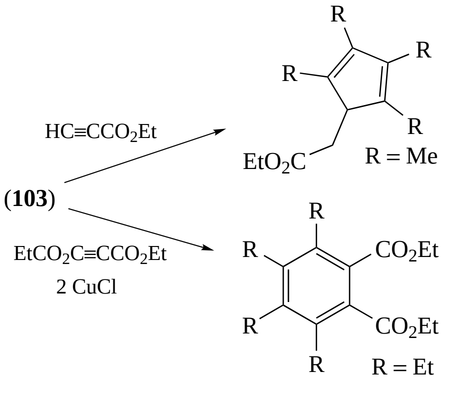
Insertion reactions of carbon monoxide and isonitriles. The carbenic character of carbon monoxide and isonitriles, which favors initial donation of an electron pair to the 16-electron Zr atom, is certainly responsible for the success of these processes.

Zirconacyclopentanes and zirconacyclopentenes readily react with CO at −78 °C to give cyclopentanones and cyclopentenones, respectively (Scheme 34). In the same conditions, zirconacyclopentadienes do not react. But reaction can be performed in the presence of $NiCl_2(PPh_3)_2$ to afford cyclopentadienones.[114]

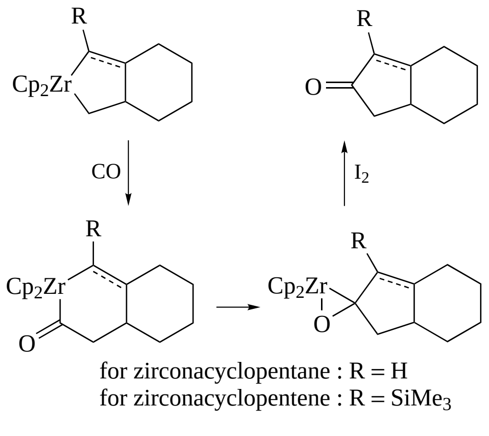
Insertion of isonitriles into zirconacycles affords η^2-iminoacyl complexes that smoothly rearrange to stable η^2-imine zirconocenes.[31] In the case of 2-phosphanozirconaindenes, rearrangement proceeds leading to η^1-imine zirconocenes (Scheme 35). Subsequent formation of a β-phosphano indenoimine is obtained by elimination of Cp_2Zr fragment for the 2,6-dimethylphenyl isocyanide.[115]

7.3 Insertion Reaction of Carbenoids

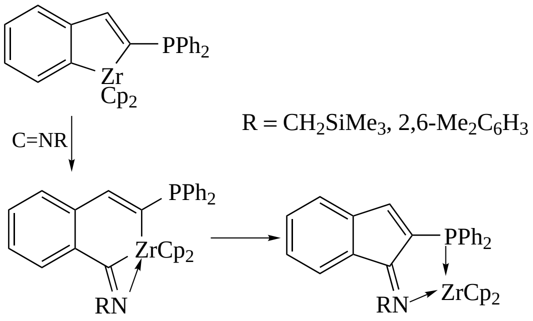
The carbenoids represent 1-halo-1-lithium species (R^3R^4 CLiX) that can cleanly react with organozirconocenes.[31] A



Scheme 33



Scheme 34

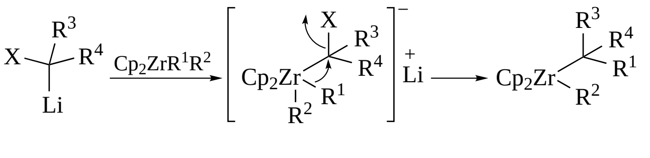


Scheme 35

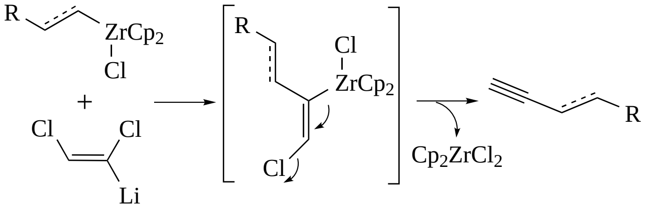
key feature of this reaction is that the product retains the carbon–zirconium bond functionality of the substrate. Similar to carbon monoxide or isonitriles, compounds containing a lithium atom and a nucleofugal group on the same carbon can react with organozirconium complexes. Initial attack on the 16-electron Zr atom (*see Electron Configuration*) leads to a 18-electron metallate complex (*see Ate Complexes*) that rearranges with loss of halogen to give a novel 16-electron complex (Scheme 36). These complexes can generate several organic molecules by protonolysis or treatment with electrophilic reagents. During the reaction, an inversion of configuration is observed at the carbenoid atom.

Alkenyl carbenoids have been generated by halogen/lithium exchange or by deprotonation of alkenyl halides. 1-halo-1-lithioalkenes insert into Zr–C bonds affording stereodefined alkenes after treatment with an electrophile. In particular, the insertion of 2-monosubstituted alkenyl carbenoids is stereospecific (*see Stereoselectivity*).[31] By elimination of hydrogen chloride followed by α-deprotonation of the alkenyl halide using two equivalents of Li(2,2,6,6-tetramethylpiperidide), (*Z*) or (*E*)-1-chloro-1-lithio-1,3-butadiene can be *in situ*-generated from (*E*) or (*Z*)-1,4-dichloro-2-butene respectively. Similarly, insertion of various carbenoids into mono or bis alkynyl zirconocenes affords dienyne or (*Z*)-enediynes. Insertion of the readily formed (*E*)-1,2-dichloro-1-lithioethene into organozirconocene chlorides generates very useful terminal (*E*)-enynes by elimination of zirconocene dichloride from the intermediate species (Scheme 37).[116]

The insertion of allenyl carbenoids into Zr–C bonds is an interesting process for the generation of cumulenyl zirconium

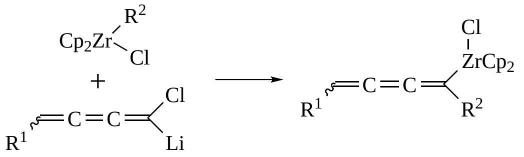


Scheme 36



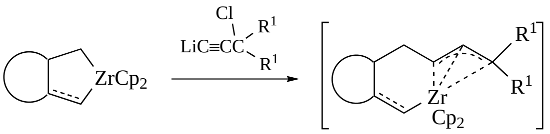
Scheme 37

complexes, precursors of enyne products (equation 62).[116]



(62)

1-lithio-3-chloro-1-propyne efficiently inserts into zirconacycles to afford η^3-propargyl/allenyl complexes, precursors of various unsaturated organic compounds (equation 63).[31]



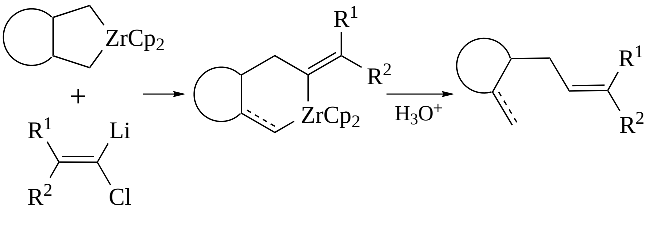
(63)

A ring-expanded process (five- to six-membered zirconacycle) can be observed by a clean insertion (*see Insertion*) of 2,2-disubstituted-1-lithio-1-chloro-alkenes into five-membered zirconacycles (Scheme 38).[31]

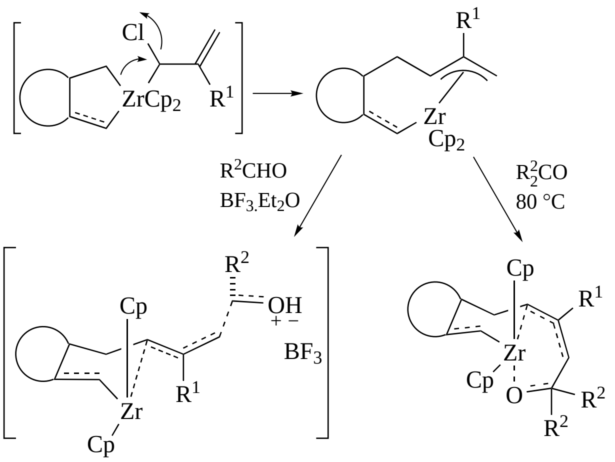
Tandem insertion of allyl carbenoids and aldehydes affords some organic compounds resulting from a three-component coupling reaction.[31] The most extensively studied application of this methodology is the insertion of allyl carbenoids into zirconacycles and subsequent elaboration of the formed allylzirconocenes with electrophiles (Scheme 39).[31]

Insertion of benzyl carbenoids into saturated bicyclic zirconacycles gives initially a 1:1 mixture of the diastereoisomeric zirconacyclohexanes (**108**) and (**109**). (**109**) undergoes a complete isomerization in a few minutes at 60 °C to the more stable diastereomer (**108**) (Scheme 40).

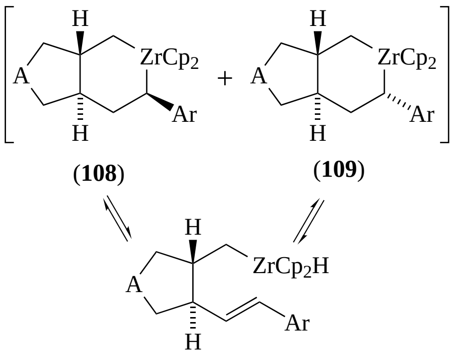
Insertion of benzyl carbenoids into zirconacyclopentenes follows a different but mechanistically related process.



Scheme 38



Scheme 39

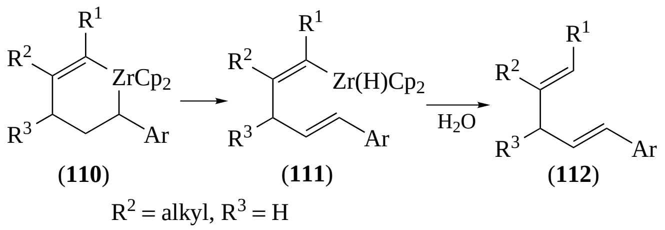


Scheme 40

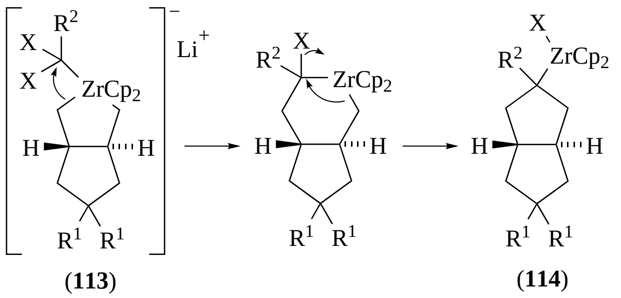
However, the course of the reaction can be different in relation with the structure of the starting complexes. For five-membered fused zirconacyclopentenes, zirconacyclohexenes (**110**) are formed as a 1:1 mixture of diastereomers (Scheme 41). No equilibrium was observed between (**110**) and zirconocene hydride (**111**). In comparison, monocyclic zirconacyclopentenes and six-membered fused zirconacyclopentenes directly form the product (**112**), resulting of a β-hydride transfer/α-elimination (*see α-Elimination*) in high yield, presumably *via* (**111**). The CG of the fused five-membered ring could be responsible for the absence of β-hydride transfer (*see Hydrides*).

1,1-dihalolithium species are readily accessible by *in situ*-deprotonation of 1,1-dihalides with LDA and efficiently insert into zirconacycles, giving a complex (**113**), which rearranges to form fused cyclopentanes (**114**) (Scheme 42).[117]

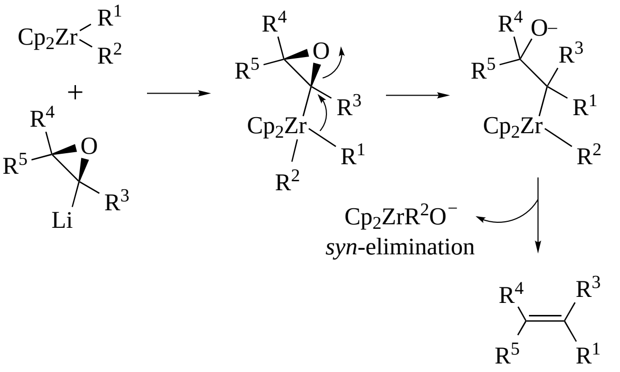
Insertion of metalated epoxides into organozirconocenes proceeds *via* 1,2-rearrangement of the ate complex (*see Ate Complexes*) initially generated affording the β-alkoxyzirconocene, which can then undergo stereospecific *syn*-elimination to yield a tetrasubstituted alkene (Scheme 43).



Scheme 41



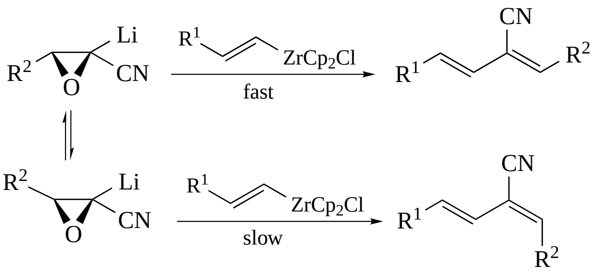
Scheme 42



Scheme 43

Insertion of lithiated epoxynitriles into alkenylzirconocenes can afford various cyano derivatives, but not often in a stereospecific way (Scheme 44).[31]

The insertion of metal carbenoids into zirconacyclopentenes that are not α-substituted on the alkyl and the alkenyl sides of the Zr shows only a 2.2:1 selectivity in favor of the alkyl side. In the case of insertion into zirconacyclopentenes in which there is an α-substituent on the alkenyl, a wide variety of metal carbenoids selectively insert into the zirconium–alkyl bond.[31] On the contrary, steric hindrance of the alkyl side leads to complete selectivity in favor of insertion into the alkenyl side. The selectivity cannot be systematically attributed to steric factors (*see Steric Effect*) especially when insertion into the more hindered side is observed. In this case, the observed selectivity can be correlated with the highest



Scheme 44

coefficient of HOMO (*see HOMO*) of the zirconacycle, rather than of the lowest LUMO (*see LUMO*), suggesting that the carbenoid may be attacking as an electrophile.

8 CATIONIC ZIRCONOCENES IN ORGANIC SYNTHESIS AND CATALYSIS

The reactivity of the cationic Zr complexes is a direct consequence of their Lewis acidity (*see Lewis Acids & Bases*): (i) various substitution reactions can occur into the Zr−solvent weak bond, (ii) unsaturated substrates (CO, alkenes, alkynes, or ketones) insert into the Zr–C bond, potentially leading to polymerization reactions (see Section 8.2), (iii) new organic ligands obtained after reaction in the coordination sphere of the metal can be spontaneously released by β-H elimination (*see β-Hydride Elimination*), or (iv) C–H bond activation of suitable ligands can occur.

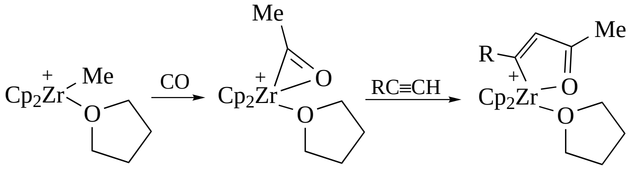
8.1 Applications in Organic Synthesis

8.1.1 For Glycosides and Nucleosides Synthesis

$Cp_2ZrCl_2/AgClO_4$ (1:1) combination and related hafnocene reagents can be used as activator of glycosyl fluorides. For example, the zirconocene-promoted glycosylation was applied in the total synthesis of antitumor monoterpene glycosides.[31] It is interesting to note that sometimes $Cp_2HfCl_2/AgClO_4$ (1:2) combination displayed a different chemoselectivity, inducing a Friedel−Crafts cyclization to a chromane skeleton.[31] For some years, these procedures have been largely used in various glycosylation processes, including glycopeptide synthesis.

8.1.2 Cationic Acylzirconocene Complexes

A cationic η^2-acylzirconocene can be quantitatively generated by treating a cationic zirconocene complex $[Cp_2Zr(R)(L)]^+$ (R = alkyl or alkenyl) with carbon monoxide (T < 23 °C, 1 atm). The use of these complexes has been

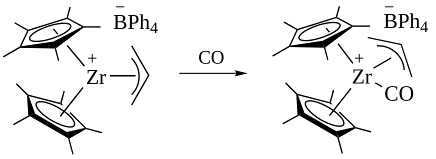


Scheme 45

exemplified by the formation of α,β-unsaturated ketones, 1,4-divinyl ketones, α-lactones, and furans (Scheme 45).[31]

The cationic zirconocene acyl complex (O-inside and O-outside isomers) unusually reacts with vinylchloride or methylvinylketone, affording in good yield a dinuclear dicationic complex, which has been characterized by X-ray diffraction (Scheme 46).[118]

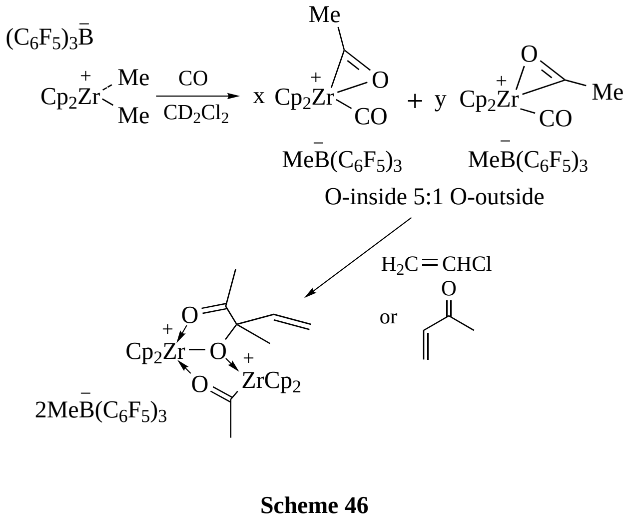
In spite of the growing number of examples, the thermal instability of d^0 carbonyl complexes (*see Carbonyl Compound*) has often precluded their isolation. The use of an allyl ligand can stabilize the corresponding complex through a strong $\sigma \rightarrow \pi^*$ donation completely inhibiting fluxionality of the complex (equation 64).[31]



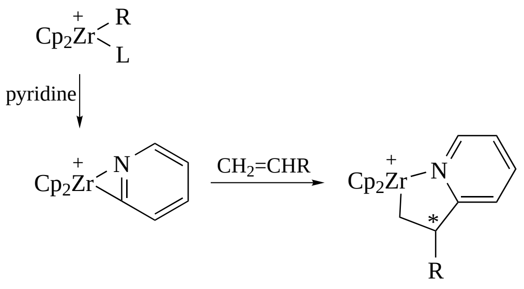
(64)

8.1.3 Applications in Heterocyclic Chemistry

Cationic zirconocene alkyl complexes of general type $[Cp_2Zr(R)(L)_n]^+$ (n = 0, 1, L = labile ligand) (*see Labile*) react readily with pyridines and other N-heterocycles by coordination and metalation (*ortho* C–H activation) to yield



Scheme 46



Scheme 47

η^2-pyridyl complexes that are quite reactive and insert α-olefins and other unsaturated substrates to yield ring expansion products (Scheme 47).[119]

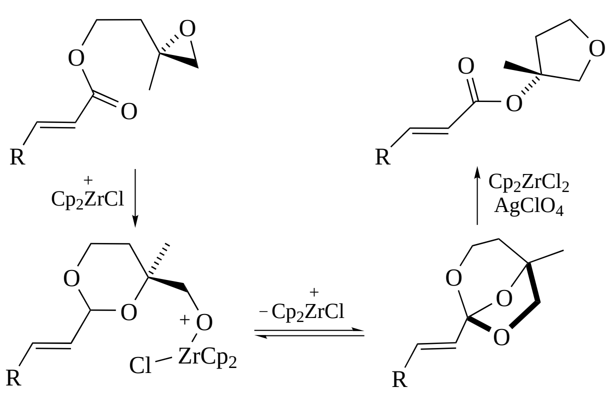
The α-olefin insertions proceed regiospecifically in the Zr–C bond, affording 1,2-insertion product, in which a stereogenic center is present at the β-position (relatively to Zr) of the metallacycle. Starting from chiral zirconocene complexes (as *rac*-[(ebi)Zr(η^2-pyridyl)]$^+$), propene insertion occurs with a high level of diastereoselectivity in cases where the η^2-pyridyl ligand contains a six-substituent.[119]

8.1.4 Miscellaneous Reactions

Cationic zirconocene complexes can be employed as Lewis acid catalysts (*see Lewis Acids & Bases*) in several reactions.

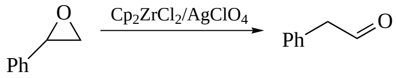
The rearrangement of isopent-3-enyl epoxy esters with $Cp_2ZrCl_2/AgClO_4$ yields asymmetric bicyclo octane esters which are base-stable protecting groups for carboxylic acids (Scheme 48). However, the orthoesters are only the kinetic products and can rearrange under reaction conditions to more stable THF derivatives.[120]

Zirconocene dichloride and catalytic amounts of silver perchlorate can easily induce the rearrangement of an epoxide



Scheme 48

to an aldehyde (equation 65).[31]

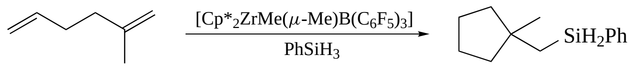


(65)

Cationic zirconocene complexes can induce cycloaddition reactions possibly in an asymmetric manner (see Section 9).

In the Mukaiyama aldol reaction, Zr cationic catalysts can be used. They act very quickly and require only low catalyst loadings (0.5% [$Cp_2Zr(OTf)_2$ thf]). But, the reactions show only modest diastereoselectivity.[121]

A sequential cyclization–silylation of dienes can be induced by a cation-like permethylzirconocene complex (equation 66).[122]

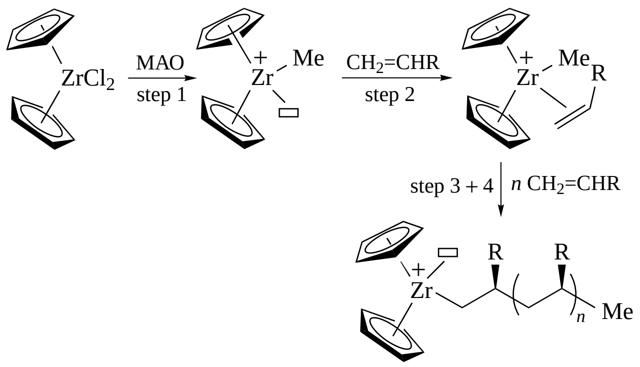


(66)

8.2 Homogeneous Polymerization Catalysis

Cationic 16-electron [$RCp_2Zr(R)(L)]^+$ and 14-electron [$Cp_2Zr(R)]^+$ complexes contain at least one low-lying metal centered empty orbital which can be used for substrate coordination. This feature prompted chemists to use these species as alkene polymerization catalysts. As heterogeneous Ziegler-Natta catalysts (*see Ziegler–Natta Catalysts*) are systems with different active sites, the polymer structure (*see Polymer*) cannot be totally controlled. In comparison, metallocene catalysts are soluble in hydrocarbons. They show only one type of active site and their chemical structures can be easily changed.[123] These properties allow to accurately predicting the properties of the resulting polyolefins. In addition, their catalytic activity is 10–100 times higher than that of the classical Ziegler-Natta systems. In combination with MAO, zirconium and hafnium complexes reveal a very high activity towards olefin polymerization. When metallocenes, especially zirconocenes, are treated with MAO, catalysts allow the polymerization of up to 10^8 g of ethene per gram of Zr. The catalyst can be remained in the polymer at such high activities. The insertion time (for the insertion of one molecule of ethylene into the growing chain) amounts to some 10^{-5} s only. In some respect, such activities compare well with biocatalysts.

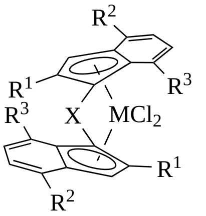
It is generally assumed that MAO firstly undergoes a fast ligand exchange reaction with the metallocene dichloride (Cl → Me). Either Cl^- or CH_3^- is further abstracted from the complex by an Al-center from MAO, thus forming a cationic species (step 1). In the step 2, the monomer (alkene) coordinates to the empty orbital of the complex. Step 3 is related to the insertion (*see Insertion*) of the alkene into the zirconium–alkyl bond which generates a new free



Scheme 49

coordination position. Step 4 is the repetition of step 3, in a very short period of time (about 2000 propene molecules per catalyst molecule per second), providing finally a polymer chain (*see Polymer*). Changing parameters like the nature of the ligand, the cocatalyst and the solvent influences each step (Scheme 49).

For the last twenty years, several hundred complexes have been synthesized with a view to extend properties of the polymer or to improve the activity of the catalysts. Selected typical examples of Zr or Hf precursors (**115–120**) are displayed below.

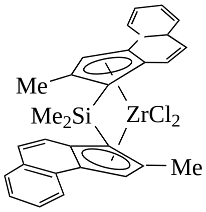


(**115**)

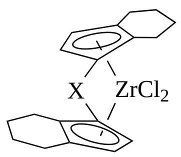
$X = C_2H_4$, $SiMe_2$

$R^1 = R^2 = R^3 = H$, Me

or $R^1 = Me$, $R^2 = Ph$, $R^3 = H$

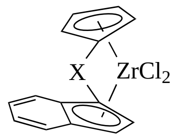


(**116**)



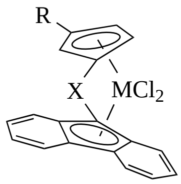
(**117**)

$X = C_2H_4$, $SiMe_2$



(**118**)

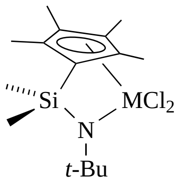
$X = CMe_2$, CPh_2



(**119**)

$X = CMe_2$, CPh_2

R = H, *t*-Bu, C_6H_{11}



(**120**)

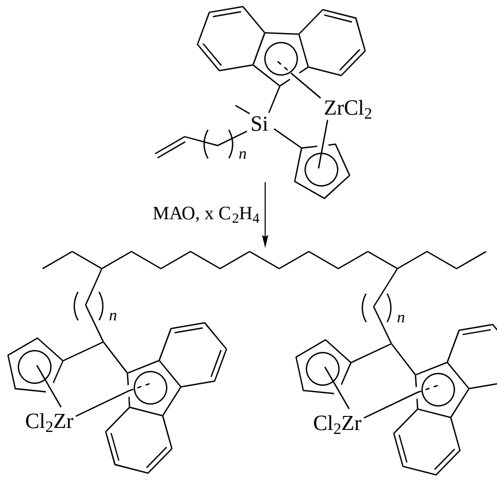
According to the symmetry of the complex and its structural features, very different polymers or copolymers have been obtained. The stereo regulation of α-alkene polymerization is one of the most important aspects of zirconocene or hafnocene-based catalysts. C_2-symmetric complexes (**115**), (**116**), or (**117**) lead to highly isotactic polypropylene, whereas C_s catalysts (**119**) (R = H) induce the syndiotactic arrangement.[1] In recent years, research has increased in the area of C_1-symmetric systems as (**118**) or (**119**) (R = *t*-Bu, C_6H_{11}), for example, which have been shown to transform propene to polypropylene with varying microstructures from aspecific to stereoblock,[124] to syndiotactic,[125] to hemiisotactic,[126] or to isotactic, depending on the nature of the hapto ligands (*see Hapticity*). This behavior is due to the fact that C_1-symmetric complexes have two coordination sites that are diastereotopically related to each other. As a result, monomer coordination can occur with different stereospecificity at each site, and the polymer chain prefers to occupy the less sterically crowded site. On the other hand, atactic polypropylene is produced when an achiral zirconocene catalyst is employed.

Group 4 metallocene catalysts are, in addition to polyethylene and polypropylene, able to generate syndiotactic polystyrene, to polymerize cycloolefins (cyclopentene, norbornene, and their substituted compounds), and to give access to various copolymers. During the polymerization of cycloolefins, only the double bond is opened and not the ring.

Half-sandwich metallocenes (**120**) (*see Half-sandwich Complexes*) play important role in the copolymerization of ethene and various α-olefins. They are distinguished by a sterically accessible active site. These catalysts are remarkably stable up to polymerization temperatures of 160 °C.

Though metallocene complexes possess excellent activities and stereospecificities for the polymerization of prochiral olefins as well as narrow molecular weight distributions of the generated polymers, they are not directly suitable for industrial applications. So, many efforts have been made to support metallocene catalysts. One approach is the use of organic support materials like cross-linked polystyrene. Another method consists to attach a ligand precursor on a polymeric support and then built up the catalyst.[127] The anchorage of the catalyst can be performed on inorganic support materials by an adsorption process at the surface of the solid particles or by a chemical bond, for instance, with silica. An interesting feature of this type of supported catalyst is that the fixation can change the stereospecificity from syndiotactic to isotactic according to the bulkiness of the support. An efficient way is to synthesize metallocene catalysts with an olefin or alkyne function that can be used as a comonomer in the polymerization process. In this case, the homogeneous catalyst is transferred to a heterogeneous system without using any support. The length of the alkenyl substituent must have some steric influence (*see Steric Effect*) on the rate of the β-hydrogen elimination reaction that terminates the growth of the polymer chain. Thus, the self-immobilization of metallocene complexes provides an elegant way to heterogeneize homogeneous metallocene catalysts

(equation 67).



(67)

8.3 Miscellaneous Catalytic Reactions

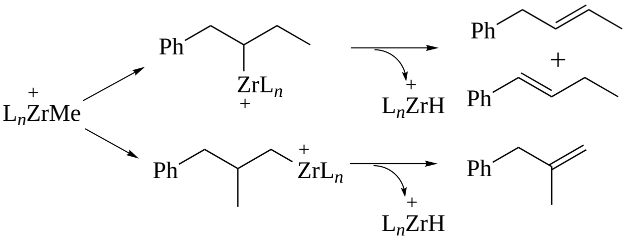
In addition to the extensive development of applications of group 4 metallocenes in polymerization, other uses have been described concerning different catalytic processes.

The dinuclear Hf dicarbolide methyl complex (η^5-$C_2B_9H_{11}$)Cp*Hf(μ-η^2:η^3-$C_2B_9H_{11}$)HfCp*Me_2 catalyses the regioselective dimerization of terminal alkynes to 2,4-disubstituted but-1-en-3-ynes (CH_2=C(R)C≡CR). A great selectivity for dimer formation rather than trimer or higher oligomers has been obtained, owing to a self-correcting mechanism. The intermediate, which could potentially produce trimers or higher rank oligomers, undergoes an intramolecular cyclization reaction. The complex finally obtained is too crowded to produce trimers in subsequent cycles.

The anionic zirconocene trihydride $[Cp_2{}^*ZrH_3]^-$ is able to promote the oligomerization (*see Oligomer*) of PRH_2 to the cyclic polyphosphanes $(PR)_5$. This is evidence of the fact that complexes of early transition metals have a propensity to mediate P–P bond formation.[22]

Group 4 benzamidinate complexes were found to be active catalytic precursors, in the presence of MAO, for the isomerization of aliphatic olefins and the disproportionation (*see Disproportionation*) of 1,4- and 1,3-cyclohexadienes (Scheme 50).[128] The active species is the cationic hydride complex obtained for aliphatic olefins by the insertion of the methyl ligand with concomitant β-hydrogen elimination, and for the alicyclic dienes by an activation of the allylic hydrogen and subsequent elimination of methane.

The silyl chloride complexes (η^5-$C_5H_4SiMe_3)_2$Zr[Si$(SiMe_3)_3$]Cl is a catalyst for the dehydropolymerization of both $PhSiH_3$ and n-Bu_2SnH_2 to relatively low-molecular weight polymers. Thus, polysilanes and polystannanes can be obtained.



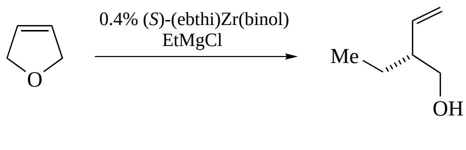
Scheme 50

9 ORGANOZIRCONIUM COMPLEXES IN ASYMMETRIC CATALYSIS

9.1 Zr-catalyzed Enantioselective C–C Bond-forming Reactions

In the area of enantioselective synthesis (*see Enantioselectivity*), the development of catalytic carbon–carbon bond-forming reactions that proceed under mild conditions in an enantioselective fashion (ee > 95%) remains a challenging objective.[129] Among a great variety of metallic complexes, Zr-containing chiral catalysts can promote efficient and highly enantioselective additions of nucleophilic fragments such as alkylmetals and cyanides to C=O and C=N bonds. Moreover, Zr-based metallocenes promote additions of alkylmetals to carbon–carbon double bonds, reactions that do not easily occur with other catalysts. One another important feature is that the product of the asymmetric addition of an alkylmetal to an alkene produces a chiral alkylmetal that can be further functionalized.

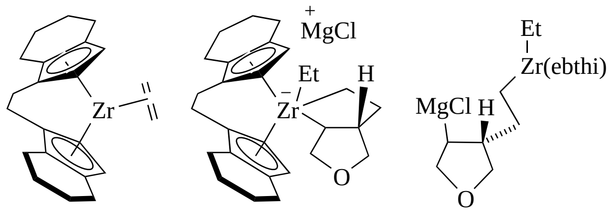
Chiral C_2-symmetric ansa metallocenes are often used to promote asymmetric C–C bond-forming transformations.[31] (ebthi)$ZrCl_2$ or its derived binaphtolate and related complexes are intensively utilized in Zr-catalyzed enantioselective alkylation of alkenes with Grignard reagents (*see Grignard Reagents*). Thus in the presence of 2.5 to 10 mol% of these nonracemic complexes and EtMgCl as alkylating agent, five-, six- and seven-membered unsaturated heterocycles undergo facile asymmetric ethylmagnesation. The unsaturated alcohol in equation (68) can be used as a key intermediate in the first enantioselective total synthesis of the antifungal agent *fluvirucin*.[31]



(68)

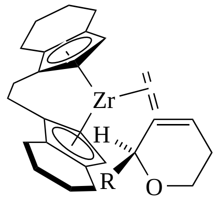
The catalytic cycle proposed for the enantioselective ethylmagnesation involves the chiral zirconocene–ethylene complex (**121**), formed upon reaction of the dichloride with two equivalents of EtMgCl. Coupling of the alkene substrate leads to the formation of the metallacyclopentane intermediate, which gives the zirconate (**122**) with a

third equivalent of EtMgCl. A Zr–Mg ligand exchange yields (**123**). Subsequent β-hydride abstraction, accompanied by intramolecular magnesium alkoxide elimination leads to the final product and regeneration of (**121**). These alkylation processes are useful when used in conjunction with well-known catalytic ring-closing metathesis.[130,131] Intramolecular variants of the above Zr-catalyzed enantioselective alkylations can be performed.[31]



(**121**) (**122**) (**123**)

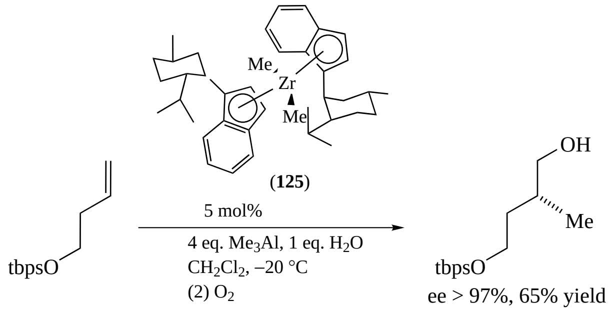
According to the high level of enantioselectivity (*see Enantioselectivity*) obtained in the asymmetric catalytic carbomagnesation and the interaction between the zirconocene–ethylene complex (**121**) and chiral unsaturated pyrans or furans, it is possible to induce differential rates of reaction leading to kinetic resolution. For instance, with a 2-substituted pyran, after 50% conversion, one enantiomer of the chiral alkene can be recovered in high enantiomeric purity. In fact, the favored model for the intermediate is the complex (**124**) that minimizes the steric interactions by preferential association of one pyran enantiomer with (ebthi)Zr complex (**121**). Consequently, in the presence of catalytic amounts of optically active (ebthi)$ZrCl_2$, a variety of chiral pyrans can be resolved in excellent enantiomeric purity (ee > 99%).[31] Moreover, this Zr-catalyzed resolution technology may be applied to medium-ring heterocycles, even if the presence of an aromatic substituent can have an adverse influence on the outcome of the catalytic resolution.[31]



(**124**)

Kinetic resolution of cyclic allylic ethers can be performed by asymmetric Zr-catalyzed carbomagnesation. Six-, seven- or eight-membered ethers can readily be resolved by the Zr-catalyzed protocol (with ee between 81 to 99%). As an example, the tandem Zr-catalyzed kinetic resolution followed by a Ru-catalyzed ring-opening/ring-closing metathesis affords chiral chromenes with high optical purity (ee > 99%).[31]

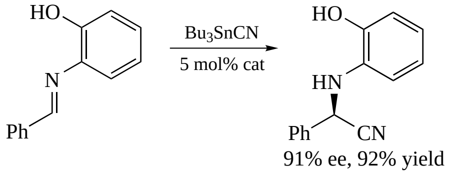
Enantioselective carboaluminations of inactivated alkenes are promoted by the nonbridged chiral zirconocene (**125**), neutral or in association with $B(C_6F_5)_3$ (equation 69).[31] An unexpected observation is that addition of water leads to substantial acceleration of the C–C bond-forming process.[132]



(69)

Application of Zr-catalyzed enantioselective additions of alkylzinc reagents to imines delivers optically enriched or optically pure amines, a class of compounds having a great significance to medicine and biology.[31] Facile reduction of substrates with Et_2Zn may be due to β-H elimination of the metal–Et complexes which generate active metal hydrides that can promote amine reduction. The catalytic asymmetric protocol can be applied to the synthesis of nonaryl imines to generate homochiral amines. A recent procedure for amine synthesis involves a three-component process with *in situ*-formation of the imine substrate followed by its asymmetric alkylation.[133]

Catalytic asymmetric cyanide addition to imines (Strecker-type reaction) is an interesting carbon–carbon bond-forming reaction. The aminonitriles obtained may be converted to nonproteogenic α-amino acids.[134] In this reaction, the binuclear complex proposed as the active catalytic species was formed starting from two equivalents of Zr(O*t*-Bu)$_4$, 6-Br-binol, and *N*-methylimidazole and one equivalent of 3-Br-binol (equation 70). The protocol can be modified by using a three-component synthesis (aldehyde/aminophenol/HCN) to avoid the use of undesirable stannane reagent. This in situ-procedure is particularly interesting for less stable aliphatic imines. In this case, the aminonitrile synthesized is the precursor of the corresponding aminoesters.[31]

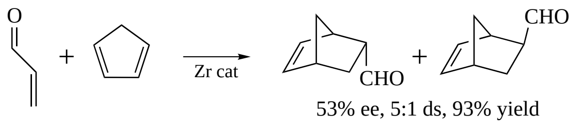


(70)

Enantioselective aldol and Mannich reactions and related transformations can be efficiently performed with several zirconium catalysts. Addition of 1-naphtol to ethyl pyruvate mediated with the chiral (diborna-Cp)$ZrCl_3$ complex is reported with an appreciable level of enantioselectivity.[1]

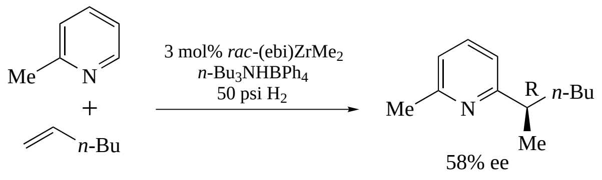
At lower temperatures higher optical purities are obtained, and curiously, addition of water improves the selectivity and the reactivity. In a similar way, additions of ketene and thioketene acetals to a range of aromatic and aliphatic aldehydes have been accomplished and demonstrated the role of protic additives on the yield and the enantiomeric excess.[31] Through the use of the chiral catalyst prepared from Br_2-binol ligand, a range of α,α-disubstituted β-amino esters can be generated by addition of ketene acetals and derivatives to imines.[31] In this catalytic process, when more electron-withdrawing chiral ligands are used (CF_3 substituted binol), enantioselectivity and reactivity levels are often enhanced. Very high ee and yields are observed in similar reactions using chiral vapol-derived catalyts.[135]

Cationic *ansa* metallocenes can be utilized as chiral catalysts in Diels–Alder reactions. For example, in the presence of the cationic zirconocene complex $[(ebthi)Zr(Ot\text{-}Bu)\cdot thf]^+$, the $[4+2]$ cycloaddition of acrolein and cyclopentadiene proceeds efficiently to afford *endo* and *exo* cycloadducts (equation 71). In reactions in which methyl acrylate is used as the dienophile, cycloadditions occur with lower levels of enantioselection (23% ee), but with significantly higher degrees of diastereoselectivity (17:1 *endo, exo*). In these processes, recent studies demonstrated the great influence of chiral metallocene structure and the dramatic solvent effect.[31]



(71)

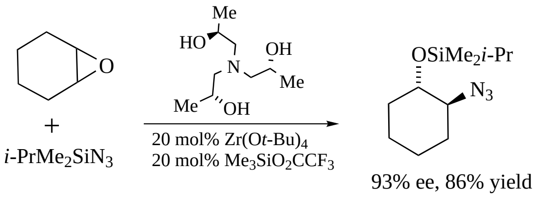
In relation with the ability of cationic *ansa* zirconocene complexes to affect stereocontrolled alkene polymerization reactions, it is possible to insert simple alkenes into the $[(ebi)Zr(\eta^2\text{-pyrid-2-yl})]^+$ and $[(ebthi)Zr(\eta^2\text{-pyrid-2-yl})]^+$ systems.[31] The derived three-membered azazirconacycles are formed with high levels of diastereoselectivity, depending on the nature of alkene substituents. Thus, the enantiopure ebthi complex catalyzes asymmetric C–C bond-forming reactions (equation 72).



(72)

9.2 Zr-catalyzed Enantioselective C–N and C–H Bond-forming Reactions

C–N bond-forming reaction is promoted by $Zr(Ot\text{-}Bu)_4$ in the presence of trimethylsilyl trifluoroacetate and a chiral amine triol (equation 73). This tightly bound multidentate ligand is very effective for transferring chirality.[136]



(73)

Ansa metallocene-catalyzed hydrogenation of various alkenes can also be performed with low to moderate enantiomeric excess. The most successful hydrogenations involve trisubstituted alkenes, for which enantioselectivity can be in the range 83–99%. However, the use of cationic (ebthi)Zr-catalysts generated with MAO require that the alkene should not be able to polymerize in a facile manner. Thus, whereas with 1-decene as the substrate, only 28% of the hydrogenation product is obtained, 2-methyl-1-pentene affords 97% of the hydrogenation adduct. Tetrasubstituted alkenes can be hydrogenated with an efficient and highly enantioselective Zr-catalyzed process.[137]

1 INTRODUCTION

The organometallic chemistry of the alkaline earth metals has been predominantly centered on magnesium. (*See* ***Beryllium & Magnesium: Organometallic Chemistry***) Originated by the groundbreaking studies by V. Grignard in 1900, it was shown that organomagnesium halides might easily be prepared by the treatment of an organic halide with magnesium metal in diethylether. The resulting compounds have important roles in synthetic chemistry, prompting extensive studies. Novel developments in this area of chemistry, such as transition metal–catalyzed cross-coupling or magnesium-halogen exchange reactions among others (discussed below) further improved the utility of these important reagents.

In contrast to the magnesium analogs, the heavy group IIA congeners are more reactive and thus more difficult to prepare. In addition, their higher tendency towards aggregation, as caused by the larger ionic radii, often leads to solubility problems. As a result, the organometallic compounds of calcium, strontium and barium were viewed as laboratory curiosities without applications, and it is not a surprise when the recent edition of Greenwood and Earnshaw mentions that from about 50 000 papers on the organometallic compounds of group IIA, less than 1% deal with the heavier triad of alkaline earth metals.[1] Magnesium's lighter congener beryllium has received only little attention owing in part to its reduced nucleophilicity as compared to magnesium. Moreover, beryllium was considered the 'most toxic nonradioactive element'. (*See* ***Beryllium: Inorganic Chemistry***) Even when in the 1990s it became clear that with appropriate precautions beryllium chemistry can be carried out in a safe manner, research intensity did not increase markedly.

The organometallic chemistry of the heavy alkaline earth metals experienced a renaissance in the 1980s when synthetic procedures for the preparation of discrete, soluble cyclopentadienide derivatives were derived, as delineated in several excellent review articles.[2,3] Today, advances in synthetic methodology and characterization techniques have allowed for detailed synthetic and structural investigations of an extended group of organometallic derivatives of the heavy metals. These research efforts are prompted by the numerous applications in a variety of disciplines including synthetic chemistry, materials, and solid-state applications, and polymer chemistry amongst others.[4–12]

This article summarizes some of the recent developments in alkaline earth organometallic chemistry. Several excellent review articles are available for more detailed discussions on the subject areas. It is important to note that radium, the heaviest alkaline earth metal, is radioactive and no organometallic compounds have been reported.

2 SYNTHESIS

2.1 General Considerations

The organometallic chemistry of the Group IIA metals is dominated by the M^{2+} oxidation state. (*See* ***Alkaline Earth Metals: Inorganic Chemistry***) The elements in the group are generally defined with the members loosely partitioned into two general classes. The first class contains the smaller beryllium and magnesium, whose chemistry is often markedly different than that of the larger congeners. The high charge/size ratio observed by these ions, particularly in the case of Be^{2+}, with an ionic radius of 0.41 Å (CN 4), and Mg^{2+} (CN 4) with 0.71 Å leads to an extremely high polarizing power and a chemistry influenced by covalent interactions.[13] Still, the significant difference in electronegativity (EN) between beryllium (1.47), magnesium (1.23) and carbon (2.50) indicates a significant polar bond contribution.[14] In many respects, the chemistry of the lighter analogs mirrors that of zinc rather than that of the heavier members of the group with the coordination sphere of the lighter group IIA metals more easily saturated by relatively small organic ligands. Organomagnesium compounds are well studied as the result of the enormous synthetic utility of the Grignard and diorganomagnesium reagents. Many of the compounds have been isolated and characterized in detail, showing a preference for low-coordination numbers. The composition of the products, especially in solution is not straightforward, as discussed below.

The second class of alkaline earth metals involves the heavier congeners, although radium, as a radioactive element, is not studied in detail. The significant increase in ionic size and reduction in electronegativity experienced by these metals (Ca (CN 6) 1.14 Å, EN = 1.04; Sr (CN 6) 1.27 Å, EN = 0.97;

Ba (CN 6) 1.49 Å, EN = 0.97) leads to chemistry dominated by electrostatic interactions. There are significant similarities between the chemistry of calcium and divalent ytterbium as well as strontium and divalent europium and samarium owing to quite similar size/charge ratios.[15] (*See* ***Scandium, Yttrium & the Lanthanides: Organometallic Chemistry*** and ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***)

Several distinct trends are exhibited in the chemistry of the heavy alkaline earth metals as one descends the group. In accord with the increased metal coordination sphere, increased metal–ligand and metal-donor lability is observed. Moreover, the increased metal diameter typically requires the presence of sterically demanding ligands often in combination with appropriate donors to sterically saturate the metal coordination sphere and prevent the formation of polymeric species. Still, oligomerization is commonly observed for the heavier metals. Partially as a result of this, and also owing to the predominantly ionic nature of the compounds, solubility generally decreases upon descending the group; most such complexes are sparingly soluble in hydrocarbons unless sterically demanding ligands with considerable methyl substitution are employed to enhance this property.

Work on heavy alkaline earth organometallics was hampered for years owing to lack of suitable synthetic access routes. The extreme air and moisture sensitivity of the compounds (even in comparison to the magnesium analogs) and difficulties in isolating pure products frustrated early work and remains a serious challenge. In addition, early efforts were predicated on straightforward conceptual routes owing to the difficulties involving the preparation of suitable starting materials for more advanced, multistep synthesis. Fortunately, growth in other fields (particularly alkali metal 'superbases' and alkaline earth metal amides) facilitated a concomitant increase in the synthetic arsenal for alkaline earth metal chemists, and now a wide range of applications is available for the preparation of these compounds.

2.2 Synthetic Methodologies

As discussed above the variation of chemical properties observed in group IIA elements requires a range of synthetic methodologies. As such, some preparative methods are not applicable for all metals. Synthetic methodologies for the lighter metals are well established and documented and will be discussed only briefly. In contrast, the development of synthetic routes towards the heavier analogs is far less established and will be discussed in greater detail. Amongst those, the term direct metallation summarizes a selection of synthetic strategies involving the reaction of a metal and neutral ligand, is now gaining prominence for the preparation of the heavier group IIA analogs. Metathesis reactions including salt-elimination, transamination, transmetallation, hydrocarbon elimination, and desilylation represent alternative avenues towards the heavy alkaline earth organometallics and will be discussed in detail below.

2.2.1 Direct Reaction of Organohalogens with the Metal

This is the classical method to prepare the Grignard analogs, and remains the most frequently used synthetic method towards the heteroleptic organomagnesium halides and the diorganomagnesium derivatives if the initial formation of the 'RMgX' is followed by the addition of 1,4 dioxane. The exothermic reaction is typically conducted in ethers and may proceed quite rapidly, especially if small alkyl or aryl substituents are employed.

Essential for the success of this reaction are the quality of the magnesium metal in the reaction since the magnesium oxide layer are all will effectively passivate the metal surface preventing access to the underlying magnesium metal. Several methods of surface activation are available: addition of a few drops of CCl_4 or $BrCH_2CH_2Br$ or a small amount of iodine that will penetrate the protective oxide layer are all commonly employed. Especially effective is the addition of iodine followed by slight heating and extended stirring under inert gas. A more reactive form of magnesium ('Rieke' magnesium) may be prepared by the reduction of a magnesium halide with an alkali metal, lithium naphthalide, on potassium graphite.[16] A recent, powerful activation method focuses on the use of di(isobutyl)aluminum hydride (DIBAH) allowing the preparation of Grignard reagents well below the boiling point of THF.[17]

Grignard-type reactions require the presence of a donor. Typically, diethyl ether is used, whose high volatility provides a vapor barrier above the solution to protect from oxidation and hydrolysis. Nevertheless, an inert gas is needed to ensure optimal yields. The introduction of sterically demanding ligands often coincides with difficulties to initiate the reaction. The presence of bulky ligands also results in reduced reaction rates, and consequent low yields and long reaction times. These problems may be circumvented by external heating, or the use of higher boiling ethers such as THF. It is important to note that the vapor barrier created by the higher boiling solvent is less effective; as such strict inert gas conditions are necessary. In addition to ligand size and the nature of the solvent, the halide substituent has an important role in the overall reaction with organoiodides being the most and organofluorides being the least reactive. Typically, fluorides may be prepared in good yields if highly active magnesium is utilized (equation 1).

$$Mg_{(act.)} + RX \xrightarrow{\text{Ether}} RMgX$$

$$\text{Act.} = \text{activated; X} = \text{F, Cl, Br, I; R} = \text{Alkyl, Aryl} \qquad (1)$$

Use of this route for the heavier metal analogs has been met with limited success with the purity of the alkaline earth metal playing a pivotal role.[18–25] This work indicated that it

is especially important to avoid any alkali metal impurities in the alkaline earth metal source.[26] Moreover, the need for an ethereal solvent is frustrated by the commonly observed ether cleavage reactions, making this a less attractive route to prepare the heavy metal analogs.

2.2.2 *Direct Metallation*

One of the earliest and most straightforward methods employed in the preparation of heavy alkaline earth organometallics involved the reaction of a metal with an acidic ligand substrate (equation 2) in an oxidative addition.

$$\mathrm{Ae_{Act.}} + 2\mathrm{HR} \longrightarrow \mathrm{AeR_2} + \mathrm{H_2}$$
$$\mathrm{Ae} = \mathrm{Ca, Sr, Ba} \quad \mathrm{Act.} = \mathrm{Activated} \qquad (2)$$

This method generally requires activation of the metal and the availability of an oxide-free metal surface. This can be accomplished in several ways, including the reduction of the alkaline earth metal iodides with potassium metal or lithium napthalide,[11,12,27] the utilization of freshly distilled metals,[28] the preparation of surface enhancing amalgams by addition of a few drops of mercury,[19] addition of a small amount of iodine, or (most commonly) the dissolution of the metals in anhydrous, liquid ammonia.[29–31] While the heavy alkaline earth metals dissolve easily in ammonia, this tendency decreases for the lighter metals. Beryllium does not dissolve, and magnesium does so only if highly active magnesium powder is employed. This trend coincides with an increase in reactivity as descending the group, allowing a smooth reaction for barium, while reflux conditions for strontium and calcium (dry ice condenser, $-35\,^\circ$C) are required. Still, calcium reactions are typically quite sluggish. The presence of a secondary donor is often required, even for the heaviest, most reactive alkaline earth metals, and products are only available if such a donor is present. As an example, the reaction of barium with the bulky amine $HN(SiMe_3)_2$ proceeds smoothly in the presence of THF whereas, no reaction is observed in the absence of THF.[32] Direct metallation has been used successfully to prepare families of amides and aryloxides, but organometallic examples remain rare.[33]

A variant of direct metallation, cocondensation, has been utilized to prepare the first σ-bonded organocalcium complex, $\{(SiMe_3)_2CH\}_2Ca(1,4dioxane)_2$,[34] in addition to a transient heteroleptic calcium hydride, C_6H_5CaH by C–H activation (equation 3).[35] The heteroleptic hydride is highly reactive and decomposes upon warming the reaction vessel above $-78\,^\circ$C. The product has been identified by its reaction with alcohols, affording quantitatively a series of calcium aryloxides.

$$\mathrm{Ca_s} + \mathrm{ArH_{excess}} \xrightarrow[\mathrm{THF}]{\mathrm{cocondensation}} \mathrm{ArCaH(THF)_2}$$
$$\mathrm{Ar} = \mathrm{benzene, toluene,}\ t\mathrm{Bu\text{-}benzene, xylene} \qquad (3)$$

The direct metallation of magnesium with anthracene in THF quantitatively affords a THF solvated magnesium anthracenide in the form of orange yellow crystals.[36–39] While the solubility of the unsubstituted magnesium anthracene derivatives is low, the substitution of the aromatic system with $SiMe_3$ groups sufficiently increases the solubility to afford crystalline samples. The magnesium anthracenides are the starting material for the formation of magnesium hydride catalysts.[40] The heavier alkaline earth metal anthracenides have been prepared by dissolving the alkaline earth metals and anthracene in a mixture of liquid, anhydrous ammonia, and THF, but solubility problems have prevented their complete characterization and widespread use.[41]

2.2.3 *Salt Elimination*

Salt elimination is currently an attractive synthetic route to prepare cyclopentadienide derivatives of group IIA. The metal halides require the presence of ethers to enable homogeneous reaction conditions. Amongst the halides, the fluorides are the least soluble, whilst the iodides display the highest solubility. For the heavier metals, homogeneous reaction condition can only be achieved if the iodides are employed. The iodides are preferentially reacted with organopotassium reagents, owing to the high lattice energy of KI, and its subsequent precipitation, even in THF solutions. Moreover, cyclopentadienide potassium salts are easy to prepare and handle, justifying the preference for this route (equation 4). The required presence of etheral solvents does not allow the direct preparation of donor-free products. If desired, an alternative synthetic strategy, such as transmetallation and the use of organomercury reagents is advisable.

While salt elimination has been employed for the preparation of the metallocenes for some time, it remains a challenging route towards an extended group of organometallics owing to the high reactivity of the potassium organometallics. Rare exceptions are the preparations of $Ca(C(SiMe_3)_3)_2$ and more recently $Ca(THF)_4(CH_2Ph)_2$.[42,43]

$$\mathrm{AeI_2} + 2\mathrm{KR} \longrightarrow \mathrm{AeR_2} + 2\mathrm{KI}$$
$$\mathrm{Ae} = \mathrm{Be, Ca, Sr, Ba} \quad \mathrm{R} = \mathrm{alkyl, aryl} \qquad (4)$$

The combination of alkaline earth iodides and organopotassium reagents has proven to be advantageous for avoiding problematic solubility and separation issues that can be formidable using this route, especially if the solubility of the product is low. Proven methods to improve product solubility include the addition of various donor systems (such as crown ethers). The success of the reaction route critically depends on the purity of both starting materials; the presence of lithium, as often introduced using potassium organometallics prepared by Schlosser conditions, or any other impurity will complicate the isolation of pure products. The introduction of

a novel method for preparing organopotassium reagents in the absence of lithium (desilylation) should help overcome this synthetic obstacle.[44]

2.2.4 Transamination

With the development and detailed characterization of the bis(bistrimethylsilyl)amides of the heavy alkaline earth metals, the transamination regime has become an attractive route to prepare a variety of alkaline earth metal derivatives, including organometallics. The attractiveness of the route is due to the good stability and excellent solubility of the metal amides in a variety of solvents (equation 5).

$$\mathrm{Ae(N(SiMe_3)_2)_2(THF)_2 + 2HR \longrightarrow AeR_2 + 2HN(SiMe_3)_2}$$
$$\mathrm{Ae = Ca, Sr, Ba \quad R = alkyl, aryl} \qquad (5)$$

The reaction route is quite flexible, but the reactant needs to be more acidic than the liberated amine. Although the alkaline earth metal amides are generally not as basic (pKa = 30−33) as the potassium organometallics used in the salt-elimination regime, they are nonetheless known to attack both crown ethers and ethereal solvents, necessitating careful control of reaction conditions to circumvent this undesirable side reaction.[45] Other side reactions involve the protonation of the liberated amine by the acid, under formation of a primary amine (equation 6). If excess acid is present, a second protonation may lead to the formation of NH_3. The cleaved $SiMe_3$ group silylates the acid, thus dramatically reducing product yields.[46] The protonation of the amine may partially be suppressed by slow and dilute addition of acid avoiding an excess of acid at all times.

$$\mathrm{HN(SiMe_3)_2 + HR \longrightarrow Me_3SiR + 2H_2NSiMe_3}$$
$$\mathrm{R = Alkyl, Aryl} \qquad (6)$$

2.2.5 Transmetallation

Transmetallation was used extensively for the preparation of heavy alkali organometallics by reaction of a heavy alkali metal alkoxide or aryloxide with an organolithium reagent under precipitation of lithium alkoxide/aryloxide. The reaction typically proceeds smoothly, the only drawback being the separation of two solid reaction products. As such, careful choice of ligands to enable the facile separation on the basis of different solubility properties is crucial. Use of this route in the preparation of alkaline earth metal organometallics has been reported for the preparation of strontium and barium dibenzyl derivatives.[10,45] Two variants of this reaction have been reported: reaction of an alkoxide (specifically the *tert*-butoxides) with benzyllithium (equation 7), or treatment of the bis(bistrimethylsilyl)amides with the lithium reagent (equation 8). Again, the principal drawbacks of these reactions focus on the separation of the two solid reaction products. Since heavy alkaline earth metal *tert*-butoxides are difficult to prepare in a pure form, it is advantageous to focus on the amide as a starting material.

$$\mathrm{Ae(O}t\mathrm{Bu)_2 + 2Li(C_7H_7) \longrightarrow Ae(C_7H_7)_2 + 2LiO}t\mathrm{Bu}$$
$$\mathrm{Ae = Sr, Ba} \qquad (7)$$
$$\mathrm{Ae(N(SiMe_3)_2)_2(THF)_2 + 2LiR \longrightarrow AeR_2 + 2LiN(SiMe_3)_2}$$
$$\mathrm{Ae = Ca, Sr, Ba;\ R = Alkyl, Aryl} \qquad (8)$$

2.2.6 Metal Exchange

The use of organomercurials to prepare organometallic reagents has been well documented and is especially powerful where the formation of 'ate' complexes is prevalent.[47] The method has been used extensively to prepare pure organoberyllium or magnesium compounds, especially in cases when a donor-free product is warranted. Even though this route might be quite powerful for the preparation of the heavier alkaline earth metal analogs, past work was limited to the preparation of dibenzyl derivatives. The dearth of further studies is likely due to the reluctance to work with highly toxic organomercurials (equation 9). (*See* ***Mercury: Organometallic Chemistry***).

$$\mathrm{Ae + HgR_2 \longrightarrow AeR_2 + Hg}$$
$$\mathrm{R = Alkyl, Aryl} \qquad (9)$$

2.2.7 Hydrocarbon Elimination

Until recently, there was no analog in heavy alkaline earth chemistry to the well-established alkane elimination route used to prepare a variety of magnesium amides and chalcogenides.[48] The attractiveness of the route for magnesium is due to the commercial availability of dibutyl magnesium. The gaseous nature of butane allows a simple work-up procedure (equation 10). However, until recently, similar chemistry for the heavier alkaline earth metals was not possible owing to the lack of suitable dialkyl or aryl reactants. Recent reports by Harder *et al.* describe the facile preparation of dibenzyl calcium and barium compounds, giving rise to the intriguing possibility of employing these reagents in a similar reaction scheme (equation 11).[10,42] Work in our group has extended the group of reagents to strontium,[45] making available all heavy alkaline earth metals in this reaction scheme.

$$\mathrm{Mg(C_4H_9)_2 + HR \longrightarrow MgR_2 + 2C_4H_{10}}$$
$$\mathrm{R = amine, thiol, selenol} \qquad (10)$$
$$\mathrm{Ae(C_7H_7)_2 + 2HR \longrightarrow AeR_2 + 2C_7H_8}$$
$$\mathrm{Ae = Ca, Sr, Ba \quad R = Alkyl, aryl} \qquad (11)$$

So far, dibenzyl derivatives remain the only hydrocarbon source for hydrocarbon elimination reactions, especially since

the well-explored bis-cyclopentadienides are not suitable as starting materials for this type of reaction. The high basicity of the benzyl reagents allows for the metallation of many otherwise inactive ligand systems, and the formation of toluene as the side product facilitates the isolation of the target molecules. Owing to the highly reactive nature of the starting materials and their low solubility in apolar solvents, this entry requires the presence of the polar solvent THF at temperatures below −40 °C to prevent ether cleavage chemistry. Efforts to modify solubility properties through substitution of the benzyl moiety are underway.

2.2.8 Alkaline Earth 'Superbase' Analogs

An intriguing new possible entry currently under development involves the application of a recently discovered route to heavy alkali organometallics through a simple desilylation reaction in which an alkali metal *tert-butoxide* is reacted directly with a trimethylsilyl substituted ligand yielding the desired product and trimethylsilyl*tert*butylether. In the case of the alkaline earth metals, this reaction requires the presence of an organolithium reagent to afford the desired product (equation 12).

$$Ba(OtBu)_2 + 2(SiMe_3)CHR_2 \xrightarrow{nBuLi} Ba(CHR_2)_2 + 2Me_3SiOtBu$$
$$R = \text{Aryl} \qquad (12)$$

The exact role of the organolithium reagent remains unclear, but it seems plausible that the components function as alkaline earth metal-containing 'superbase' analogs, with a alkali-alkaline earth metal alkoxide/organometallic aggregate as the metallating species.[44]

2.2.9 Hydride Elimination

The reaction of metal hydrides MH_2 with acidic hydrocarbons seems an attractive way to prepare the target compound since a commercially available metal source can be utilized. Moreover, the formation of only gaseous by-products ensures a facile work-up (equation 13). However, only few compounds have been prepared using this route owing to the low reactivity of the hydrides caused by their polymeric, insoluble nature. Moreover, the unreliable purity of the commercial hydrides poses significant problems. As such, rather acidic ligands and enforced reaction conditions are required for the reaction to proceed.

$$MH_2 + 2RH \longrightarrow MR_2 + 2H_2$$
$$M = \text{Be-Ba}, R = \text{acidic hydrocarbon} \qquad (13)$$

3 STRUCTURAL FEATURES AND BONDING

The structural features in the target compounds are quite diverse and bonding within the target compounds may involve σ- and π-type interactions. The following chapters are divided by ligand type to allow a more direct comparison of trends within the group of metals.

Owing to the significant lability within the target compounds, ligand exchange reactions are frequently observed. This is especially relevant for heteroleptic compounds, where complex solution equilibria complicate the isolation of pure species. As such, solution chemistry of the organometalhalides is discussed below.

3.1 Disproportionation/Redistribution (Schlenk) Equilibria

Despite their role as the most widely used organometallic reagents, the constitution of Grignard reagents in solution has been a source of uncertainty for some time. It is now well established that solutions of Grignard reagents can contain many different species interlinked by complex equilibria. The position of the equilibria depends on many factors including but not limited to (1) the nature of the halogen, (2) the nature of the solvent, (3) the concentration of the solution, (4) the size and electronic properties of the ligand, and (5) the temperature of the solution.[49] Schlenk and Schlenk proposed the now-familiar representation of the organomagnesium halides by an equilibrium between the dihalides and the diorgano compounds (equation 14).

$$MX_2 + R_2Mg \rightleftharpoons 2RMgX$$
$$X = F, Cl, Br, I; R = \text{Alkyl, Aryl} \qquad (14)$$

This suggestion was further justified by extensive VT-NMR studies offering additional useful information on the rate of exchange.[50] In the presence of small groups such as methyl, lowering the temperature allows the observation of distinct signals, rather than averaged resonances allowing the identification of individual components. Lower rates of exchange are also observed if the ligand size increases, as shown for ligands as small as *tert*-butyl. Important information in regards to the equilibria was also obtained on studies involving the heavier alkaline earth metal analogs. Only in the presence of very sterically demanding ligands, such as substituted cyclopentadienides, heteroleptic species may be isolated.[51]

For the magnesium reagents, the influence of 1,4 dioxane or other complexing agents typically results in the formation of the diorganomagnesium species,[49] owing to the precipitation of the dihalide dioxane adduct, which can be removed by filtration (equation 15).

$$2RMgX + C_4H_8O_2 \longrightarrow MgR_2 + MgX_2(C_4H_8O_2)\downarrow$$
$$X = F, Cl, Br, I; R = \text{Alkyl, Aryl} \qquad (15)$$

If the ligand system is sterically demanding, the rates of exchange are very slow allowing the isolation of heteroleptic RMgX. In this case, addition of 1,4 dioxane does not afford the diorganomagnesium reagents, even if reflux conditions are employed. As an example, 2,4,6-$Ph_3C_6H_2MgBr(THF)_2$ (Figure 1) does not afford the diorganomagnesium species even if an excess of 1,4 dioxane and reflux conditions are employed. A likely explanation is based on an unfavorable transition state owing to the large steric demand of the ligand. The smaller size of beryllium and the increased covalency of its bonds allows the more ready isolation of heteroleptic species, especially if sterically demanding ligands such as terphenyl are employed.[52]

3.2 Alkaline Earth Metallocenes

Cyclopentadienide (Cp) derivatives are known for all alkaline earth metals, and trends observed within the group nicely represent the changes in properties within the group of metals.[53] As for the heavy metal triad, cyclopentadienide derivatives remain the largest well-explored group of organometallics known, with the earliest examples dating back as early as 1956.[54] Several excellent review articles summarize trends observed within this group of compounds.[2,3,53,55]

The large variability of the Cp ligand through various substitution patterns on the ring such as pentamethyl, triisopropyl, and tetraisopropyl led to a large selection of compounds, whose structural features are largely driven by steric considerations. Frequently, smaller substituents will result in oligomeric species in the solid state, as shown with the polymeric $(Me_5Cp)_2Ca$ (Figure 2),[56] while bulkier groups on the ring, despite increasing metal radii, will support the formation of monomeric species, as shown in Figure 3.[57]

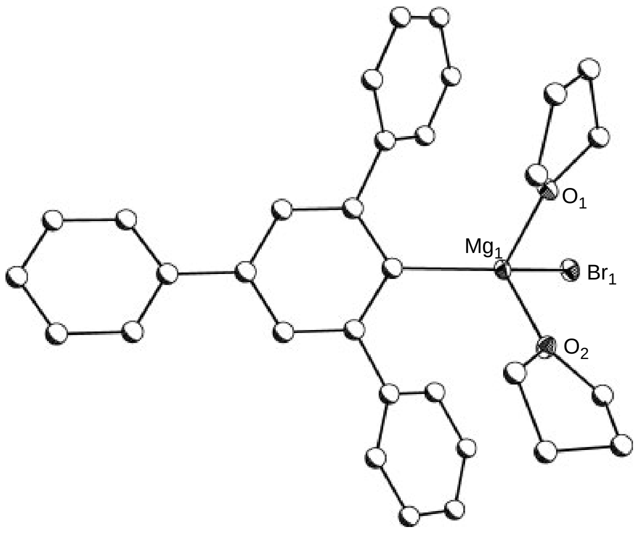

Figure 1 The structure of 2,4,6$Ph_3C_6H_2MgBr(THF)_2$. Hydrogen atoms have been omitted for clarity

Altering the substituents on the Cp rings also has radical effects on a variety of physical properties, including solid-state geometries, solubility, stability to hydrolysis, oxidation, and ligand extrusion, and others.

Cyclopentadienide derivatives appear both as simple complexes, reminiscent of ferrocene, or as heteroleptic systems. Because of the primarily electrostatic bonding models attributed to alkaline earth organometallics, the range of geometries available even for simple homoleptic alkaline earth metallocenes Cp_2M (M = Be–Ba) is surprising.

Beryllocene, Cp_2Be, prepared in 1956 by E. O. Fischer, was intensively examined to determine its structural features. This work quickly abandoned a structural model based on ferrocene, and different bonding modes for the two Cp rings were demonstrated by Cp_2Be's high dipole moment in solution. The slipped sandwich (η^5/η^1) structure, with beryllium disordered between the two nonequivalent Cp rings was confirmed by electron diffraction and crystallographic studies.[58–60] Coinciding with the disordered solid-state

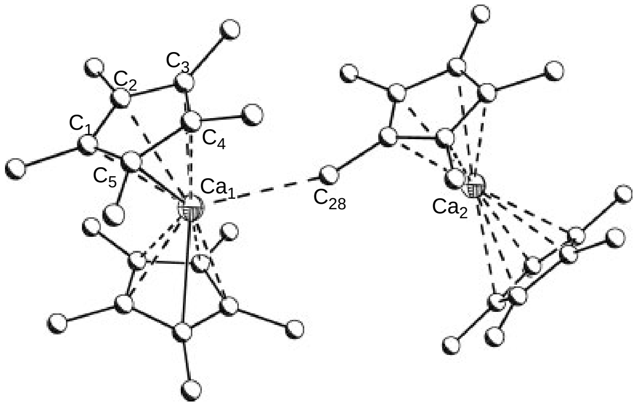

Figure 2 The structure of $[(Me_5Cp)_2Ca)]_n$. Hydrogen atoms have been omitted for clarity

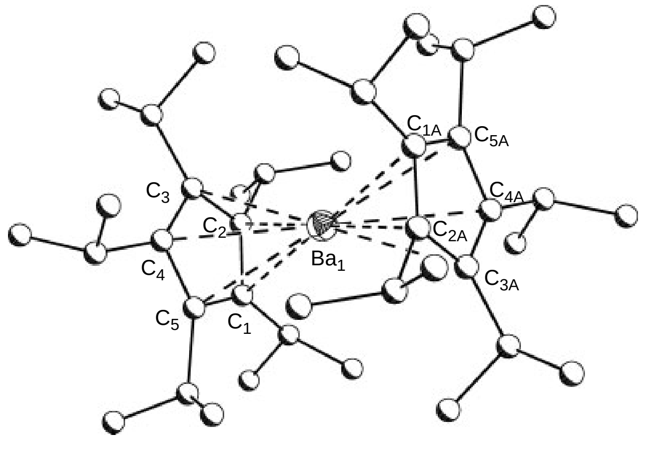

Figure 3 The structure of $[(iPr_5)Cp]_2Ba$. Hydrogen atoms have been omitted for clarity

structure, beryllocene is highly fluctional in solution, with only one set of resonances in both ^{1}H and ^{13}C NMR studies down to $-135\,°C$.[61,62] The fluctional nature of beryllocene may be explained by the small radius of beryllium. The optimal Cp–Be distance is shorter than half the Van der Waals distance between two Cp rings. More details on beryllocene can be found in a comprehensive review on organoberyllium chemistry.[63]

The larger size of magnesium allows a more symmetrical structure of magnesocene, Cp_2Mg. X-ray diffraction studies show the two Cp rings to be antiprismatic with Mg–C distances of 2.304(8) Å.[64] Electron diffraction data indicate an ecliptic orientation of the rings in the gas phase (D_{5h} symmetry) with slightly elongated Mg–C distances of 2.339(4) Å. However, a model with staggered rings (D_{5d}) cannot be ruled out. The permethylated analog displays quite similar structural features.[65,66]

The chemistry of the cyclopentadienide derivatives of the heavier alkaline earth metal derivatives has been summarized in several excellent review articles.[2,3,55,67] The structural features of the heavier cyclopentadienide derivatives are characterized by an increasing trend towards bent geometry upon descending the group−observed both in the gas phase (electron diffraction studies) and the solid state (X-ray diffraction).[68–72] While permethylated magnesocene exhibits a linear structure, the Me_5Cp-Ae-Me_5Cp (centroid) angle deceases to 131° (solid state) and 148° (gas phase) for the analogous barium compound.[73] This trend follows structural pattern also reported for the halides, with the strongest deviation from linear geometry for the corresponding fluorides.[74] With an increasing degree of ionicity in the metal−ligand bond upon descending the group, the exact degree of covalent contribution towards the metal-carbon bond is still the topic of some debate. Several theories have been developed to rationalize the deviation from linear (VSEPR) geometry, with extensive MO calculations showing that the energy needed to obtain a bent structure are small (4−12 kJ mol^{-1}). The bent geometry within the heavier metallocenes is so typical of this group of compounds that examples in which the system does *not* display such behavior in the solid state are particularly noteworthy, such as in $[(i\text{Pr}_5)\text{Cp}]_2\text{Ba}$, shown in Figure 3.

The library of substituted cyclopentadienide systems expanded rapidly, most notably by Hanusa *et al.*, and Sitzmann *et al.*[2,3,55,57,67] This work also demonstrated that various base adducts of these complexes could be obtained, resulting in the preparation of compounds with various donors to examine structural changes and concomitant variation in physical properties. In this context, the homoleptic metallocenes were treated with a host of Lewis bases including phosphines,[56] isonitriles, pyrazines,[75] carbonyl[76] and even unsaturated carbon systems such as in $(Me_5Cp)_2(Me_3SiCC{\equiv}CCSiMe_3)Ca$, through weak π-interactions with the alkynyl moieties[77] (Figure 4).

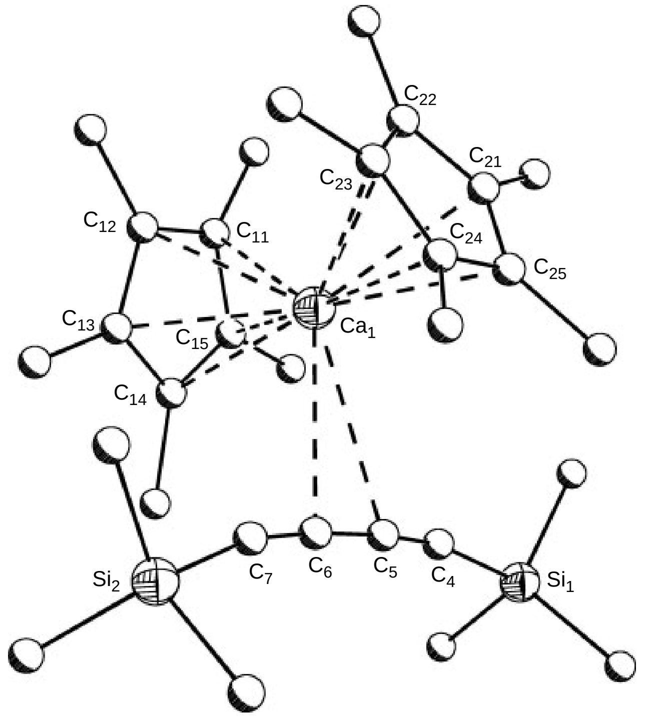

Figure 4 The solid-state structure of $(Me_5Cp)_2(Me_3SiCC\text{-}CCSiMe_3)Ca$. Hydrogen atoms have been omitted for clarity

An interesting class of compounds of this type are the alkaline earth metal carbenes in which the metal center is ligated by two Me_5Cp rings in addition to carbene (1,3,4,5-$Me_4C_3N_2$).[78] Several of these compounds have been isolated and characterized, with both mono- and di-adducts known in the solid state. These compounds all display similar bent geometries as defined by the centroids of the rings through the metal, and the smaller magnesium congener displays a ‘slipped’ $\eta^5-\eta^3$ coordination with the rings as a result of steric strain by the bulky carbene. The strontium analog is as shown in Figure 5. The strongly donating carbene can displace a wide variety of other donor adducts, even THF, which is often difficult to remove for the smaller metals even under harsh conditions. Interestingly, the variation of Lewis donors in the metallocenes has little influence on the overall bent geometries of these compounds.

An interesting variant of metallocenes is the tripledecker $\{(i\text{Pr})_4\text{Cp}\}\text{cotBa}_2$ (cot = cyclooctatetraene), shown in Figure 6.[79] This centrosymmetrical compound displays a π-coordinated central cyclooctatetraene to two barium atoms, which complete their coordination sphere by two tetraisopropyl-substituted cyclopentadienides.

Related metallocenes utilizing indenyl and fluorenyl ligands have been described. The bis-indenyl and bis-(di-isopropyl)indenyl systems can be easily prepared by metathesis from the potassium indenide and the heavier alkaline earth metal iodides.[80] The resulting compounds adopt the familiar bent geometries despite the large steric bulk of the ligands,

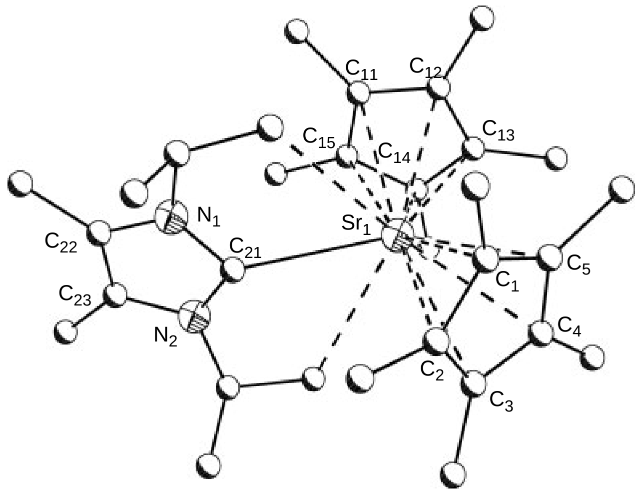

Figure 5 The solid-state structure of $(C_5Me_5)_2Sr(N,N\,^iPr_2 3,4\text{-}Me_2\text{-}C_3N_2)_2$. Hydrogen atoms have been omitted for clarity

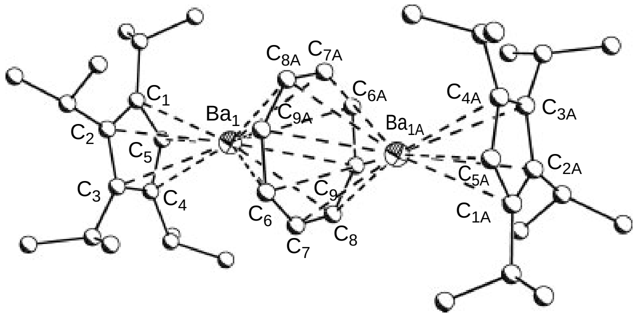

Figure 6 The solid-state structure of $\{(i\text{Pr})_4\text{Cp}\}\text{cotBa}_2$. Hydrogen atoms have been omitted for clarity

although there is variation in the solid state with the calcium and barium structures being monomeric while the strontium congener is a coordination polymer, as shown in Figure 7.

The bent structural motif observed in the cyclopentadienides and the indenides is continued even if the sterically more demanding fluorenyl ligand is coordinated to the metal center, as seen in bis(fluorenyl)barium$(NH_3)_4$, shown in Figure 8.[81] Even though the ligands are large enough to prevent oligomerization, the metal coordination sphere is saturated by the small ammonia donors. The steric bulk of the ligand does not appear to affect the molecular geometry with the compound displaying a centroid–Ba–centroid angle of ca. 115°, considerably deviating from a VSEPR prediction of linearity.

A selection of *ansa*-metallocene derivatives in which two dimethylsilyl or ethyl-bridged Cp, indenyl or fluorenyl moieties encapsulate the alkaline earth metal center have been prepared (see Figure 9).[82,83] The structurally enforced narrow bite angle of these fused ligands correlates well with the bent metallocene geometries observed previously. *Ansa* derivatives may be prepared as chiral compounds, and as such open up possibilities for their application as catalysts or reagents for stereocontrolled organic synthesis.[82] The *ansa* derivatives of the heavier metals exhibit a slightly slipped coordination between the metal center and the ligand, with both of these favoring η^3 or η^5 coordination and the inclusion of higher numbers of donor solvent molecules (three for calcium, four for barium) as opposed to the more centrally mounted magnesium compounds.

3.3 Alkaline Earth Metal Organometallics Exhibiting Metal–Ligand π-Bonding

Several groups of heavy alkaline earth metal derivatives, exhibiting metal–ligand π-bonding, in addition to the metallocenes have been studied resulting in allyl and alkenyl derivatives in addition to 'open metallocenes'.[53,84] The *bis*-allyl calcium complex $(C_3(SiMe_3)_2H_3)_2Ca(THF)_2$, shown in Figure 10, displays a symmetrical orientation of the metal over the π-system.[85] In contrast, magnesium allyl derivatives

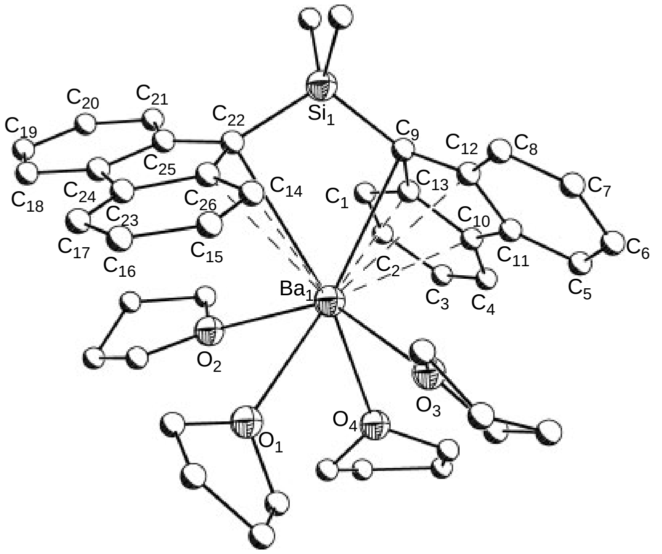

Figure 9 The solid-state structure of $Me_2Si(fluorenyl)_2Ba(THF)_4$. Hydrogen atoms have been omitted for clarity

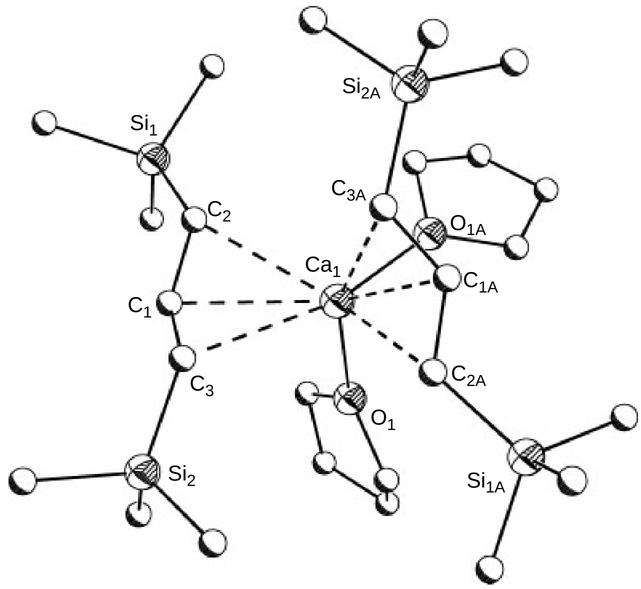

Figure 10 The solid-state structure of $(C_3(SiMe_3)_2H_3)_2Ca(THF)_2$. Hydrogen atoms have been omitted for clarity

feature a σ-bond to the allyl group. The different metal–ligand bonding modes have been put to use by Yamamoto *et al.* with allylbarium reagents to overcome the synthetic obstacles inhibiting comparable organomagnesium compounds.[4–9]

Variation of extension of the π-system and substitution thereof allowed for characterization of several magnesium, calcium, strontium, and barium species. Trimethylsilyl substitution on the alkenyl chain led to the formation of a magnesium TMEDA adduct,[86] while the terminal phenylation of the alkenyl system leads to the formation of monomeric compounds of calcium and strontium with solvation by THF filling the coordination sphere.[87] Similar compounds have been prepared with phosphorus ylids, leading to the characterization of several barium organometallic species bearing phosphorus supported ligands.[88,89] Further substitution can lead to metal-carbon interactions, such as in the coordination of barium to a highly conjugated system bearing a phosphacyclopentadienyl moiety, and a coupled diphenylbutadiyne system to give an intriguing complex, shown in Figure 11.[90]

Further documenting the breadth of metal–ligand π-interactions is an 'open' calcocene derived from an acylic pentadienyl ligand.[84] With the addition of trimethylsilyl

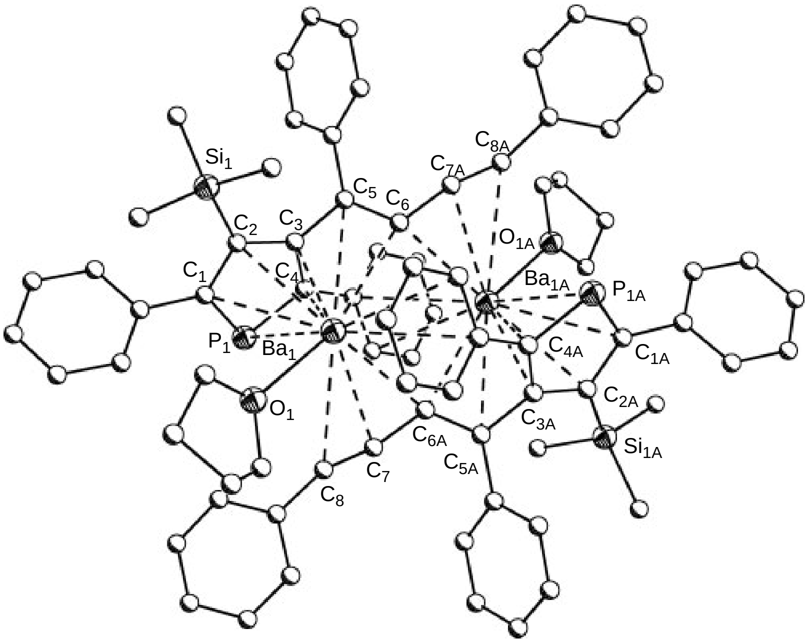

Figure 11 The solid-state structure of [(2,5-diphenyl-3-(1,4-diphenylbutene-3-yne-2-ide-1-yl)-4-TMS-1-phosphacylopentadienide)Ba (THF)]$_2$. Hydrogen atoms have been omitted for clarity

moieties to stabilize the system and assist with solubility, this ligand is of particular interest because of the variety of possible binding modes available. In the solid-state complex, as a single THF solvate, the system displays the ligands in an *anti* orientation with the TMS substituents pointing away from each other. Both π systems display η^5 coordination, and the complex shows the familiar bent geometry so commonly observed in alkaline metal organometallics.

Derived from the reaction of anthracene with the alkaline earth metals in a donor solvent, and of particular interest owing to its utility as a source for highly pure metal, the anthracenide derivatives have received some attention. (Anthracenide)Mg(THF)$_3$, shown in Figure 12, was initially reported in 1967,[91] its structural characterization followed in 1988.[36] The compound is known for its easy reaction with hydrogen in the presence of transition metal catalysts.[40] The resulting MgH_2 can be added to 1-alkenes. Owing to the low solubility of the anthracenides, substitution of the aromatic ring increases solubility to afford a selection of structurally characterized species.[36] In all cases, the metal is bridging the two central carbon atoms. The coordination environment at the metal is completed by three THF donors. Thus far, no structural information is available on the heavier congeners, likely owing to the low solubility of the complexes and associated problems with the growth of suitable single crystals.

A variant of these compounds, magnesium anthracenylmagnesiumbromide etherate, shown in Figure 13, displays a dimeric structure with a somewhat surprising metal–ligand

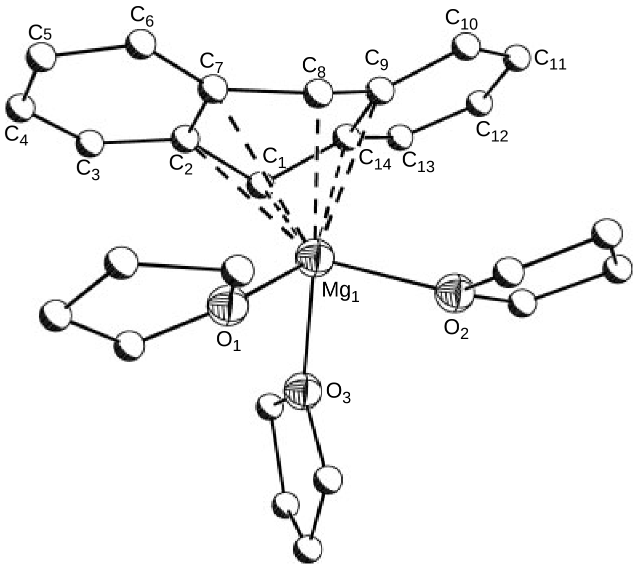

Figure 12 The solid-state structure of (anthracenide)Mg(THF)$_3$. Hydrogen atoms have been omitted for clarity

σ-interaction.[92] The two magnesium centers do not bind to the central anthracenide ring, rather, a η^1 metal–ligand bond with bridging bromides is completing the magnesium coordination sphere. It is anticipated that the greater need for steric saturation for the heavier metals, together with increased ionic bond character would necessitate an extended coordination sphere, achieved either by additional solvation or aggregation.

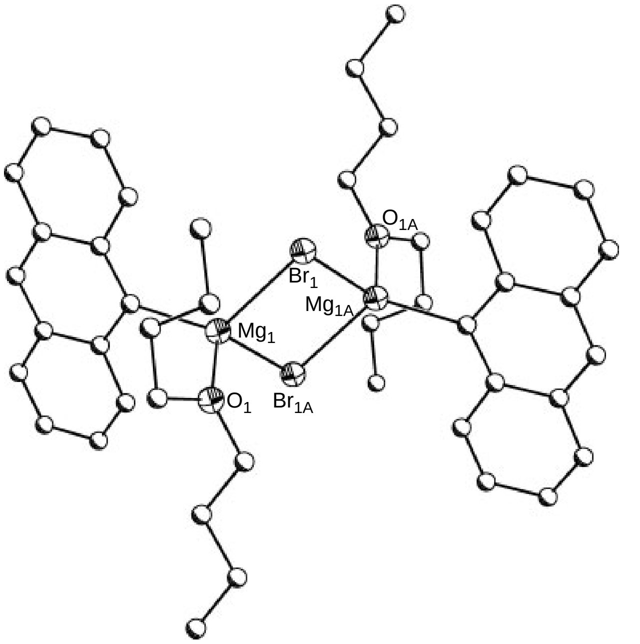

Figure 13 The solid-state structure of (magnesium anthracenyl-magnesiumbromide etherate. Hydrogen atoms have been omitted for clarity

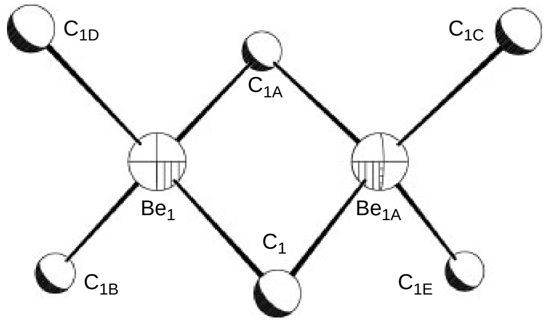

Figure 14 The solid-state structure of $(Me_2Be)_n$. Hydrogen atoms have been omitted for clarity

Even in the presence of bulky ligands, the addition of Lewis bases affords base adducts, as observed for the three coordinate $(2,4,6\text{-}Me_3C_6H_2)_2BeOEt_2$.[96] Heteroleptic beryllium species display the same trend, with a coordination number of two if Lewis bases are absent and the ligands are large, as seen in the terphenyl derivative $2,6\text{-}(2,4,6\text{-}Me_3C_6H_2)_2C_6H_3BeN(SiMe_3)_2$, shown in Figure 15.[97] However, not even extremely bulky ligands such as terphenyl can prevent the addition of donor molecules.

3.4 σ-Bonded Organometallic Systems

A range of σ-bonded organometallic complexes of beryllium and magnesium has been reported, and we will briefly discuss some central structural trends observed within this group of compounds. Owing to the wealth of information, especially in regards to organomagnesium chemistry, we refer to several excellent review articles.[67,93,94] In contrast to the steady progress on metallocenes and π-stabilized compounds for the heavier metals, σ-bonded calcium, strontium, and barium organometallics were languishing in obscurity while simple alkyl derivatives for the larger metals eluded characterization. Partially as a result of the extremely high reactivity, low solubility, and difficulties in characterization posed by these compounds, and partially because of the perceived lack of application as compared to organomagnesium chemistry, it was not until 1991 that the first structurally characterized compounds of this type became available.

By far the largest group of compounds of this type has been reported for magnesium, while the high toxicity of beryllium and its compounds dampened interest. Dimethylberyllium, shown in Figure 14, is a polymeric species, exhibiting four-coordinate beryllium centers through 2e3c-CH_3 bridges.[95] In the gas phase, the compound exhibits monomeric Me_2Be molecules with linear geometry, as analyzed by electron diffraction.[47] An increase in ligand size reduces aggregation tendencies, as demonstrated with $(t\text{Bu})_2Be$, which exhibits a monomeric structure in the solid state.

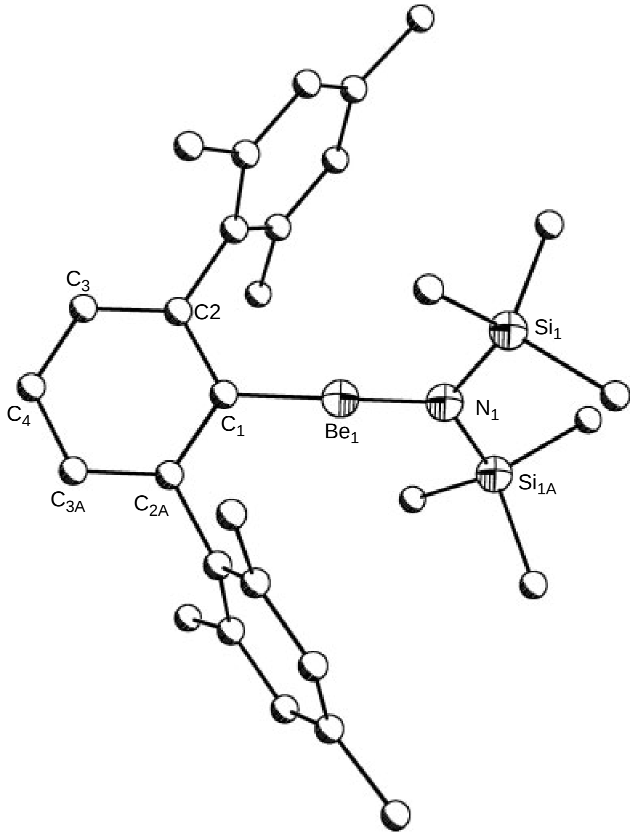

Figure 15 The solid-state structure of $2,6\text{-}(2,4,6\text{-}Me_3C_6H_2)_2C_6H_3BeN(SiMe_3)_2$. Hydrogen atoms have been omitted for clarity

Similar trends are seen for the magnesium species, and the use of bulky ligands in the absence of Lewis bases allows the preparation of rare two-coordinate alkyl magnesium species. Examples include the linear $(Me_3Si)_3C)_2$ Mg.[98] Interestingly, utilization of the bulky Mes* (Mes* = 2,4,6-tBu$_3$C$_6$H$_2$) ligand also affords a two-coordinate compound (2,4,6-tBu$_3$C$_6$H$_2$)$_2$ Mg, but with a bent structure, shown in Figure 16.[99] The bent metal geometry might be explained on the basis of agostic interactions originating from the *ortho tert*-butyl groups at the ligand. These interactions are also likely responsible for the lack of donor coordination, even in the presence of THF. The reduction of ligand size affords complexes with a coordination number of four or higher.

The clean isolation and structural characterization of heteroleptic Grignard species remains problematic, owing to complex solution equilibria. Still, a number of compounds have been analyzed in an effort to further understand aspects contributing towards the formation and composition of these important reagents. In all cases, donor-containing compounds were obtained, with the coordination environment of the metal strongly dependent on ligand and donor size and the nature of the halide. Generally, the presence of sterically demanding ligands facilitates the isolation of the heteroleptic species. The bulky ligands also support the isolation of species with a low metal coordination number as demonstrated with the dimeric, four-coordinate [(2,6-(2,4,6-Me$_3$C$_6$H$_2$)$_2$C$_6$H$_3$)MgBr(THF)]$_2$,[100] (Figure 17) or the four coordinate, monomeric (2,4,6-Ph$_3$C$_6$H$_2$)MgBr(thf)$_2$, (Figure 1), (2,6-(2,4,6-iPr$_3$C$_6$H$_2$)$_2$C$_6$H$_3$)MgBr(THF)$_2$[101] and PhMgBr(OEt$_2$)$_2$.[102] In the presence of smaller ligands and donors the metal coordination number increases, as demonstrated with the five-coordinate MeMgBr(THF)$_3$.[103] While intense efforts have led to a much-improved understanding of the Schlenk equilibrium and the reagents involved, numerous questions regarding mechanistic rationales and structure-function relationships keep the field active.

Simple alkyl complexes for the heavier congeners, calcium, strontium, and barium remain scarce. Even as information on Grignard reagents became more widely available owing to improved synthetic and spectroscopic techniques (particularly in the field of X-ray crystallography) progress with the larger metals lagged behind. Although several reports of preparation of such compounds were disseminated, little detailed information was provided. As of now, only a few simple alkyl complexes of the heavier alkaline earth metals have been isolated and well characterized, perhaps as the result of the higher demand for electronic and coordinative stabilization required for such compounds as compared to

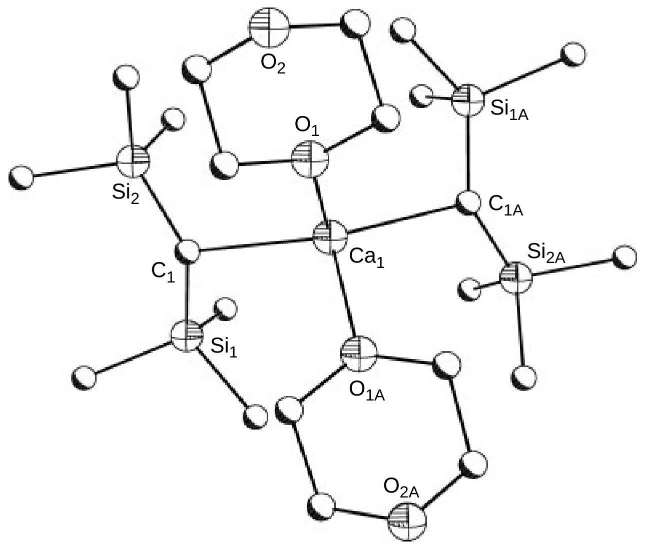

Figure 18 The solid-state structure of (CH(SiMe$_3$)$_2$)$_2$Ca(dioxane)$_2$. Hydrogen atoms have been omitted for clarity

magnesium and beryllium. In addition, the (relatively) more ionic metal-carbon bonds render the metal–ligand bonds more labile without high degrees of stabilization by other donors or solvent molecules contributing to the structure.

Beginning in 1991, the first structurally characterized σ-bound heavy alkaline earth organometallic appeared with the four-coordinate $(CH(SiMe_3)_2)_2Ca(dioxane)_2$ (Figure 18).[104] Although the synthetic pathway was highly technical (cocondensation of calcium vapor and the bromoalkyl at 77 K) the final product could be isolated and structurally characterized. Further progress did not come until 1997 with the two-coordinate $((SiMe_3)_3C)_2Ca$, a σ-bonded 'unstabilized' (i.e. lacking other metal-donor interactions beyond the organometallic bond) organometallic (Figure 19), which remains the only example of such a compound. Interestingly, bent metal geometry is observed in this compound, whose origin may be explained on the basis of agostic interactions rather than trends observed for the halides or cyclopentadienide derivatives.[43]

With σ-bonded organometallic compounds of the heavy alkaline earth metals still limited to calcium, the expansion of the library of such compounds to the heavier metals was achieved with a family of crown ether stabilized alkaline earth metal acetylides $M(CCSiPh_3)_2$(18-crown-6) (M = Ca, Sr, Ba) (Figure 20).[105] The compounds presented important information for the comparison of reactivity and structural trends for the heavy alkaline earth metals. Interestingly, the acetylides display increased bending at the metal center as descending the group, and also increased bending at the ipso-carbon atom within the acetylide ligand. Carbon-metal-carbon angles within the barium compound display values as low as 163° for the L-M-L moiety, with angles at the ipso-carbon atom as narrow as 127 and 141° for the sp hybridized ligand atoms. In contrast, acetylides of magnesium and beryllium display linear geometry at the ipso ligand atom. The deviation from ideal geometry can largely be explained by the low directionality of the sp-hybrid orbital and associated facile distortion from ideal geometry. Interestingly, though, a closely related group of acetylides, M(18-crown-6)(CC4-tBuC$_6$H$_4$)$_2$ displays an almost identical deviation from linear geometry with angles at the ipso atom as low as 126°.[106]

While the acetylides took advantage of the coordinative and electrostatic stabilization afforded by the crown ethers, other means of stabilizing σ-bonded organometallics involve the use of intramolecularly coordinated ligands, as elegantly applied in the preparation of the simple alkyl complexes $((Me_3Si)_2(MeOMe_2Si)C)_2M$(donor) (M = Sr (donor = THF); Ba (donor = DME ($MeOCH_2CH_2OMe$); Figure 21).[107]

3.5 Substituted Phenylmethanides and π-stabilized Alkaline Earth Organometallics

Early work on the dibenzyl derivatives of the heavier alkaline earth metal triad suggested that they could be

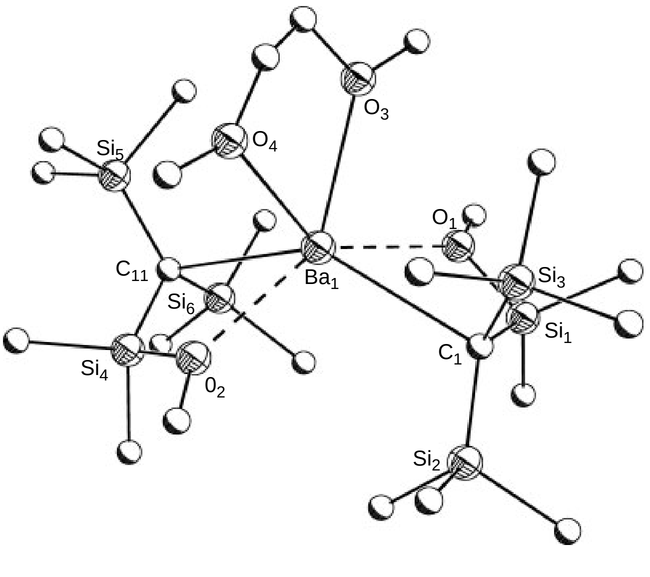

Figure 21 The solid-state structure of $((Me_3Si)_2(MeOMe_2Si)C)_2Ba$(DME). Hydrogen atoms have been omitted for clarity

valuable reagents to be employed in various polymerization applications.[108,109] However, this work was limited to in situ examinations and NMR studies, and the inability to determine the exact nature of the reagents hampered further progress in this field. It was not until Harder *et al*. developed a facile method for the preparation of pure calcium and barium dibenzyl derivatives including in-depth structural characterization and structure/function studies, that the role of dibenzyl derivatives in polymerization chemistry could began in earnest.[10]

Relying on a transmetallation scheme for the preparation of dibenzylbarium, the common problem of separating the two solid reaction products (see above) was addressed by careful choice of reaction condition.[10] Nevertheless, it remained difficult to isolate the strontium derivative, and further manipulation of the solvent system was needed to allow the isolation of the pure compound.[45] The separation problem was exacerbated for calcium, requiring the use of salt elimination for its preparation.[42]

Shortly after Harder's report of isolable dibenzylbarium, various other related compounds appeared in the literature. Continuing with the approach of tuning solubility, both through substituent effects as well as solvent choice, it was discovered that substitution of toluene with trimethylsilyl substituents allowed for the isolation and characterization of crystalline complexes of *bis*-(α,α-*bis*(trimethylsilyl)benzyl) potassium and calcium.[110] Similar to the proposed structure of dibenzylbarium, the calcium compound was a THF solvate, although the potassium congener (used as a precursor *via* metathesis) was a linear polymer without additional Lewis donor coordination. This compound also displayed interesting deformations in the phenyl rings as a result of metal coordination, which occurred in an η^3 fashion (Figure 22).

While $SiMe_3$ coordination significantly improved the solubility of the complexes, the increased steric demand

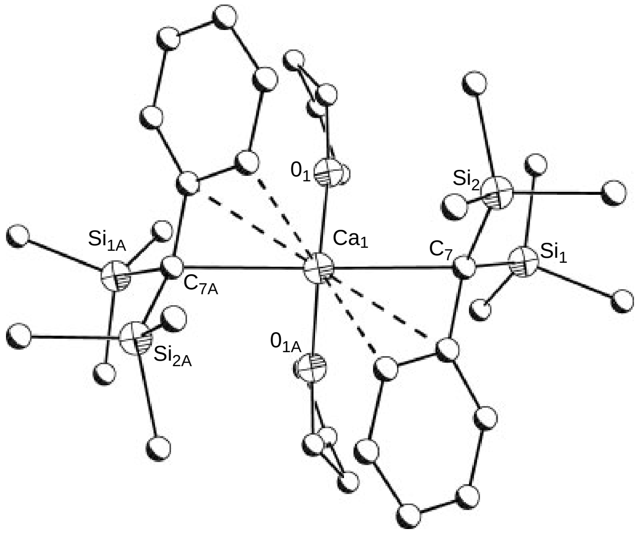

Figure 22 The solid-state structure of $Ca[(SiMe_3)_2CC_6H_5)]_2[THF]_2$. Hydrogen atoms have been omitted for clarity

of the ligand significantly reduced the compound's activity towards styrene polymerization. Continuous work focused on the introduction of alternative substituents, and their introduction in other but the α-positions. As a result of this work, benzyl complexes of calcium have been prepared using the combination of a single $SiMe_3$ substituent on the α-carbon in addition to an *ortho*-dimethylamino moiety (Figure 23).[111] Prepared through metathesis with the corresponding potassium salt, this compound afforded highly pure compounds with a high tendency for crystal formation. Unlike the *bis*-$SiMe_3$ substituted complex, where significant metal-arene interactions are observed, the dimethylamino derivative displays no such interaction, likely owing to the intramolecular stabilization of the ligand.

This compound demonstrates two diastereomers in slow exchange as viewed through NMR studies in benzene, although only one set of THF signals is observed. A dissociative mechanism of exchange between disastereomers has been proposed. Unlike the *bis*-Me_3Si-substituted compound, this complex does act as a polymerization initiator, giving predominantly atactic product. The only other example of a heavier alkaline earth metal dibenzyl system is the strontium analog of the calcium dimethylamino stabilized system. This compound is a more effective initiator than the analogous calcium system, likely owing to the more exposed metal center.[112]

The steric bulk of the substituted benzyl ligands allows the preparation of heteroleptic species, examples include the combination of the dimethylamino stabilized dibenzyl reagent and 9-Me_3Si substituted fluorene, as shown in Figure 24.[113] Despite the presence of sterically demanding ligands and intramolecular coordination, this complex still displays additional Lewis base donation, although the steric demand of the fluorene ligand only permits a single THF to

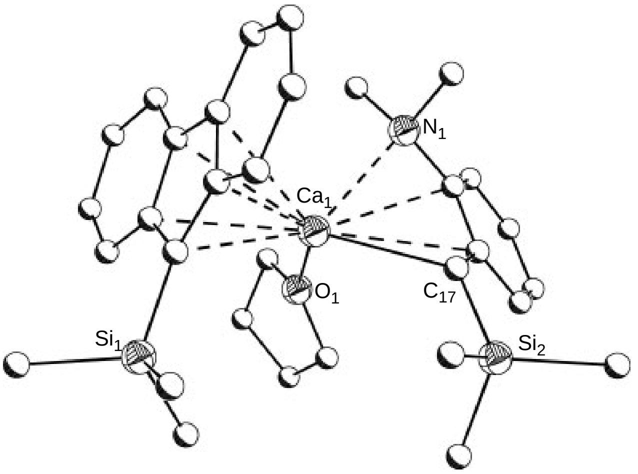

Figure 24 The solid-state structure of [9-SiMe$_3$-fluorene][*o*-NMe$_2$-(TMS)CHC$_6$H$_4$]Ca. Hydrogen atoms have been omitted for clarity

approach the metal center. The metal sits squarely over the center of the larger π-center while maintaining a single metal-carbon bond to the benzyl carbon as well as an interaction with the dimethylamino moiety. This compound is also an active polymerization initiator, although product control is difficult owing to the inability of the calcium compound to maintain stereochemical integrity during the reaction. However, under certain conditions, the inversion of the compound can be circumvented to produce polymers with high syndiotacticity.

Introduction of secondary stabilization in the form of –NMe$_2$ functionalities, and removal of the SiMe$_3$ moiety allows the formation of heteroleptic complexes. Unlike the larger Me$_3$Si substituted ligand, the steric requirements of the metal are fulfilled by dimerization. Examples include products involving the dibenzyl ligand in addition to ligation to 9-Me$_3$Si fluorene or Me$_4$EtCp, as shown in Figure 25.[114]

As these studies seemed to indicate that substitution on the benzylic carbon tends to slow activity as a polymerization initiator, attempts were made to isolate simpler compounds with as little crowding near the metal center as possible. This was realized with the preparation of *para*-substituted homoleptic dibenzyl complexes of calcium, as well as the isolation of the elusive unsubstituted dibenzylcalcium derivative by salt elimination.[42] Preparation of the *para*-*t*Bu compound was possible through metathesis of the potassium salt, and led to a six-coordinate tetra-THF solvate. Interestingly, this complex displays η^1 coordination product in the solid state, with the benzyl ligands taking axial positions over four equatorially located THF molecules, shown in Figure 26. This geometry is altered in the unsubstituted dibenzylcalcium compound Figure 26 with the ligands adopting a cis orientation with four THF donors completing the coordination sphere. The somewhat surprising differentiation in coordination geometry is ascribed to the charge localizing effect of the *para* substituent that removes some of the electronic imperative to adopt a trans geometry in the solid state. The dibenzyl compounds appear to be promising metallation reagents for a variety of less acidic compounds, and in fact have been applied in such a manner.

Replacement of one α-carbon atom in the benzyl ligand by a phenyl group affords diphenylmethane, with a second replacement giving triphenylmethane, several compounds of which have been isolated in conjunction with the heavy alkaline earth metals by utilizing the dibenzyl reagents as alkaline earth metal source materials. The di- and triphenylmethanides are easily available owing to the increased acidity of the parent hydrocarbons, as compared to toluene. In the presence of a stabilizing crown ether, a rare example of a compound exhibiting barium-ligand σ-bonding, (HCPh$_2$)$_2$Ba(18-crown-6), shown in Figure 27, is obtained.[44]

This compound displays a slightly pyramidal geometry at the α-carbons, and the phenyl rings are not coplanar, which is typical for sterically congested multiphenyl-substituted ligands of this type. The increased steric demand of the ligand together with the electronic and coordinative stabilization provided by the crown ether enable increased stability as compared to the dibenzyl derivative. Remarkably, crown ether-stabilized barium diphenylmethanide is sufficiently stable to allow for recrystallization from hot THF, whereas dibenzylbarium reacts readily with THF at temperature above −40 °C.

Although these compounds have considerable synthetic difficulties surrounding their preparation and characterization, the interesting questions of metal-carbon bonding and potential application in polymer synthesis ensure further research efforts.

3.6 '-Ate' Complexes of the Alkaline Earth Metals

'Ate' complexes of the alkaline earth metals are most prominent for magnesium, and to a significantly lesser extent for the heavier metals. The compounds are often observed in the presence of encapsulating donors such as crown ethers or cryptates; a representative example is shown in Figure 28.[115]

The number of 'ate' complexes for the heavier congeners is smaller, owing to the significantly reduced metal charge density. As such, the polymeric barate $[Bu_4P]$ $[Cp_3Ba]$, shown in Figure 29, represents a significant example of this class of compounds. The barate was prepared through the combination of Cp_2Ba, $Bu_3P{=}CH(CH_2)_2CH_3$ and CpH employing the Wittig reagent to generate the cyclopentadienide anion while avoiding undesirable side products.[116] The anions form infinite chains further stabilized by agostic interactions to the phosphonium units.

Not unexpectedly, the Cp–Ba bond lengths within the barate are considerably lengthened as compared to the simple Cp_2Ba systems, and the Cp rings exhibit rotational disorder. The η^4-metal coordination of the Cp rings is particularly interesting. With four such interactions, the metal coordination sphere seems to be sufficiently stabilized rendering further

donor solvent-metal interaction unnecessary. Representing an approximate tetrahedral geometry, the Cp–Ba–Cp angles range from 106.3−114.6°. Other results from this study seem to indicate that it may be possible to prepare the dianionic barate anion, $[Cp_4Ba]^{2-}$.

Led by the efforts of Westerhausen and coworkers, a variety of heavy alkaline earth metal zincates or aluminates under formation of alkaline earth metal-carbon contacts have been prepared. Examples include the reaction of trialkylalanes with donor-free calcium *bis*-amides to afford dimeric aluminates, shown in Figure 30.[117] Noteworthy is the planar Ca_2N_2 center of this complex, in addition to close calcium−aluminum contacts, which may indicate the presence of three-center, two-electron bonding.

Other examples of this series include a selection of 'ate' complexes prepared by the treatment of alkylzinc reagents with freshly distilled alkaline earth metals under extrusion of elemental zinc.[28] This route was employed to prepare a strontium zincate in which the alkaline earth metal center adopts a distorted octahedral geometry completed by two THF solvent donors.[28] Similar reactions with barium metal lead to structurally closely related compounds. Flexibility in solvent choice is noted by the preparation of related complexes in toluene, displaying metal-toluene π-interactions.

The compounds prepared by these reactions are highly susceptible to rearrangements in situ; reaction of barium bis[tris(trimethylsilylmethyl)zincate] with excess barium gives a unique barium cubane, shown in Figure 31.[118] Acting through a proposed alkylbarium intermediate, this compound is stabilized by agostic interactions surrounding the metal core. This complex displays carbon atoms in the relatively rare coordination number of six, with extended contacts to the zinc centers.

3.7 Charge-separated Alkaline Earth Organometallics

A category of organometallic alkaline earth complexes does not involve metal−ligand bonding. Such compounds, while common in aqueous solution for many cations, are much less prevalent for the alkaline earth organometallics. Nonetheless, under carefully controlled reaction conditions these highly reactive compounds may be synthesized, isolated, and characterized. In order to accomplish this feat, both the anion and the cation must be appropriately stabilized. A combination of two factors should be considered when attempting to induce

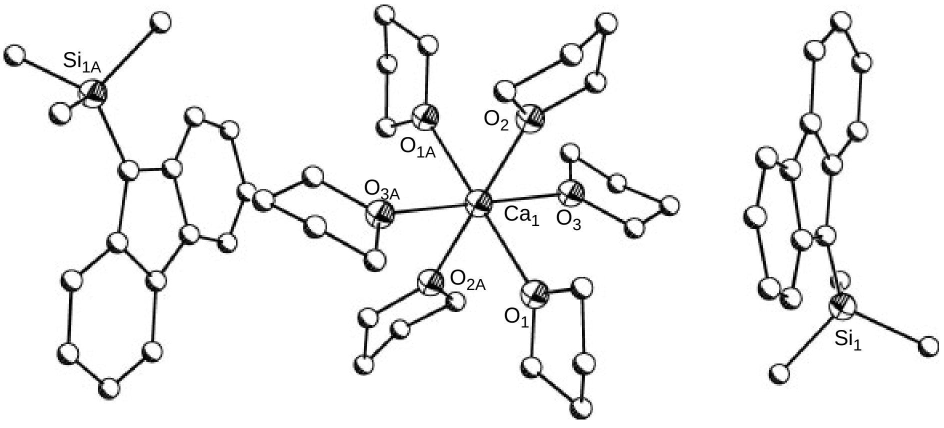

Figure 32 The solid-state structure of $[Ca(THF)_6][Me_3Si(fluorenyl)]_2$. Hydrogen atoms have been omitted for clarity

charge separation in these organometallics. The simplest route involves the application of donor solvents to saturate the cation as a solvent-separated ion pair (SSIP). The formation of separated ions is facilitated if the anion is capable to delocalize the negative charge, as seen in $[Ca(THF)_6]^{2+}$ $[Me_3Si(fluorenyl)]_2{}^{2-}$, shown in Figure 32.[119] The extensive resonance stabilization in the anion allows ion separation despite cation coordination to only six monodentate THF donors. Clearly, the highly oxophilic nature of the calcium cation leads to energetically favorable cation interactions that trump the stability offered by direct metal-carbon contacts. Indeed, this balance between metal-donor and metal-carbon favorability is the deciding factor in determining the final solid-state geometry of the complex. This can be predicted with considerable accuracy when taking into account the size and nature of the donors versus the anion as well as the degree of electronic stabilization offered by each of these. Especially for resonance-stabilized anions, it is generally possible to induce separation, although isolation of these highly reactive compounds can be a challenge.

It has been suggested that considerable stability for solvated alkaline earth cations in such systems is granted by the ‘metal-in-a-box’ model, in which the arrangement of anionic ligands surrounding the solvated cation provides considerable electronic stabilization *via* long-range π-interactions in the presence of benzene as a ‘lid’ for the box.[119] In such systems, considerable stabilization between the THF protons and the anionic π-systems can be envisioned (Figure 33).

An alternative example of the metal-in-a-box model is provided by the monocationic $[(Ph_4B)Ba(thf)_4][BPh_4]$, shown in Figure 34. Here, the metal coordination sphere is completed by π-arene interactions to a BPh_4 anion, which binds in a sandwich-type interaction to the metal. Secondary, nonclassical interactions between the monocation and the noncoordinated anion provide additional stabilization. Interestingly, analogous reaction conditions for the smaller metals calcium and strontium afford the dicationic species $[M(thf)_n][BPh_4]_2$ ($M = Ca$, $n = 6$; $M = Sr$, $n = 7$), that are

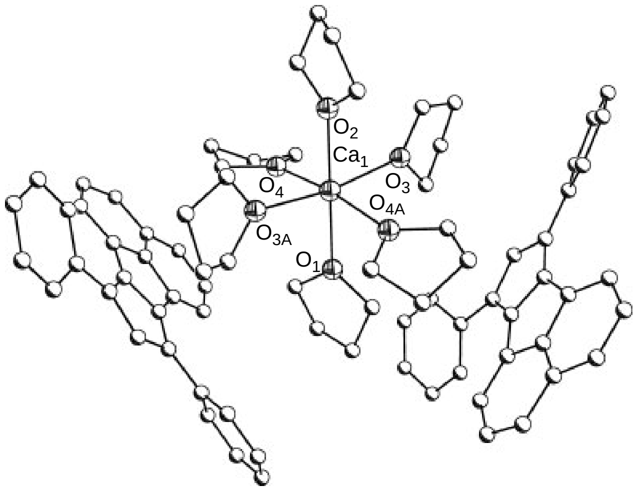

Figure 33 The solid-state structure of $[Ca(THF)_6]$[7,9-diphenyl-cyclopenta [*a*]acenapthadienide]$_2$. Hydrogen atoms have been omitted for clarity

also stabilized by the nonclassical interactions. Clearly, the large barium center cannot be sufficiently stabilized by THF solvation alone.[120]

An alternate, though related, approach to the formation of charge-separated ion pairs is to induce separation not through the solvent alone, but rather through application of appropriate donor systems and cosolvents (donor-assisted ion pairs – DAIP) to more effectively encapsulate the cation. This method has been employed most successfully for the larger congeners strontium and barium, whose coordination sphere is less easily filled by small donors such as THF. Most commonly employed for this technique are the versatile crown ethers, and the variety of cavity sizes allows for considerable flexibility in metal-donor bonding design. Also used successfully is the cosolvent hexamethylphosphoramide (HMPA), which is a powerful donor in its own right.

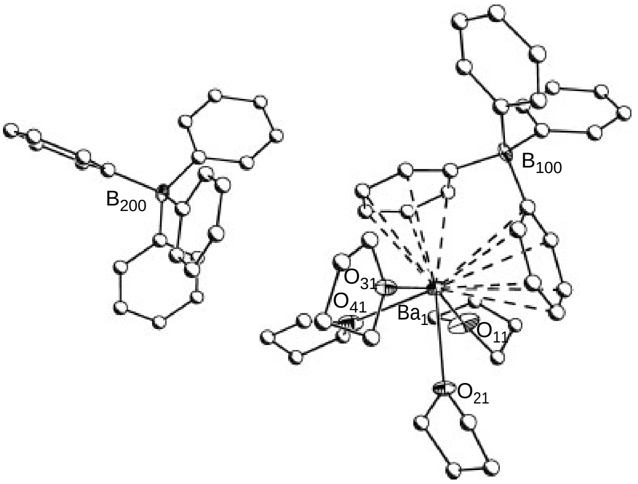

Figure 34 The solid-state structure of $[(Ph_4B)Ba(thf)_4][BPh_4]$. Hydrogen atoms have been omitted for clarity

As noted above, the ability of ligands with multiple phenyl rings positioned to allow resonance stabilization in an anion makes them ideal candidates for DAIP. Recent reports have demonstrated this with the presentation of a family of heavy alkaline earth triphenylmethanides, all of which occur as charge-separated complexes in the solid state.[45] Reaction of dibenzylbarium or strontium with triphenylmethane in the presence of 18-crown-6 and HMPA leads to the isolation of the DAIP triphenylmethanide, the barium compound of which is shown in Figure 35.

In the triphenylmethanides, the metal is coordinatively and electronically saturated by the encompassing crown ether that occupies an equatorial plane around the metal, as well as by the axially located HMPA donors. This favorable cation coordination environment is well established in alkaline earth metal chemistry. The ligands are free to adopt the most conformationally stable orientation, and steric demands force the rings away from planarity and in both the strontium and barium systems the rings display the familiar ‘propeller’ geometry, comparable to that seen for related alkali systems.

The calcium congener, while prepared through similar routes, eluded satisfactory structural determination until the application of pure, substituted benzylcalcium starting materials in the absence of additional donors.[42] While this compound crystallizes as a SSIP, the structural motifs are very similar to those of the DAIP systems, with the octahedrally coordinated calcium center surrounded by the anionic ligands.

The formation of separated ions for both cations, $[Ca(thf)_6]^{2+}$ and $[Ca(18\text{-crown-}6)(HMPA)_2]^{2+}$ points to the effective resonance stabilization in the triphenylmethanide anion. In addition, the high steric demands of the three phenyl rings discourages direct contact between the metal and either the central carbon of the ligand or the π-system of the phenyl rings. π-metal–ligand bonding is also disfavored owing to the effective cation-donor stabilization.

Similar chemistry for the diphenylmethanides demonstrates some interesting facets of the structural chemistry of separated ion pairs. Treatment of dibenzylbarium with diphenylmethane in the presence of 18-crown-6 does not lead to separated ion pairs, but somewhat surprisingly to the contact species $Ba(18\text{-crown-}6)(CHPh_2)_2$, shown in Figure 27.[44] In this compound, the combination of the strength of the metal-carbon bond as well as the decreased steric demands of the smaller diphenylmethanide ligand allow for a contact structure. Coordination with the metal also lends to a pyramidalization of the *ipso* carbons. In addition, the phenyl rings are tipped noticeably away from coplanarity, which is in contrast to similar alkali metal structures.[121] Attempts to induce DAIP through application of additional donors was initially unsuccessful in the presence of the crown ether, but a reaction system involving excess HMPA led to the isolation and partial characterization of a system in which the metal is coordinated by six HMPA molecules in an octahedral orientation with the anions completely separated from the metal center.[44]

Attempts to further pursue this chemistry were plagued with difficulties although significant progress was seen. Concentrations of reaction mixtures containing dibenzylstrontium, crown ether, and diphenylmethane led to dimeric ether

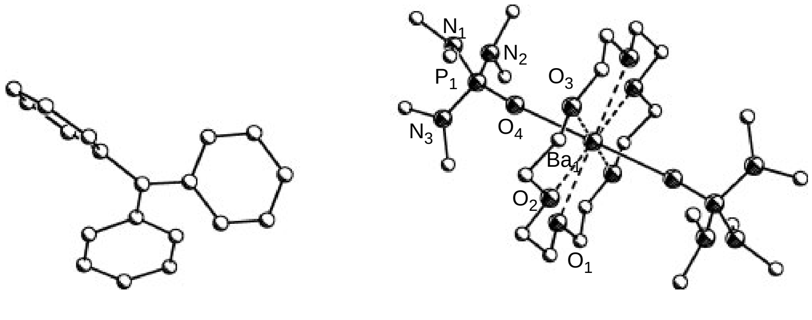

Figure 35 The solid-state structure of $[Ba(18\text{-crown-}6)(HMPA)_2][CPh_3]_2$. Only one of the symmetry equivalent $[CPh_3]^-$ anions is shown. Hydrogen atoms have been omitted for clarity

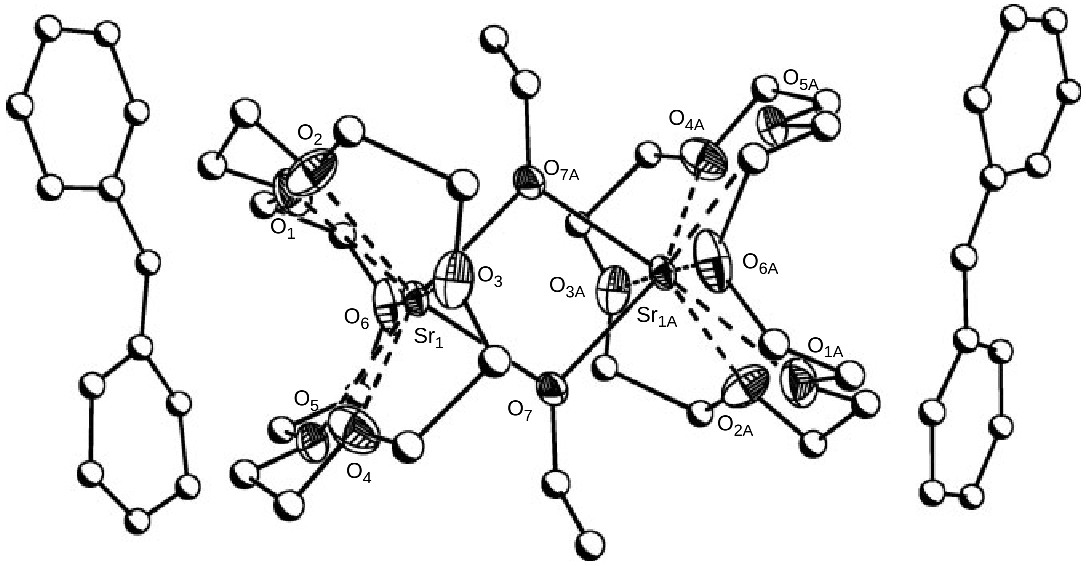

Figure 36 The solid-state structure of $Sr(18\text{-crown-}6)(HCPh_2)(OC_2H_4)]_2$. Hydrogen atoms have been omitted for clarity

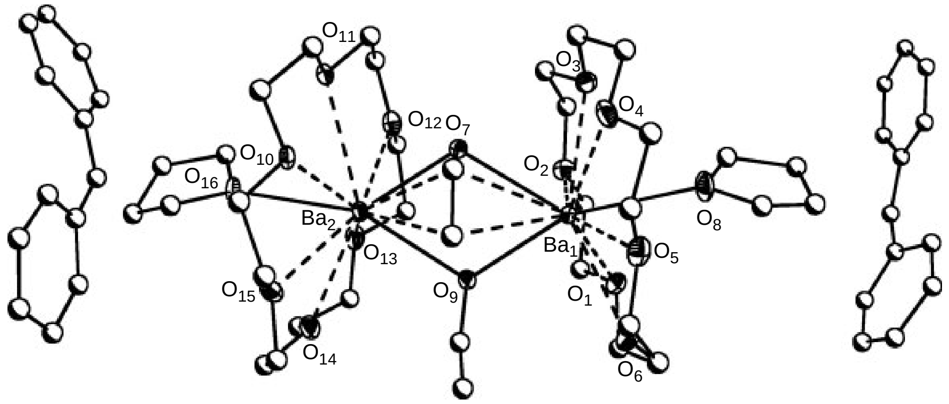

Figure 37 The solid-state structure of $[Ba(18\text{-crown-}6)(HCPh_2)(THF)(OC_2H_4)]_2$. Hydrogen atoms have been omitted for clarity

cleavage products in which each strontium center is coordinated by a crown ether and an enolate. Charge neutrality is ensured by a separated diphenylmethanide anion, as shown in Figure 36.

Here, the ligand adopts a planar geometry, while the crown ether is highly folded as the result of the approach of the two bridging enolates taking up a considerable portion of the metal coordination sphere.

Effects of metal size on the coordination environment are nicely demonstrated in the analogous barium compound, obtained in an effort to circumvent the ether cleavage problem using gentler synthetic methods developed for heavy alkali metals. In this method, barium alkoxides were combined with $SiMe_3$ substituted diphenylmethane. While the method did lead to desilylation in the desired location, upon concentration of the mother liquors of these compounds, ether cleavage products were observed as well, as shown in Figure 37.[44]

In this compound, the larger size of the barium cation allows for less steric congestion around the enolate bridges, leading to a dramatically less folded crown ether, permitting the coordination of an additional THF donor. Again, the $CHPh_2$ ligand is separated, adopting an almost identical geometry as in the strontium complex.

4 APPLICATIONS

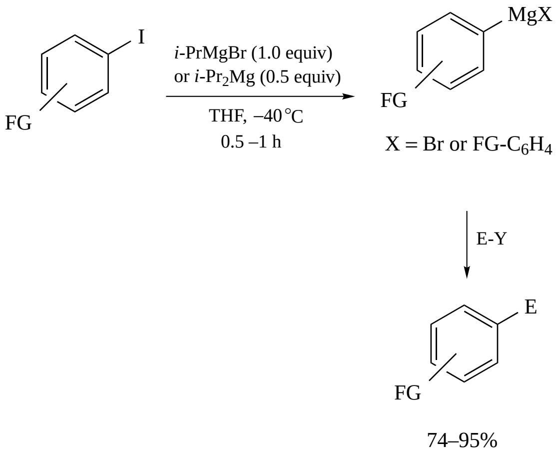
With applications for the heavy alkaline earth organometallics discussed throughout this article, we will here

specifically focus on some recent developments of Grignard reagents in synthetic chemistry.

The huge scope of the chemistry of Grignard reagents reflects the utility of these organometallic species in synthetic chemistry. Most prominently, Grignard reagents participate a) in nucleophilic substitution and addition reactions (uncatalyzed and catalyzed) with various organic functional groups, b) as strong bases by abstracting protons from even weakly acidic substrates, and c) in magnesium-halogen exchange reactions. In-depth accounts of the preparation and uses of organomagnesium reagents and mechanisms of their formation and reactions are found in the *Handbook of Grignard Reagents* (editors Silverman and Rakita, 1996),[122] *Grignard Reagents New Developments* (editor Richey, 2000),[123] and *Magnesium in Organic Synthesis* (Inoue and Oshima, a chapter in *Main Group Metals in Organic Synthesis*, editors Yamamoto and Oshima, 2004);[124] older literature on the reactions of Grignard reagents with nonmetallic substrates is summarized in the classic monograph by Kharasch and Reinmuth.[125] This account focuses on selected areas of Grignard chemistry in which significant progress has been reported since ca. 1997; references are included through part of 2004.

4.1 Halogen–Magnesium Exchange Reactions

Since Grignard's initial work in 1900 until very recently, organomagnesium compounds were prepared almost exclusively by reaction of carbon-halogen bonds with metallic magnesium, under conditions (e.g. in solvents such as Et_2O or THF) that forbade the presence of polar carbon-element multiple bonds (C=O, C=N, C=N, N=O, etc), strained polar carbon-element single bonds (epoxides, aziridines, etc) or even weakly acidic hydrogens (terminal alkynes) in the substrate.[49] By the 1970s, a few examples of formation of Grignard reagents (from Grignard reagents) via bromine- and iodine-magnesium exchange had appeared, enough to show that exchange was facilitated by electronegative structural elements in the organic halide.[126] However, none of the Grignards thus prepared contained any of the above-cited 'incompatible' functional groups. Then, seminal work by Cahiez and Knochel[127] showed that exchange with ^{i}Pr$_2$Mg or ^{i}PrMgBr in THF at −40° could transform aryl iodides containing bromide, ester, amide, or cyano groups to the corresponding functionalized arylmagnesium bromides. These react with allyl bromide or benzaldehyde at low temperature to give very good product yields (equation 16). In 1999, Knochel extended this exchange reaction to functionalized aryl and heteroaryl bromides, particularly those containing electron-withdrawing and/or ortho metallation-directing groups.[128]



(16)

Functional group (FG) = Br, CONR$_2$, CN, CO$_2$Et, CO$_2$*t*Bu;
E-Y = aldehyde, allyl bromide

Also in 1999, Cahiez and Knochel prepared functionalized alkenylmagnesium reagents by exchange of functionalized alkenyl iodides with *i*Pr$_2$Mg or *i*PrMgBr.[129] Soon after, Oshima reported that trialkylmagnesiates (R$_3$MgLi) can induce facile halogen-magnesium exchange of aryl halides even in the absence of electron-withdrawing groups, and facile halogen-magnesium exchange of unfunctionalized alkenyl iodides and cyclopropyl bromide; the reactivity of the magnesiate can be tuned by the choice of alkyl groups (Me, ^{n}Bu, ^{i}Pr) (equation 17).[130,131] Reactions with electrophiles sometimes are facilitated by the presence of a transition metal catalyst (CuCN·2LiCl).[126,131] In 2003, Knochel's group reviewed the expanding developments and applications of this methodology;[126] selected examples are described briefly here.

$$\mathrm{RX} \xrightarrow[\mathrm{THF},\ <0\,^\circ\mathrm{C}]{\mathrm{R'_3MgLi}} \mathrm{RR'_2MgLi} \xrightarrow{\text{Electrophile, E}} \mathrm{RE}$$

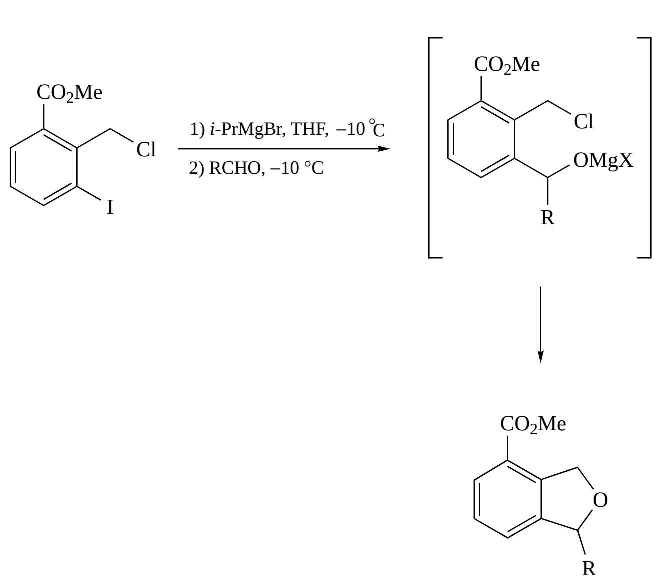
R = (un)functionalized aryl, heteroaryl, alkenyl, or cyclopropyl

$R' = \mathrm{Me}, n\mathrm{Bu}, i\text{-Pr};\ X = \mathrm{I, Br}$ (17)

Unfunctionalized aryl Grignard reagents (alkyl Grignards are too reactive) undergo iodine−magnesium exchange with electronegatively functionalized *ortho*-iodonitroarenes. The nitroarylmagnesium products react smoothly with benzaldehyde. In addition stoichiometric transmetallation with CuCN·2LiCl affords arylcopper reagents that couple efficiently with allylic bromides or benzoyl bromide.[126]

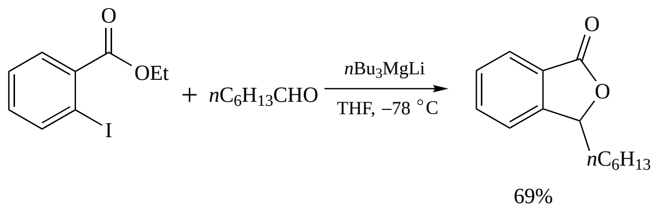
2-Chloromethyl-1-iodobenzene and its 3-methoxycarbonyl analog undergo selective iodine−magnesium exchange with ^{i}PrMgBr. The new Grignard can be used to construct various substituted heterocycles; for example, reaction with aldehydes and subsequent intramolecular displacement of chloride

affords a range of substituted isobenzofurans (equation 18).[132]



(18)

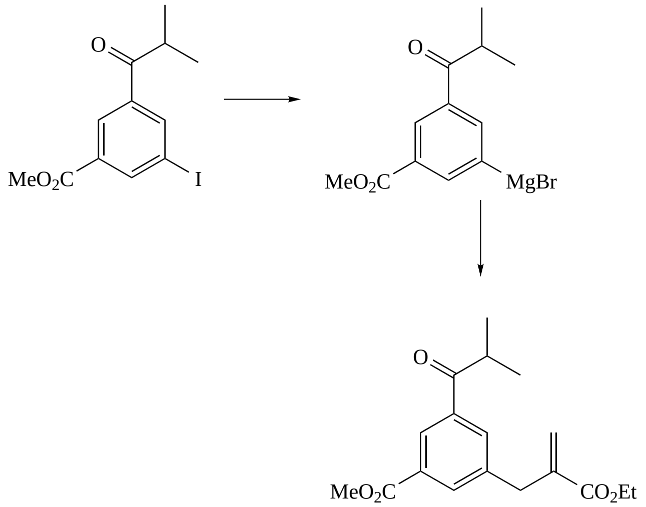
In a variation of this methodology, Oshima demonstrated the rapidity of the low-temperature iodine–magnesium exchange of ethyl *o*-iodobenzoate with $^{n}Bu_3MgLi$ by adding the reagent to a mixture of the ester and heptanal. Only 3-hexylphthalide (69%) was obtained, showing that the exchange was much faster than attack of the magnesiate on the aldehyde (equation 19).[131]



(19)

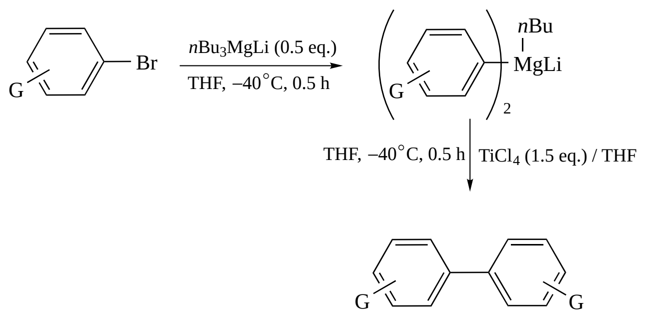
A Merck group, in developing a synthesis of a promising antidepressant/antiemetic, found that the rapid exchange (0 °C) between 3,5-bis(trifluoromethyl)bromo-benzene and *i*PrMgBr is the safest preparation of the potentially explosive aryl Grignard, and suitable for multikilo scale-up.[133]

In 2002, Knochel added aryl- and heteroaryl ketones to the list of functions that can tolerate iodine–magnesium exchange of iodoarenes.[134] Use of *neo*-pentylmagnesium bromide (NpMgBr) instead of $^{i}PrMgBr$ removed the possibility of competing ketone reduction via hydride transfer, and addition of a polar aprotic cosolvent [N-methylpyrrolidinone (NMP) or *N*,*N*-dimethylacetamide (DMAC)] with THF enabled rapid exchange at −45 °C to −25 °C. Even aryl ketones bearing an α (acidic) proton reacted with minimal enolate formation; transmetallation of the functionalized Grignard to the corresponding organozinc reagent and Cu(I)-catalyzed reaction with an allyl bromide gave the desired ketone in good yield (equation 20).



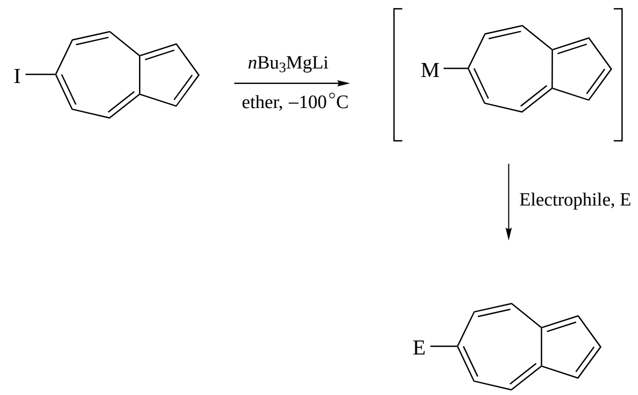
(20)

Oshima used the halogen-magnesium exchange power of n-Bu_3MgLi in a mild, one-pot preparation of a wide range of functionalized biaryls from functionalized bromo- or iodoarenes (G = esters, amides, and nitriles).[135] Treatment of the assumed butyl diarylmagnesium ate-complexes with $TiCl_4$ induced oxidative self-coupling to form the biaryls in moderate to good yields (equation 21).



(21)

Recent use of n-Bu_3MgLi enabled the first reported iodine–magnesium exchange with sensitive iodoazulenes, and subsequent reaction with a range of electrophiles (equation 22).[136]

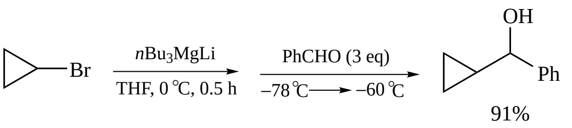


(22)

The use of halogen-magnesium exchange has been extended to a variety of functionalized heteroaryl bromides and iodides. As with the aryl halides, the nature of the heterocycle greatly influences the rate of the exchange; electron-poor heteroaryls react faster.[126] Again, use of trialkylmagneriates results in higher reactivity and selectivity, but $^nBu_3MgLi$ needs to be replaced by $^nBuMe_2MgLi$ to avoid side reactions.[131] Examples include functionalized iodo-[126,137] and bromopyridines,[126,138] halogenated diazines,[126] iodouracils,[126] halogenated imidazoles and antipyrines,[126,139] as well as pyrazoles[140] and thiophenes.[126,141]

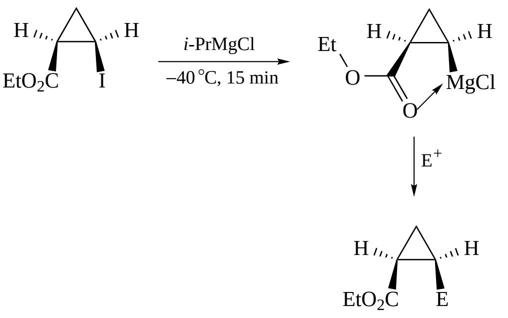
After the initial report on preparation of functionalized alkenylmagnesium reagents, Knochel's group studied these systems further.[126,142] Alkenyl halides exchange more slowly than do aryl halides, but again, iodides exchange more easily than do bromides, and the presence of proximal/conjugated electron-withdrawing or chelating groups facilitates the process. Vinyl bromides containing certain electron-withdrawing groups (CN, SO_2Ph, CO_2tBu, and $CONEt_2$) geminal to the bromide exchange readily with *i*PrMgBr. A variety of systems and synthetic applications has been explored.[126,142] Oshima's reactive magnesiates rapidly undergo exchange with nonactivated alkenyl iodides, with complete retention of configuration of the double bond.[131]

Halide-magnesium exchange of alkyl halides rarely has been used to prepare new organomagnesium compounds. Early studies with simple bromides and Grignards in Et_2O or Et_2O-hydrocarbon solvents largely failed to give any observable exchange.[125] One of the more positive results of a thorough 1964 study by Zakharkin was a 17% exchange between *n*-pentylmagnesium bromide and CH_3I after 1 h in THF at 0 °C.[143] Results with other paired systems showed that Wurtz coupling was a major reaction (also seen in the earlier studies), that the exchange rate for a given R group was RI > RBr > RCl, and that any success could be expected only if the organic moiety in the organomagnesium compound to be produced was more electronegative than the organic moiety in the initial Grignard. Alkyl Grignards were recognized to be more reactive (in several ways) than aryl or alkenyl Grignards, so little effort was expended for many years to prepare functionalized alkyl Grignard reagents. In 2001, knowing that exocyclic cyclopropyl bonds have abnormal s character for a 'saturated' hydrocarbon, Oshima showed that bromocyclopropane and $^nBu_3MgLi$ readily undergo bromine–magnesium exchange; subsequent reaction with benzaldehyde gave a 91% yield of α-cyclopropylbenzyl alcohol (equation 23).[131]



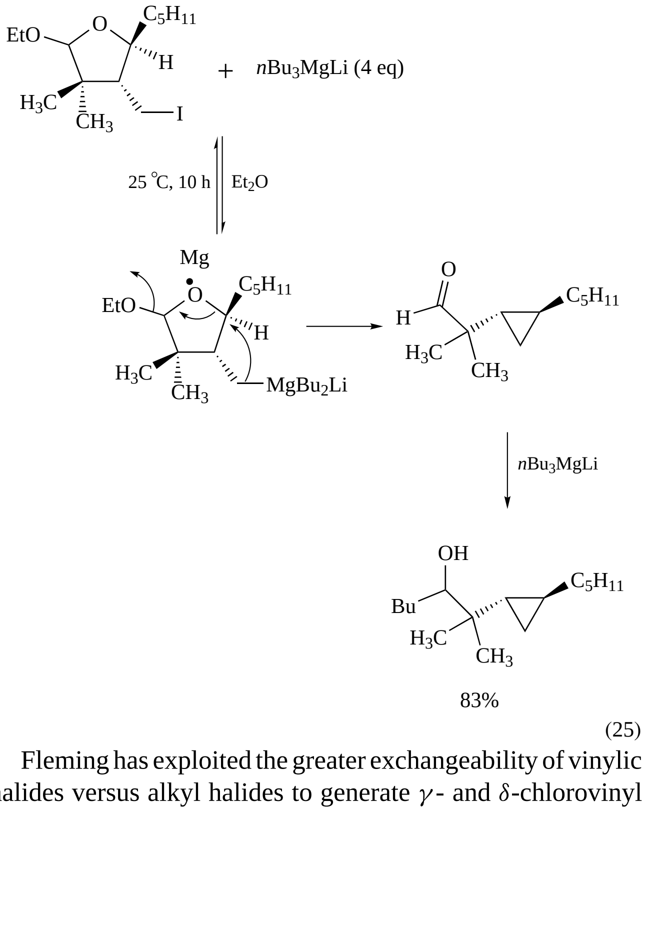
(23)

Soon thereafter, Knochel reported synthesis of the first cyclopropyl Grignards bearing an ester group.[144] The cis reagent, stabilized by the chelating ester function, gave good yields of products with a variety of electrophiles, all with retention of configuration (equation 24). The trans isomer, lacking chelation stabilization, nonetheless formed readily, and after transmetallation to the copper derivative, reacted with benzoyl chloride to give the pure trans keto ester in 65% yield.



(24)

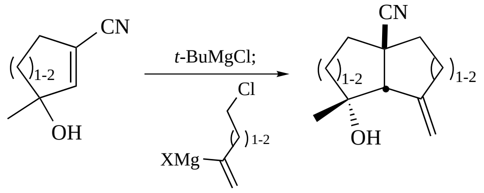
In 2004, using carefully designed 3-iodomethyl-1-oxacyclopentanes, Oshima was able to achieve iodine–magnesium exchange between the primary iodide and secondary or tertiary Grignard reagents, or $^nBu_3MgLi$ (equation 25).[145] Factors in the success of the reaction included an excess of the initial organomagnesium reagent, Et_2O (not THF) as solvent, and a facile intramolecular reaction pathway (cyclopropane ring closure) to drain off the primary Grignard reagent formed in the possibly reversible exchange process.



(25)

Fleming has exploited the greater exchangeability of vinylic halides versus alkyl halides to generate γ- and δ-chlorovinyl

Grignards, usable in reactions with cyclic γ-hydroxy-α,β-alkenenitriles to generate bicyclic ring systems in a single operation (equation 26).[146]



(26)

Magnesium carbenoids (compounds containing a carbon atom bonded to magnesium and to a geminal electron-withdrawing heteroatom), form extremely rapidly at low temperatures (−78 °C) via halogen-magnesium exchange.[126,147] The initial observation of this type of reaction[148] was extended in the 1990s to general preparation of magnesium carbenoids.[126] Knochel further extended this chemistry, performing the exchange between substituted *gem*-dibromocyclopropanes and *i*PrMgCl in Et_2O to stereoselectively prepare cyclopropylmagnesium carbenoids; subsequent reaction with electrophiles proceeds with retention of configuration.[126] Knochel also found that selected iodomethyl carboxylates undergo iodine−magnesium exchange with *i*PrMgCl in THF/*n*-butylpyrrolidinone at −78 °C; the generated carbenoids give very good yields in reaction with a variety of electrophiles.[147] Oshima has worked extensively on the exchange reactions of other substituted *gem*-dibromocyclopropanes and dibromodisilylmethanes with R_3MgLi, and the reactions of the resulting products with various electrophiles.[149]

Satoh has developed a related sulfoxide-magnesium exchange reaction between aryl α-chloroalkyl- and α-chlorovinylsulfoxides, and has extensively studied the chemistry of the resulting magnesium carbenoids and magnesium alkylidene carbenoids.[150]

References in Knochel's review and other recent scattered publications report some applications of halogen-Grignard or halogen-magnesate exchange reactions to synthesis of natural products and pharmaceuticals; these are certain to appear with increasing frequency.

4.2 Nucleophilic Substitution

4.2.1 Displacement at Carbon: Uncatalyzed Cross-coupling Reactions

The formation of a new carbon−carbon bond is a general reaction of organometallic reagents with organic electrophiles. Typically, the 'carbanion' component of the Grignard reagent (RMgX) serves as the nucleophile that displaces various leaving groups of the organic substrate (equation 27).

$$\mathrm{RY + R'MgX \longrightarrow R\text{-}R' + MgYX}$$

$$\text{R = alkyl, aryl; Y = leaving group; R}' \text{ = alkyl, aryl; X = halide} \qquad (27)$$

This methodology continues to be important in the preparation of a wide variety of research compounds, pharmaceutical intermediates, and fine chemicals. However, the efficiency of Grignard reagents for cross-coupling reactions often has been restricted by competing reactions that include β-elimination, reduction, magnesium-halogen exchange, and electron-transfer reactions. The exact mechanism of the formation of a new carbon−carbon bond by displacement of a leaving group often is uncertain. Three commonly considered mechanisms are a) an S_N2 (direct nucleophilic substitution) process, b) an S_N1 process wherein a stable carbocation is formed upon Lewis acid-assisted departure of the leaving group, and c) a SET (single electron-transfer) process arising from electron transfer and involving radical intermediates.[151]

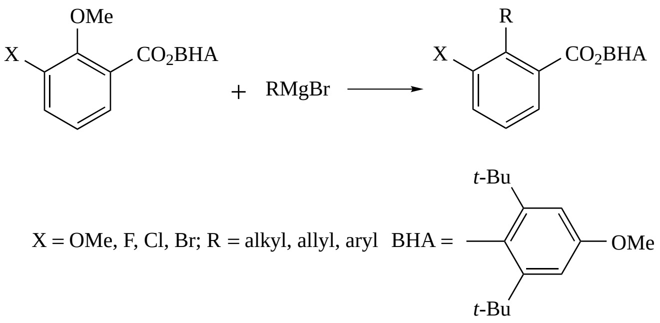
Halides in the organic substrates are considered the most useful leaving groups owing to availability and effective polarization of the carbon-halogen bond.[122] Among the halides, iodides usually react most rapidly, but most easily undergo Mg-halogen exchange. Generally, the reactivity of halides follows the trend $I > Br \gg Cl \gg F$. Before the advent of effective catalysts, simple (unfunctionalized) alkyl halides, except methyl iodide, were not commonly used for coupling, owing to their slow reactions with Grignard reagents.[125] In contrast to simple alkyl halides, allylic and benzylic halides often give useful yields owing to greater ease of displacement (milder reaction conditions).[49] Transition metal-catalyzed reactions will be discussed in detail below.

Another class of leaving groups is the oxyanions, including sulfates and sulfonates (e.g. mesylates, tosylates, and triflates), that often are easily displaced to afford coupling products in good yields. Alkoxy groups incorporated into acetals, ketals, and orthoesters usually do not react with Grignard reagents, but their displacement can be facilitated by coordination of the alkoxy group with the Lewis acidic magnesium ion. The order of reactivity of such leaving groups is aryloxy > alkoxy > thioalkoxy > amino.[152] Other displaceable C–O bonds are found in phosphate esters, carboxylate esters, certain ethers, and epoxides.[151] Nucleophilic ring opening reactions were also demonstrated in the reaction of 3-aza-2-oxabicyclo[2.2.1]hept-5-enes[153] and β-lactones[154] with Grignard reagents.

Uncatalyzed nucleophilic substitution reactions of Grignard reagents with aromatic compounds is much more difficult than with alkyl species, unless the leaving group (sometimes halide; usually alkoxide is preferred) is activated by one or more potent electron-withdrawing substituents, such as an oxazoline, nitro, or ester moiety, most often at the ortho

position.[49] Such displacement is hypothesized to follow an addition-elimination pathway.

In 1998, methoxy and halogen substituents *meta* to a highly hindered benzoate ester were found to increase the rate of displacement of the sandwiched *ortho* methoxy leaving group.[155] (equation 28) In 2001, *meta*-alkoxy rate enhancement was found applicable also to displacement of a methoxy group *para* to a benzoate ester.[156]



(28)

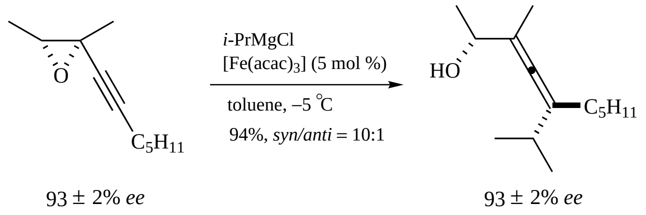
In 2003, the 2-methoxy substituent in a 2-methoxy-3- or 4-methyl furoate was found to be displaceable by EtMgBr in Et_2O.[157] Hattori and Miyano have applied the alkoxy displacement method to the reaction of 2-methoxy-1-naphthyl Grignard with 1-menthoxy-2-nitro naphthalene; the departing chiral menthoxy group imparted a high level of optical purity (78% ee) to the axially chiral binaphthyl so formed.[158] An Otsuka Pharmaceutical research group has successfully coupled a highly substituted aryl Grignard with a highly substituted *ortho*-methoxybenzoate (with displacement of the methoxy group) to produce (on a multikilo scale) a biphenyl intermediate in the synthesis of a promising pharmaceutical agent.[159]

In 2001, Makosza reported an improvement in the known oxidative nucleophilic substitution of *ortho* hydrogen in *p*-methoxy- and *p*-chloronitroarenes via *ortho* addition of an alkyl group from a Grignard reagent.[160] The intermediate σ^H additive was oxidized to the final alkylated nitroarene by addition of liquid ammonia and powdered $KMnO_4$ to the reaction mixture in THF at −70 °C, producing better yields than previous oxidizing agents.

4.2.2 *Transition Metal–Catalyzed Cross-coupling Reactions*

In tandem with the above-described recent advances in the preparation of Grignard reagents containing functional groups, great strides have been made recently in the development of transition metal-catalyzed cross-coupling reactions of Grignard reagents. The rise of nickel- and palladium-catalyzed coupling of Grignard reagents with alkenyl and aryl halides in the 1970s, and the renaissance of iron-catalyzed coupling that started in the late 1990s have been described in a summary by Fürstner of some of his group's recent extensive work on iron catalysis.[161] Contributions to the field of iron-catalyzed Grignard cross-coupling by the groups of Kochi, Cahiez, and Knochel are cited therein, as well as in the 2003 review by Knochel's group,[126] and in Shinokubo and Oshima's 2004 review.[162] The recent success of iron catalysis in carbon–carbon bond formation has attracted intense interest because of the cheap availability, stability, and environmental compatibility of many iron salts. Fürstner's 2002 paper summarized existing evidence suggesting that an iron species with the formal composition $[Fe(MgX)_2]$ propagates the coupling process.[161] This paper reported high yields of coupling between alkyl Grignards and electron-poor aryl chlorides and tosylates, and electron-rich aryl triflates. Aryl chlorides, triflates, and tosylates are better coupling partners than the corresponding iodides and bromides; the latter tend to undergo competitive reduction. Competing Grignard attack on substituents such as carboxylate and sulfonate esters, sulfonamides, and nitriles was not observed. Heteroarene substrates include a dibenzofuran, a thiophene, and numerous nitrogen-containing arenes. Coupling of aryl Grignards with arene substrates succeeds only with π-electron-deficient heteroaryl chlorides; Figadère had reported a similar finding months earlier.[163]

In 2003, Fürstner's group reported applications of this methodology to total syntheses of some natural products,[164,165] and to the stereospecific S_N2' reaction of alkyl and aryl Grignards with optically enriched propargyl epoxides to yield alkyl- and aryl-substituted 2,3-allenols with high stereochemical fidelity (equation 29).[166]



(29)

In 2004, his group described in some detail the iron-catalyzed cross-couplings of alkyl and aryl Grignards with enol triflates, acid chlorides, and dichloroarenes.[167] Enol triflates give good to excellent yields; many substrate functional groups (e.g. esters, enones, carbamates) are tolerated, and several functionalized Grignards work well.

A much broader variety of functionalized acid chlorides was studied than was reported in previous literature; all combinations of aromatic and aliphatic acid chlorides and aryl and alkyl Grignards work very well, proceeding in less than 15 min at −78 °C; attack on the product ketone is negligible. Substrate stereogenic centers are not racemized, and radical intermediates appear to be unlikely. Results of dichloroarene couplings are variable; while good yields of the desired monoalkylated product usually are obtained, *ortho*-substituted substrates can be problematic, and function-bearing Grignards are much less reactive.

Also in 2004, papers by the groups of Hayashi[168] and Nakamura[169] were followed shortly by a Fürstner paper,[170] all reporting efficient iron complex-catalyzed couplings of aryl Grignards with alkyl halides. Each group employed a differently ligated Fe species and different solvents (Et_2O or THF) and temperatures; each reported results superior to previously reported palladium- and nickel-catalyzed processes, and to stoichiometric arylation with organocopper reagents. Salient features of these couplings include excellent tolerance of polar groups (e.g. ketones, esters, enolates, chlorides, nitriles, isocyanates), greater reactivity of secondary over primary bromides (RI > RBr > RCl), and complete racemization during arylation of secondary bromides, indicating formation of radical intermediates.

In the presence of manganese chloride, functionalized aromatic halides and aromatic Grignard reagents cross-couple under mild conditions.[171] Likewise, synthetically important heterocycles cross-couple in the presence of cobalt catalysts.[172]

Although there has been much recent progress in the development of transition metal-catalyzed coupling between alkyl Grignards and, for example, aryl or vinyl halides and triflates, between aryl Grignards and alkyl halides, and the corresponding aryl–aryl and aryl-vinyl combinations (including heteroarenes), satisfactory alkyl–alkyl coupling has remained elusive. Stoichiometric organocuprates can couple with alkyl halides with high yields and chemoselectivity[173] but large excesses of the organocuprate often are needed, and large-scale industrial applications are discouraged by the prospect of disposing of large-scale copper residues; higher order or mixed cuprates have provided some improvement.[174] Fürstner[170] (and others) has discussed some of the problems attending palladium- and nickel-catalyzed cross-coupling involving alkyl halides and/or alkylmetal reagents, and cited some of the groups continuing to work on the alkyl–alkyl coupling problem. In 2000, Cahiez showed that copper-catalyzed coupling of primary, secondary, and tertiary alkyl Grignards with primary alkyl bromides proceed in very good yields, if *N*-methylpyrrolidinone (NMP) was used as a cosolvent with THF.[175] NMP as a cosolvent has also facilitated iron- and manganese-catalyzed Grignard cross-couplings.[161,171,175] The reactions proceed smoothly under mild conditions, even in the presence of esters, nitriles, ketones, and alkyl chlorides. However, secondary bromides do not react. In earlier work (1998),[176] van Koten's group (with Cahiez as coauthor) reported very good coupling of primary, secondary, and tertiary Grignards with primary and secondary alkyl bromides, cocatalyzed by THF-soluble tridentate diamino organo-manganese(II) complexes and CuCl. Ketone and ester functions do not interfere. No follow-up of this promising, little-cited method has been found.

In 2004, Oshima's group reported full details of cobalt-catalyzed cross-coupling of primary, secondary, and tertiary alky halides with allylic and benzylic Grignard reagents.[177] Bis-diphenylphosphinoalkane catalyst ligands sometimes are needed, and iodides and bromides give better yields than chlorides; amides, esters, and carbonates are attacked, even at −78 °C. For facile synthesis of quaternary carbon centers, this method is better than use of palladium, nickel, or copper catalysts; the reaction mechanism probably includes generation of an alkyl radical.

In addition to iron, recent uses of manganese, chromium, and cobalt catalysts for Grignard cross-coupling are described in the Shinokubo–Oshima review.[162]

4.2.3 *Displacement at Electrophilic Main Group Elements and Transition Metals*

Similar to substitution reactions with organic substrates, the nucleophilic attack of the alkyl or aryl groups of Grignard reagents on main group elements and transition metals requires suitable leaving groups and effective solvent systems. Because these reactions proceed favorably only when the electrophilic centers are more electronegative than magnesium, reactions involving alkali and heavy alkaline earth metals are not viable.

Elements within group 13 (B, Al, Ga, In and Tl), group 14 (Si, Ge, Sn and Pb), group 15 (N, P, As, Sb and Bi), and group 16 (O, S, Se and Te), and a variety of transition metals from groups 3 to 12 are known to undergo alkylation and arylation with Grignard reagents.[152] The products of these reactions have found vast applications in various fields that include catalysis and materials science. Recently, the interaction of Grignard reagents with phosphaalkynes was described to successfully produce phosphavinyl Grignard regents, [RP=C(Bu^t)MgCl] R = alkyl or aryl.[178,179] These reagents were subsequently employed for the preparation of phosphovinyl-main group complexes by reaction with several groups 13, 14, and 16 monohalides.[180] Use of these reagents has been extended as well to reactions with transition metal complexes.[181,182]

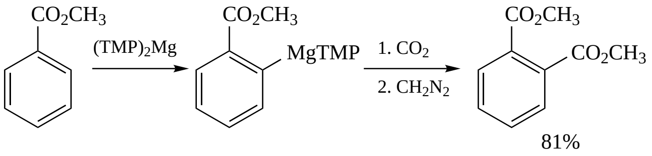
4.3 Grignard Reagents as Bases

Grignard reagents are very strong bases; parameters that affect their base strength have been reviewed.[122] They are convenient bases (particularly ethylmagnesium bromide) for irreversible deprotonation of terminal alkynes (equation 30). Many uses of the resulting acetylenic Grignards have been described, including addition to a variety of carbonyl compounds, in which they are less prone to side reactions than are the corresponding lithium reagents.[122]

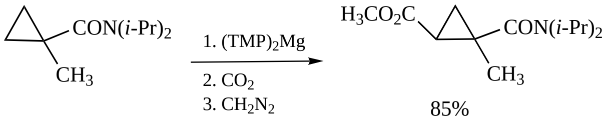
$$RC{\equiv}CH + R'MgX \longrightarrow RC{\equiv}CMgX + R'H$$
$$\text{where: R, R}' = \text{alkyl, X} = \text{halogen} \qquad (30)$$

Grignard reagents readily deprotonate alcohols, secondary amines, and secondary amides; in certain substrates, the resulting magnesiated species can undergo inter- or intramolecular addition, or intramolecular rearrangement.[122]

In 1989, Eaton extended the utility of amido-Grignards, showing that highly hindered magnesium amide bases (e.g. bis(2,2′,6,6′-tetramethylpiperidino)magnesium, $(TMP)_2Mg$)) are much more stable in THF than are the corresponding lithium amides, yet effectively ortho magnesiate, for example, methyl benzoate without attacking the ester function (equation 31).[183] Amide-activated strained systems such as, the carboxamidocyclopropane in equation (32) undergo analogously directed magnesiation in good yield.

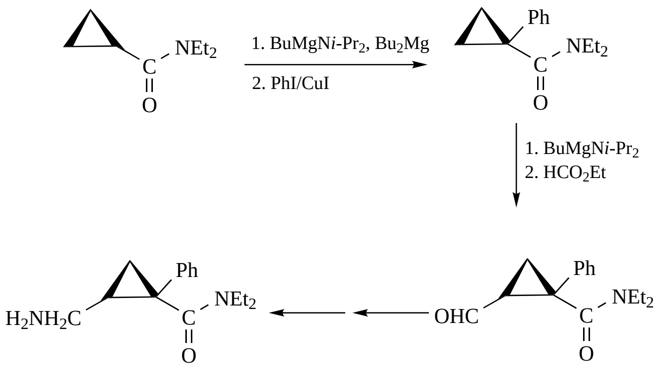


(31)



(32)

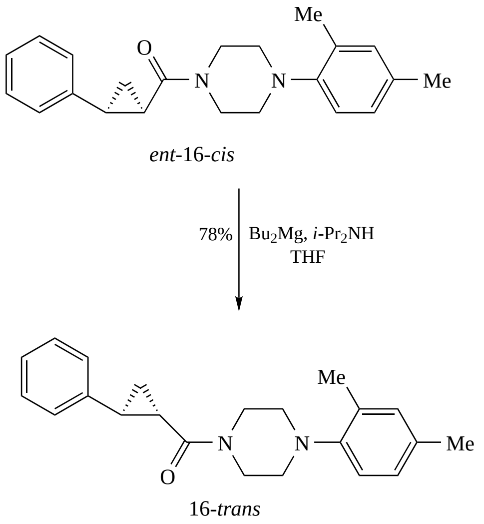
In 2002, Eaton introduced an even stronger deprotonating/metallating reagent, $BuMgN\textit{i}Pr_2$, which also is usefully stable in THF, and can completely deprotonate amide-activated cyclopropanes by irreversible formation of butane.[184] This process was applied in a new synthetic route to the antidepressant, Milnacipran (equation 33).



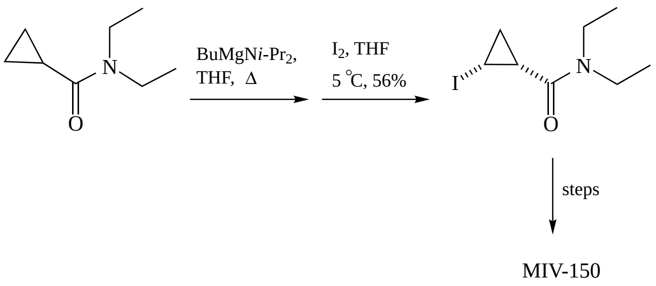
Milnacipran

(33)

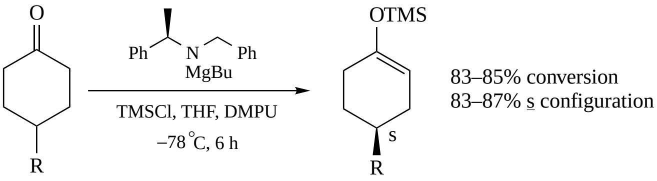
More recently, Shuto used $BuMgN\textit{i}Pr_2$ to effect the cis-trans isomerization of the cyclopropanecarboxamide shown below (equation 34),[185] and a Chiron group found $BuMgN\textit{i}Pr_2$ best for deprotonation of a similar substrate in a formal synthesis of the potential anti-HIV agent MIV-150 (equation 35).[186]



(34)

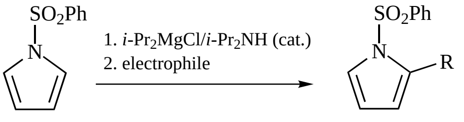


(35)



(36)

Eaton's base also has stimulated use of an enantiopure alkylmagnesium amide for enantioselective deprotonation of a set of 4-substituted cyclohexanones (equation 36);[187] further work in this area can be expected. Finally, efficient ortho-magnesiation of *N*-phenylsulfonylpyrrole has been achieved with an excess of $\textit{i}PrMgCl$ and a catalytic amount (5 mol%) of $\textit{i}Pr_2NH$ to serve as a proton transfer agent; subsequent reaction with a range of electrophiles afforded decent yields of products (equation 37).[188]



(37)

R = (e.g.) I, alkyl, $SiMe_3$, aryl, heteroaryl

5 CONCLUSIONS

The structural chemistry of the alkaline earth metals is continuing to grow at a rapid rate. New synthetic methods,

new applications in a variety of fields and fascinating questions pertaining to the very nature of the chemical bond guarantee that further investigations will continue to be well deserved. Through the work of the several groups pioneering the renaissance in heavy alkaline earth organometallics, a new appreciation for this previously dismissed class of reagents is emerging that will undoubtedly lead to further developments sure to contribute considerably to the library of knowledge of these metals.

1 INTRODUCTION

Biological systems display exquisite control in the mineralization of nanoparticles (*see Nanocrystals*; ***Semiconductor Nanocrystal Quantum Dots***; ***Metal Nanoparticles, Synthesis of*** and ***Metal Nanoparticles, Organization & Applications of***) as a result of highly developed detoxification mechanisms, regulatory processes, and requisite structural components, by the use of diverse biomolecular templates (*see* ***Biomineralization***). These templates include amino acids, peptides, proteins, and viruses which offer precisely defined metal binding sites, spatial organization, structurally confined cages/cavities/pores, and an environment that protects against oxidizing conditions/nanoparticle aggregation. Consequently, the corresponding biogenic nanoparticles exhibit superior quality (i.e. 24 carat gold), dispersity, crystallinity, morphology, and optical/electronic properties. Presently, synthetic approaches that mimic biomineralization processes have gained interest along with the wealth of viable nanoparticle templates. Herein, we describe the methodology, biologically derived templates and motifs, and the resultant nanoparticle characteristics/properties. The scope of this review will begin by examining synthetic nanoclusters stabilized by individual amino acids and proceed to nanoparticles stabilized by increasing complex peptides (Table 1) and finally proteins and virus templates.

2 AMINO ACIDS AS STABILIZING LIGANDS

2.1 Cysteine

2.1.1 Zero-valent Metals

The most studied single amino acid capping ligand is cysteine. Cysteine is the only free thiolate amino acid occurring within the standard twenty amino acids and represents an ideal ligand for use as a size directing capping ligand with soft metal substrates such as gold, silver, platinum, copper, and type II–VI semiconductors.

Cysteine has been shown to be an excellent monodentate ligand in the formation of zero-valent gold nanoclusters using standard reduction conditions.[1] Under anaerobic conditions, free cysteine was added to a solution of Au (III). Subsequently, the gold sol was further reduced using sodium borohydride to form zero-valent Au^0.[1,2] With the reduction of gold, the thiolate ligand of the cysteine moiety capped the surface of the newly formed nanoparticle, preventing Oswald ripening and maintaining a monodisperse set of nanoparticles.

The Au^0 nanoclusters formed were relatively monodisperse with a typical size distribution of 3.8 ± 1.0 nm in diameter. Additionally, the cysteine passivated gold nanoclusters were highly crystalline, confirmed by the major diffractions of the (100), (200), (220) and (020) of the face-centered cubic lattice for the gold.[1] The overall size dimensions were slightly larger than previously reported values for gold-alkenethiol nanoclusters, but the diffraction patterns from both nanostructures were similar.[3]

Gold nanoclusters were also obtained through a place exchange reaction. Taylan *et al*. were able to substitute surface stabilized citrate Au^0 nanoclusters with cysteine by incubation of the particles with the free amino acid,[4] providing a handle to conjugate other biologically relevant molecules to the surface of the cluster. This reaction was driven through the surface affinity for the thiolate moiety. As the cysteine thiolate ligands have a stronger binding affinity for gold surfaces than oxygen from the perspective of enthalpic considerations, the thiolate could favorably displace the oxygen moieties and bind to the gold surface.

Many different applications for gold cysteine nanoclusters have been proposed. One application is the use of citrate capped nanoparticles as sensors for the detection of thiol containing structures. This application relies on the fact that thiols can easily displace oxygen coordinated moieties. Zhong *et al*. have studied this process between cysteine and homocysteine to develop an assay for the homocysteine biomarker, a correlate to cardiovascular disease. When citrate stabilized particles of 13 nm were incubated with either thiolate structure, the solution color changed from a dark red to a deep blue. The displacement of citrate by these moieties resulted

Table 1 Summary of amino acid and peptide stabilized nanoparticles

Ligand	Nanoparticle	Diameter (nm)	UV absorbance (nm)	Synthesis method	Reference
Cysteine	Au^0	3.8 ± 1.0	511	Reduction	1
Cysteine	Au^0	123	620	Place Exchange	4,5
Cysteine	Ag^0	4.4 ± 0.3	400	Reduction	1,7
Cysteine	Cu^0	3.5 ± 0.8	398	Reduction	1
Cysteine	Pt^0	16.9 ± 8.4	–	Reduction	1
Cysteine	CdS	2–4	360–400	Metal Sulfide	10
Cysteine	ZnS	–	260–275	Metal Sulfide	11
Cysteine	Ag_2S	9 ± 2.25	300	Metal Sulfide	13

in a noticeable shift of the UV absorbance of the particles from 550 nm to 620 nm.[5] This shift in the plasmon resonance occurs through the formation of self-assembled structures of the nanoparticles though hydrogen bonding interactions of the amine and carboxylate groups of the cysteine and homocysteine substrates once substitution was complete.

Another application for cysteine capped gold nanoparticles is the use as a solid support for oligomerization of amino acids in solution. This application has environmental applications in which free amino acids can be extracted from aqueous solutions. In this method, the amino groups on the surface of the nanoparticle mediates the formation of linkages for oligomerization when a standard peptide coupling agent is added. Following the reaction progress by UV spectroscopy, a plasmon resonance peak shift (510 nm to 598 nm over 1 h) is observed as the result of the formation of larger aggregates. Once a critical oligomer size domain is obtained, the particles precipitate from solution and can be collected by filtration. The oligomers can be recovered by oxidative cleavage from the particle.[6]

A second well studied cysteine stabilized nanocluster is the zero-valent silver nanocluster. Nanoclusters of this type, prepared via $NaBH_4$ reduction, have been reported to have discrete monomodal size distributions on the order of 4.4 ± 0.3 nm. From UV–vis spectroscopy and transmission electron microscopy (TEM), Mandal *et al.* have shown that the silver nanoclusters can self assemble into a larger structure through hydrogen bonding of the capping cysteine ligand. The surface exposed amine and carboxylate formed a network of hydrogen-bonded nanoparticles. The plasmon resonance at 400 nm showed a broadening trend over a 7 hour reaction period, at which point the self-assembly process of Ag^0 nanocluster networks was completed. Further analysis of Ag^0 cysteine stabilized nanoparticles by powder X-ray diffraction (XRD) has shown a high degree of crystallinity and a face-centered cubic lattice constant of 4.34 Å.[1] Thermal studies indicated a stable network to ∼55 °C.[7]

Similar to Ag^0, zero-valent platinum nanoclusters were synthesized with cysteine capping ligands under reducing conditions. The platinum clusters showed a larger size

distribution of 16.9 ± 8.4 nm and no noticeable plasmon resonance peak in the visible spectrum. The electronic and dielectric properties of platinum gave rise to the featureless spectra, reminiscent of the spectra of polyacrylate stabilized Pt^0 clusters.[8]

Cysteine ligands have also been reported in the synthesis of intricate copper nanoparticles following a literature modified reduction procedure.[2] The Cu^0 nanoclusters revealed a plasmon resonance band at 398 nm and an average size distribution of 3.5 ± 0.8 nm by TEM. Infrared analysis of the stabilized nanoparticles showed a weakened S–H stretch at 2598 cm^{-1} suggesting uncoordinated cysteine thiols, supporting the possible involvement of the amine functional group from the cysteine alpha carbon in particle stabilization.[1] These particles displayed extreme O_2 sensitivity, degrading under aerobic conditions to Cu (I) and then Cu (II) cysteine complexes. Additionally, this sensitivity precluded the convenient determination of nanoparticle crystallinity.[9]

2.1.2 Metal Sulfides Nanoclusters

Cysteine has also been shown to passivate the surface of highly fluorescent CdS bionanocrystallites. These nanocrystals have been of interest owing to their possible use as fluorescent labels and photocatalysts. Generally, the nanoparticles were formed by the addition of inorganic sulfide (Na_2S) to solutions of a cadmium cysteine precursor complex. This synthetic process yielded nanocrystals of a size dimension between 2 and 4 nm in diameter.[10]

The synthetic conditions for CdS formation were explored with different ratios of cadmium:cysteine and cadmium:sulfide in order to further manipulate and refine the resultant nanocrystal properties. While a great deal of reaction space was examined to optimize the ratios of the cluster components, the different ratios of cysteine to cadmium produced little to no tangible difference between reactions. This suggests that prior to the addition of the sulfide nucleating component, the cysteine forms a cadmium/amino acid precursor complex.[10] In contrast, the ratio of sulfide to cadmium was critical in tuning the size of the nanoparticle. As the ratio of sulfide to Cd approached and surpassed 1, the UV absorbance began to shift toward the red indicating the formation of larger capped CdS nanocrystals with higher sulfide ratios. The fluorescence spectra of these particles also showed a dependence on the equivalents of sulfide added, reflecting the characteristic quantum confinement of these nanoparticles. By keeping the amino acid in excess, there was always sufficient capping ligand to stabilize the particle and prevent aggregation to the bulk.

In addition to fluorescent CdS nanocrystals, cysteine represents an excellent ligand for ZnS nanocrystals. Again, inorganic sulfide is incorporated into a zinc cysteine complex to initiate cluster formation. An examination of reaction temperatures suggests optimal formation occurred at 45 °C. Once formed, the clusters were highly fluorescent and gave rise to an absorbance around 274 nm blue shifted from the bulk band gap for ZnS. From the UV data and size fractionation studies monitored by UV–vis, it appeared that the cysteine moiety was able to form clusters of rather uniform size and distribution.[11]

As was previously determined with CdS, titration experiments of sulfide produced varying sizes of ZnS nanoparticles. By maintaining a constant ratio between cysteine and Zn (II) of 1:1, varying equivalents of sulfide (0–1.5 eq.) were added. From UV–vis, the collection of ZnS-(Cys) nanocrystals displayed absorption shoulders between 260–275 nm. As the equivalents of sulfide increased, the shoulder red shifted indicating the formation of larger nanoparticles in solution. Additional characterization by Mehra *et al.* of the ZnS nanocrystal products revealed only a small variation of particle sizes obtained after separation of the reaction mixture by gel permeation chromatographic methods.[11]

Given the unique photophysical properties of semiconductor quantum dots, one potential application of these materials is as photocatalysts. When the ZnS-(Cys) nanoparticles were introduced to paraquat and irradiated with light at 254 nm, efficient reduction of the dye occurred. Ultimately, the photoreducibility offered by ZnS nanoclusters is advantageous to many applications, including wastewater treatment.[11] By using this unique synthetic method, batches of gram scale quantities have been produced that are quite stable for up to 30 months,[12] making ZnS a commercially viable catalyst and environmental agent.

Ag_2S was also effectively stabilized by cysteinyl ligands. These clusters are synthesized using a molar ratio of 2:1 cysteine:silver ions upon which stoichiometric amounts of inorganic sulfide were added to nucleate the nanoparticle, with subsequent size-selective precipitation.[13] The resultant nanoparticles had an absorbance shoulder at 300 nm. Further analysis using high-resolution transmission electron microscopy (HRTEM) revealed a particle size of approximately 9.00 ± 2.25 nm in diameter. Selected area electron diffraction (SAED) analysis also demonstrates the highly crystalline nature of the product.[13]

2.2 Histidine

2.2.1 Zero-valent Metal Nanoclusters

Among metal chelating ligands, histidine exhibits numerous physical properties amenable to nanocluster stabilization including good nucleophilicity, side-chain pK_a, known metal binding, and good hydrogen bonding. Histidine has been shown to stabilize various nanoclusters through the imidazole side chain, which acts as a capping agent to passivate the nanocluster surface. Given the pK_a of the histidine side chain is 6.00,[14] its use as a ligand occurs upon deprotonation at neutral to slightly basic pH. This unique amino acid has been shown to

cap several metal nanoclusters, including gold, silver, copper, platinum, and ZnS quantum dots with good results.[1,15]

Based on synthetic methods developed for cysteine stabilized clusters, histidine encapsulated Au^0 nanoclusters were prepared by the formation of a histidine/Au (III) precursor complex with subsequent reduction by $NaBH_4$. UV analysis confirmed the synthesis by the presence of a plasmon resonance peak for Au^0 at 518 nm. Further confirmation by TEM showed particles with an average diameter of 3.8 ± 1.0 nm with a good deal of crystallinity as determined by XRD.[1]

Silver histidine nanoclusters were produced by similar methods, whereby silver ions were complexed to histidine and reduced using $NaBH_4$ for four hours under anaerobic conditions. UV absorbance showed a broad peak at 393 nm indicating formation of the clusters. TEM and XRD analysis revealed nanoclusters on the size dimensions of 10.0 ± 3.0 nm with a high degree of crystallinity.[1]

Interestingly, Pt^0-(His) nanoclusters prepared by standard $NaBH_4$ reduction from precursor complexes of Pt (II) and histidine in aqueous solutions produced nanoclusters with a plasmon resonance at 270 nm as compared to a theoretical maximum plasmon band predicted at 345 nm for particles $\leq$20 nm.[8] A high degree of crystallinity was confirmed by the (100), (200), (220), and (020) diffractions in the powder XRD diffraction peaks. TEM analysis demonstrated a tight distribution of particles with an average diameter of 3.4 ± 1.0 nm.[1]

Novel copper nanoclusters were also synthesized using histidine as the surface ligand. As described for Cu^0-(Cys), these clusters were highly air sensitive, therefore an anaerobic environment was necessary to prevent nanocluster degradation to copper oxides during characterization. UV studies revealed a plasmon resonance at 571 nm with TEM analysis confirming a size distribution of 6.9 ± 2.4 nm.[1]

Further insight into histidine encapsulation of nanoclusters (Au, Ag, Cu, Pt) was provided by infrared spectroscopy. IR spectra of free histidine showed a set of stretching bands for the N–H bond of the amine and strong peaks (1630 cm^{-1}, 1413 cm^{-1}) attributed to an asymmetrical and symmetrical CO_2^- stretch. As a result of nanocluster stabilization and the subsequent formation of a metal-N(His) interface, the N–H stretching frequencies broadened and the number of bands decreased relative to free histidine due to the interactions with the dielectric field at the nanocluster surface.[1]

2.2.2 *Metal Sulfide*

Histidine has been shown by Mehra *et al.* to stabilize fluorescent nanoparticles of ZnS. Nanoparticle synthesis is similar to ZnS-(Cys) methods (see Section 2.1.2). It was noted that the best ratio for nanoparticle formation is 2:1 for histidine to zinc (II). Titrations of sulfide into solutions of the complexed metal and amino acids showed formation of larger particles as the sulfide equivalents increased. This formation gave rise to many absorbances in the UV between 260 to 305 nm. When only one equivalent of sulfide was added, formation of two peaks appeared in the UV at 265 and 285 nm, indicating the formation of two different populations of nanoclusters synthesized. Fluorescence studies revealed strong fluorescence with peak maxima around 425 nm.[15] By using size exclusion chromatography (SEC), researchers were able to separate the two different populations of ZnS particles, providing a route for improved monodispersity.[15]

Further analysis of the particles using HRTEM confirmed formation of the nanocrystalline material. For nanoparticles of an average diameter of 4.24 ± 0.66 nm, distinct lattice planes could be observed with spacings of 3.0 ± 0.3 Å. Furthermore, SAED patterns displayed a wurtzite crystal structure with diffraction rings at 3.12 Å, 1.92 Å and 1.63 Å.[15]

Based on the above synthetic routes, ZnS-(His) nanoclusters were doped with manganese to improve the photophysical properties of the quantum dots. To synthesize these unique doped clusters, the zinc (II) ions were allowed to complex with the histidine in solution, followed by addition of manganese. During nucleation induced by the addition of sulfide, manganese was doped into the reaction mixture. Each nanocluster was doped with approximately 1% manganese. The resulting ZnS:Mn clusters had a typical absorbance (387 and 412), but exhibited a strong distinctive orange fluorescence originating from the d–d transition of the Mn^{2+} ion.[16]

2.3 Lysine

Similar to histidine, lysine has also been shown to bind gold nanoparticle surfaces through the ε-primary amine of the side chain. The lysine capped Au^0 nanoparticles synthesized from reduction by $NaBH_4$ were approximately 65 ± 7 Å in diameter and showed an initial strong plasmon resonance at 510 nm that broadened and red shifted slightly over time. This broadening was attributed to the formation of a self-assembled structure from hydrogen bonding of surface capping lysines between individual nanoclusters.[17]

Evidence for the formation of the self-assembled structure was based upon the pH behavior of the nanoparticle solution. At acidic pHs, the plasmon resonance showed little to no broadening of the peak. At neutral conditions, the peak broadened due to the formation of larger structures in solution. More basic solutions of nanoclusters produced spectra with even broader plasmon resonances, supporting the hypothesis that the more basic a solution was, the larger the network of hydrogen-bonded nanoparticles. Upon heating the solution, hydrogen bonds were disrupted and the surface plasmon resonance peaks shifted and became much more pronounced. These results were further confirmed with TEM analysis which showed either individualized nanoparticles or tightly associated random networks of particles depending upon the pH of the solution studied.[17]

2.4 Aspartic Acid

Inspired by the citric acid reductive route to gold nanoparticles,[18] aspartic acid was used as both reductant and surface capping ligand. In this method, refluxing chloroauric acid in solution with aspartic acid caused the reduction of gold by the amino acid eventually forming the nanoparticles. UV analysis has shown a typical plasmon resonance peak at 530 nm for these particles. TEM analysis of the particles showed a size distribution of 24 ± 3 nm, which is considerably larger than that reported for the citric acid method.[18] This is likely due to the difference in the inherent reducing ability of the aspartic acid relative to citrate.

2.5 Metathesis/Transmetallation of Amino Acid Stabilized Nanoparticles

In contrast to standard borohydride reductive nanoparticle synthesis, we have developed an alternative strategy to amino acid encapsulated nanoparticles by utilizing a metal nanoparticle (M^0-(Ligand))/metal ion (M^{n+}) precursor redox pair with matched oxidation/reduction potentials. Simply, a metal nanoparticle such as Pt^0-(Cys) acts as the principal reductant to a complimentary selected metal ion of Au^{3+} resulting in a new stabilized metal nanoparticle of Au^0-(Cys) and the oxidation product of the original nanoparticle Pt^{n+}. Malow *et al.* have reported a metathesis/transmetallation type reaction between a platinum colloid and a Au^I cyanide compound.[19] Similarly, we employed a Pt^0-(Cys)/$AuCl_4^-$ pair and 0.5–2.0 equivalents of Au^{III} to Pt^0-(Cys). XRD analysis of the nanoparticle products revealed differences in crystallinity as the equivalents of Au^{3+} were increased, whereby 0.5 and 1.5 equivalents of Au^{3+} yielded low crystalline products likely due to incomplete reactions/substitutions with the platinum lattice (Figure 1). At 1.0 eq. of Au^{3+}, both crystalline Pt^0 and Au^0 are present as observed by two sets of diffractions. Upon addition of 2.0 eq., only one set of diffractions attributed to fcc Au^0 are present. After ethanol purification of oxidized products, the atomic % of gold increased to 95.6% as the atomic % of platinum decreased to 4.4% at 2.0 eq as explained by energy-dispersive system (EDS). Analogously, a Cu^0-(Cys)/Pt^{2+} pair produced stabilized platinum nanoparticles by copper mediated reduction of Pt^{2+}. This approach provides a means to synthesizing a variety of metal nanoparticles which are difficult to synthesize under borohydride reduction via the judicious selection of a redox pair. The choice of metal nanoparticle, oxidation state, and stabilizing ligand are all critical considerations.

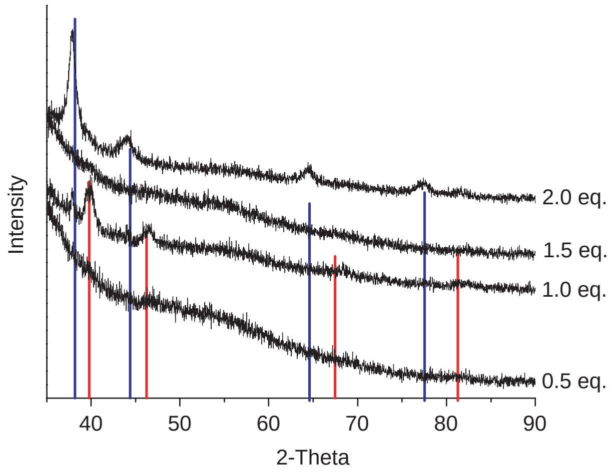

Figure 1 XRD analysis of Pt^0-(Cys)/nAu^{3+} reaction. 0.5–2.0 eq. of Au^{3+} added to 1.0 eq. of Pt^0-(Cys), precipitated, and scanned on a Scintag X_1 θ/θ automated powder diffractometer with a Cu target, a peltier-cooled solid-state detector, and zero background Si (510) sample support. Both line sets of standard diffractions are included for fcc Pt^0 (red lines) and Au^0 (blue lines). Reaction scheme for metathesis/transmetallation reaction between Pt^0-(Cys)/Au^{3+}

3 PEPTIDES

The main inspiration for the formation of nanoparticles from single amino acids arose from the fact that in nature, many particles are formed from short chain peptides that contain a cysteine or histidine amino acid.[1,2,20] These short chain peptides are principally used as a form of detoxification from the effects of high heavy metal ion concentrations *in vivo*. From these biological examples, the chemistry of these peptides has been expanded to form novel zero-valent and semiconductor nanoparticles under *in vitro* conditions (Figure 2).

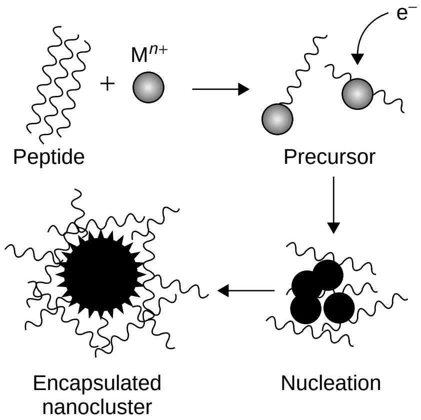

Figure 2 Biomimetic synthesis strategy for peptide encapsulated nanoclusters. Synthesis begins with complexation of peptide ligand to metal ion, followed by borohydride reduction of metal complex, nucleation, and formation of peptide stabilized nanocluster. 3.1 Glutathione (GSH)

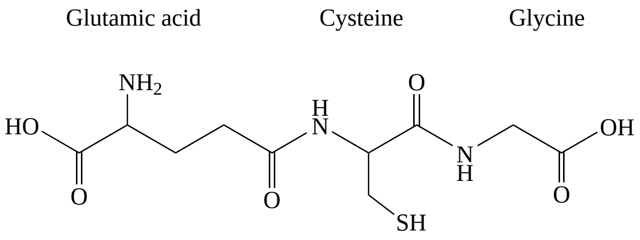
The simplest of all peptides used in the formation of biologically relevant nanoclusters is the reducing peptide GSH.[21] Glutathione is a peptide comprised of three amino acid residues with the sequence γECG (**1**).



(**1**)

With the free thiolate moiety, this peptide demonstrates similar surface chemistry to cysteine ligands, and as a result is available to bind to the surface of nanoclusters, Au^0, Ag^0, Cu^0, Pt^0, CdS, and ZnS.

3.1.1 Zero-valent Noble Metals

Glutathione has been shown to stabilize zero-valent gold nanoclusters through a gold thiol interaction. Whetten *et al.* have used various spectroscopic methods, from mass spectrometry to powder X-ray diffraction, to characterize these nanoparticles. A typical synthesis of Au^0-(GSH) particles starts with the formation of a Au(III)GSH complex which is reduced using a strong reductant to form the nanoparticles in a solution of 2:3 water:methanol. Mass spectrometry analysis of the Au^0 nanoparticle products revealed the zero-charged spectrum had a cluster mass of approximately 10 417 amu corresponding to a formula mass of $Au_{28}(GSH)_{16}$.[22] Powder X-ray diffraction revealed broad peaks which correlated to a face-centered cubic gold structure. Scherrer's analysis of the diffraction peaks estimated a core diameter of approximately 0.9 nm based on peak widths.[22] These glutathione encapsulated particles also showed a plasmon peak at 675 nm.[22] These results, armed with the proof that a GSH monolayer immobilized on a surface remained biochemically active to stabilize glutathione S-transferase on the monolayer,[23] gave rise to speculation that GSH encapsulated zero-valent nanoclusters can be used as a bioremediation agent *in vivo*.

In another study of Au^0-(GSH), Wright *et al.* have synthesized nanoparticles in a completely aqueous media under anaerobic conditions. Following the standard reduction preparations with sodium borohydride, gold nanoparticles were produced with a plasmon resonance band at 512 nm. Powder XRD analysis match a face-centered cubic lattice, while TEM showed that the particles had an average diameter of 4.5 ± 1.2 nm.[1]

Zero-valent silver nanoparticles have also been synthesized using GSH as a surface passivant. Under standard reducing conditions, a preformed Ag(I)GSH complex was reduced to form nanoparticles of Ag^0-(GSH). After isolation and purification of the nanoclusters, characterization showed a plasmon resonance band at 486 nm, a face-centered cubic lattice structure revealed by powder XRD, and a particle diameter of 8.6 ± 3.5 nm by TEM.[1]

Additionally, Pt^0 nanoclusters were synthesized with glutathione as a ligand. Upon reduction of a preformed Pt(II)GSH complex, nanoparticulate material of Pt^0-(GSH) was formed. These nanoparticles had an average diameter of 17.0 ± 6.2 nm and demonstrated no plasmon absorbance due to the electronic and dielectric properties of the metal.[8] Powder XRD analysis confirmed a face-centered cubic lattice structure for the material.[1]

Formation of zero-valent copper clusters with glutathione has been studied anaerobically. The ligand has been reported to provide a substantial degree of surface passivation. Reduction of a Cu(II)-GSH complex produced nanoparticles with a plasmon resonance band at 363 nm. These nanoparticles possessed a diameter of 9.7 ± 4.3 nm as demonstrated by TEM analysis.[1] Under aerobic conditions, the nanoparticles oxidatively degrade as evinced by the loss of the plasmon absorption band over time.

3.1.2 Metal Sulfide Nanocrystals

Glutathione has been shown to mediate the formation of CdS semiconductor nanocrystals. GSH encapsulated nanocrystals were first observed *in vivo* in the yeast *Candida glabrata* as a consequence of detoxification processes, when grown under conditions of high Cd^{2+}.[23,24] Mechanistic investigations revealed that the primary step-in CdS formation involved the chelation of glutathione to Cd^{2+} to generate a $Cd(II)\text{-}(GSH)_2$ precursor complex. Following complexation, inorganic sulfide was titrated in varying ratios (0.25 to 2.0) to determine the optimal ratio for nanocrystal formation. Ethanol precipitation mediated size separation of CdS nanoclusters in good yield.[25]

Mehra *et al.* noted a red shift in nanocluster absorption when different ratios of sulfide samples were compared. As the ratios increased, the UV–vis peak shifted toward the red corresponding to an increase in nanocluster size.[25] This was undoubtedly from the incorporation of more sulfide into the cluster core to form larger overall nanoparticles. For instance, a ratio of 0.75 (sulfide to cadmium) produced a product that absorbed between 319 and 346 nm, while samples formed from a ratio of 1.0 showed absorbances between 343 and 364 nm.[25] Using the Brus approximation, these nanoclusters had diameters of 22.8 Å and 24.6 Å, respectively.

Research has also been conducted on the ratios of GSH to cadmium for nanocluster formation. Clusters were formed at ratios as high as 1:1, but these reactions did not produce a uniform distribution of particles. In fact, the most reproducible

results arose from reactions with Cd:GSH ratios of 0.25 to 0.5. With these ratios, nanoparticles on the order of 10.7 to 20.3 Å were formed, respectively.[26] This small size regime displayed a unique photoreactivity.

Photolytically, CdS-(GSH) nanoclusters reduced *p*-nitrophenol[25] and methylviologen[26] by surface-mediated phenomena. This is most likely due to the potential of photo-generated electrons at the nanocluster surface. Samples with cadmium to sulfide ratios of <1.25 showed a better ability to reduce the organic molecule.[26] The rate of reduction was dependant upon the sample and the pH of the reaction. The reaction proceeded with similar kinetics at pH 8 and 9, while it was significantly slower at pH 10, degrading only 80% of the substrate.[25] Mehra has suggested that such photocatalytic systems may have environmental applications for organic remediation.

As expected, the formation of ZnS-(GSH) nanoclusters is analogous to CdS. Beginning with the $Zn(II)(GSH)_2$ precursor complex, nanocluster formation is initiated by the addition of the sulfide. Mehra *et al.* has shown that the precursor Zn(II)GSH complex does indeed closely follow the synthetic route of CdS-(GSH) nanoparticles.[27] Considering the similarities between the thiol chemistry of zinc and cadmium, studies to optimize ZnS nanocluster formation primarily focused on the ratio of zinc to sulfide ions in solution. Varying equivalents of sulfide (0.1–2.0) were studied for the formation of nanoclusters. An optimal ratio of Zn^{2+}:S^{2-} was obtained at 1:1. The average size of nanoparticles prepared at this ratio was shown to be about 3.45 ± 0.5 nm.[28] Elution profiles from SEC highlighted the dispersity of nanoparticle populations synthesized in aqueous solutions.[27] By size dependent absorption, the reaction mixtures revealed two cluster populations with an approximate diameter of 22.6 Å and 19.54 Å, respectively. Any excess of sulfide added greater than 1 equivalent was volatilized and not incorporated into the nanoclusters.[27]

Another common similarity between the CdS-(GSH) and ZnS-(GSH) nanoparticles was the ability to photoreduce methylviologen[27] and *p*-nitrophenol (PNP)[28] in solution. Under an inert atmosphere, reduction was evident from the clear formation of the characteristic spectrum of reduced methylviologen.[27] *P*-nitrophenol was similar in that an optimal reduction occurred when the ratio of PNP to nanocrystal was approximately five to ten. In fact, when the ratio was higher, a decreased reduction rate was evident. Over time, complete reduction of the PNP occurred.[28]

A third type of metal sulfide nanoparticle stabilized by GSH is Ag_2S. Ag_2S nanoparticle synthesis is challenging particularly in aqueous media due to the tendency to form bulk material rather than discrete nanoparticles. Mehra *et al.* have developed a standard synthesis for efficient production of this material. In this synthesis, silver ions are reacted with GSH to form a Ag(I)-$(GSH)_n$ complex (where n is undetermined) and after sufficient reaction time, the inorganic sulfide is added to the solution in stoichiometric amounts to induce nucleation of the silver sulfide core. Subsequently, the nanoparticles were precipitated using a size-selective precipitation method.[13] Under this preparation method, Mehra and coworkers have isolated nanoparticles of Ag_2S on the order of 9 ± 2.25 nm. Using HRTEM and SAED, the particles appeared as a highly ordered crystalline material. Furthermore, the electronic absorption spectra obtained from these nanoparticles showed a strong absorbance shoulder at approximately 300 nm.[13]

3.2 Phytochelatin Peptides

An analogue of glutathione is a group of peptides known as phytochelatins (PC). These multi-dentate chelating agents (*see Chelating Ligands*) have the chemical structure of $(\gamma\text{-EC})_n$G and are naturally found at rather high concentrations in yeast and plants in response to heavy metals (n ranging from 2 to 11).[23,24,29] The primary structural motif of the phytochelatins is the repeating cysteine subunit making it an excellent heavy metal chelator known to bind many heavy metal ions, including cadmium,[30] copper,[31] lead,[32] silver,[33] and mercury.[34]

Research, pioneered by Dameron and Winge, investigated the formation of CdS nanoclusters with phytochelatins. As with glutathione, synthesis begins with the formation of a stoichiometric metal/peptide complex dependent on the length of the phytochelatin peptide ($[\gamma\text{EC}]_n$G where $n = 2$–4) and the number of reduced cysteine binding sites. Molar equivalences of 0.5, 1 and 1 of peptide produced maximal complexation with peptides of n equal to 2, 3 and 4 respectively.[35] With the ratios of cadmium to peptide known, titrations of sulfide were analyzed for the formation of the nanocluster. The optimal equivalent was different depending upon the peptide used to passivate the nanocluster surface.[35] As an example, the phytochelatin with $n = 3$ was extensively studied for sulfide formation of nanoparticles. As sulfide was increasingly titrated, the absorbance band shifted until a maximal equivalence of 0.57 was added to solution. At this equivalence, the absorbance band became maximally shifted to 318 nm, with fluorescence activity at 430 nm.[35]

3.2.1 *Combinatorial Peptide Library Based upon Phytochelatins*

To understand the mechanistic formation of CdS nanocrystals using phytochelatins, a spatially addressable combinatorial set of peptides (Figure 3) was designed based on the $n = 3$ phytochelatin peptide by Spreitzer *et al.*[36,37] The library was comprised of 125 peptides with the sequence of **X**Cys**Y**Cys**Z**CysGly; whereby X, Y, and Z were varied with the spacer residues of α-Glu, γ-Glu, α-aminobutyric acid (GABA), SerGly, and ε-aminohexanoic acid (ε-Ahx). These linkages were chosen to attenuate the distance between cysteine binding sites by varying the spacing from 3.75 to 8.7 Å.

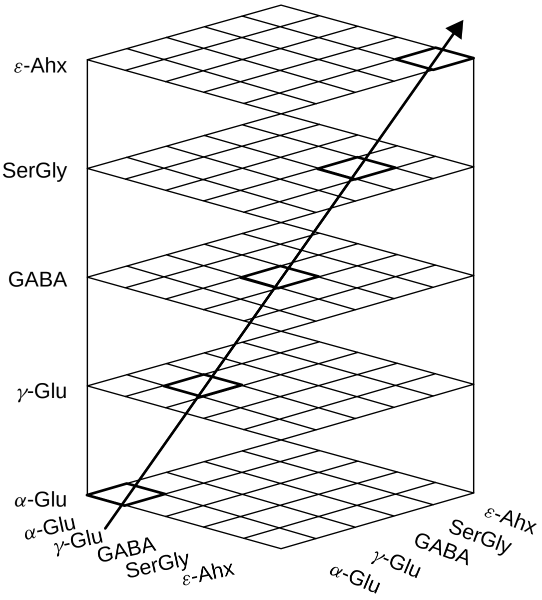


Figure 3 Spatially addressable combinatorial peptide library comprised of 125 peptides with the sequence of **X**Cys**Y**Cys**Z**CysGly, whereby X, Y, and Z are spacer residues of α-Glu, γ-Glu, GABA, SerGly, and ε-aminohexanoic acid (ε-Ahx). (Reproduced by permission of Wiley VCH)

Each peptide was screened for CdS nanoparticle stabilization and characterized by UV–vis, fluorescence, SEC, and photophysical properties to develop selection criteria. Size exclusion results showed nanoclusters with molecular weights of approximately 28 kDa consistent with a composition of 80 Cd atoms, 62 sulfur atoms, and 22 (γ-EC)$_3$G peptides.[36,38] Analysis of the characterization results showed that when an α-linked glutamic acid was substituted in all three positions (X, Y, and Z) and the cysteine spacing was kept small, smaller sized CdS nanoparticles were formed.[30] The analysis of the library elements suggest that the mechanism for nanocluster size selectivity is likely due to the various library peptides trapping growing CdS nanoclusters and the stability of these particles when the surface of the aggregate presents sites which match the spacing of the peptide and/or complex.

To further explore what properties of the stabilizing ligand controlled the distribution of cluster sizes, an informatic analysis based on quantitative structure activity relationships was performed. The results of such an analysis showed there was a correlation between nanocluster molecular weight and the dipole of the peptidyl ligand. Ligands with greater dipoles produced larger sized nanoclusters.[37] This analysis explains the differences in cluster size when different peptides were compared.[36]

3.3 Histidine-rich Peptide

Another important class of metal binding peptides conducive to the formation of metal nanoclusters are histidine-rich peptides. These proteins and peptides have been discovered in the digestive vacuole of the malarial parasite *Plasmodium*,[39] the vitellaria of the liver fluke *Fasciola hepatica*,[40] human saliva,[41] and blood serum;[42] and implicated in the biomineralization of copper, zinc, and heme.[43] In particular, a histidine-rich protein (HRP II) from *Plasmodium falciparum* is responsible for mediating the biomineralization of hemozoin crystallites by functioning as a nucleation template for heme. Examination of HRP II reveals a common repetitive binding domain with the sequence of Ala-His-His-Ala-His-His-Ala-Ala-Asp (HRE) within the protein scaffold.[39] Consequently, this 9-mer linear peptide epitope represents a versatile ligand for the synthesis and stabilization of various nanoclusters by offering several binding sites for metal ions and then multiple surface stabilizing groups.[43,44]

The HRE peptide was shown to mineralize a total of seven nanoclusters, ZnS, Au^0, Ag^0, Pt^0, Cu^0, TiO_2, and Ag_2S. All nanoparticles were formed by mixing appropriate ratios of metal to peptide to form a metal peptide precursor complex. To this solution, sulfide or reductant was added to form the appropriate encapsulated metal nanocluster. Condensation of titanium isopropoxide in the presence of HRE was used for synthesis of TiO_2-(HRE) nanoparticles. Once formed, all of the nanoclusters were characterized using UV–vis, IR, powder XRD, transmission electron microscopy, and an antigen capture assay.[1,2]

Each nanocluster possessed a UV–vis spectrum that was specific to each particle (Figure 4). The absorption maxima for the ZnS nanoclusters was observed at 288 nm with a blue shifted shoulder reminiscent of the spectra from the work of Mehra *et al.* using glutathione.[2,12] The noble metals of gold and silver displayed typical plasmon resonances at 524

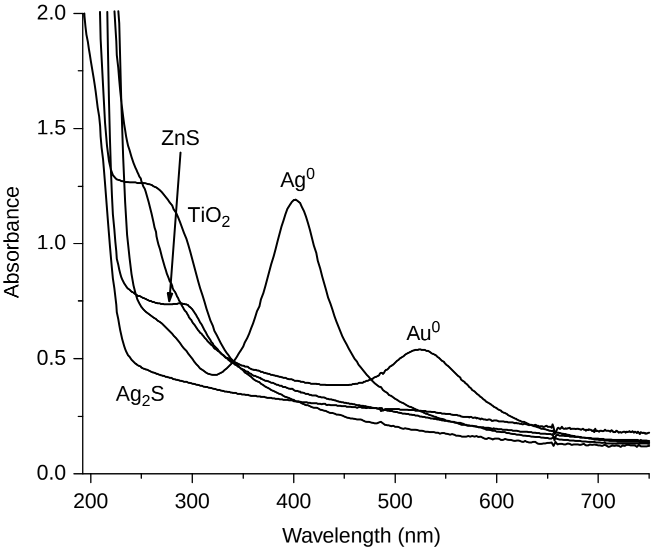

Figure 4 UV–vis absorption spectra of HRE peptide encapsulated nanoclusters. (Reprinted with permission from Ref. 2. © 2002 American Chemical Society)

and 402 nm respectively confirming nanoparticle formation.[2] For nanoparticles of copper and platinum, plasmon resonance bands were observed at 574 nm and 317 nm respectively.[1] Furthermore, the novel TiO_2 nanoclusters absorbed at 282 nm, and are of great interest since they represent the only water-soluble example yet reported. Finally, the Ag_2S nanoclusters displayed no absorbance within the scanned regime.[2]

IR analysis confirmed the existence of peptides bound to the nanocluster surface. Vibrations attributed to the histidine side chains as well as from the amide stretches were present in the purified nanocluster spectra. Also, a loss of the N–H stretching band of histidine was noted, indicating a coordination mode for the peptide-metal nanostructures.[1,2] This analysis confirmed the attachment of the HRE peptide to the surface.

Powder X-ray diffraction showed that most of the clusters formed, ZnS, Au^0, Ag^0, Pt^0, Cu^0, and Ag_2S, were crystalline with the exception of the TiO_2 nanoclusters which showed no discernable crystalline pattern. The lack of crystallinity for the titania was most likely a consequence of the synthetic route adopted. Transmission electron microscopy revealed average nanocluster sizes of 3.1 nm for ZnS, 9.5 nm for Au^0, 11.2 nm for Ag^0, 7.9 nm for Pt^0, and 11.3 nm for Ag_2S.[1,2]

The most fascinating aspect of these biomimetically derived clusters was the biological activity of the HRE peptide recognition elements incorporated onto the nanocluster surface. A commercially available ***Para***sight F test for HRP II of *P. falciparum* malaria was used to screen for antibody recognition of the peptide encapsulated nanoclusters. Consequently, the HRE encapsulated nanoclusters of ZnS, Au^0, Ag^0, Pt^0, and Cu^0 elicited a monoclonal antibody response. This suggests that the HRE peptides adopt a suitable conformation along the surface by repeating itself as multiple epitopes.[1,2] Negative results were observed for TiO_2-(HRE) and Ag_2S-(HRE) due to surface anomalies associated with the crystal lattice structures making it unrecognizable to the antibody.

To study the nonspecific interactions between the metal-HRE peptide interface and a nickel chelating surface, an affinity assay for histidine was conducted. In this study, a nickel nitrolotriacetic acid complex coated on a commercially available well plate (Xenopore) was incubated with Au^0-(HRE), Ag^0-(HRE), and ZnS-(HRE) nanoparticles. Assuming the HRE peptide has histidine residues not involved in surface stabilization and are presented toward the bulk solution, then nanocluster binding to the plate would occur through Ni-(His) coordination. Binding of HRE stabilized nanoparticles was highlighted by binding efficiencies of 79% and 42.4% for silver and gold, respectively. Ni surface binding of ZnS-(HRE) was observed by fluorescence microscopy (Figure 5). These results indicate the presence of uncoordinated histidine residues on the surface of the particles which are available to interact with the nickel surfaces. This also suggests that the peptide interface presented two types of histidines; one type stabilizing particle formation while the opposing type interacted with the nickel coated well plate.[1]

3.4 Phage Displayed Peptide Libraries

A novel method for the elucidation and isolation of random polypeptides with the ability to form nanoparticles is through phage display (Figure 6). In this process, randomized peptides of the same length are expressed along the coat protein of a nonpathogenic virus. The virus then infects a bacterial sample upon which it rapidly multiplies to yield a vast quantity of phage particles which are then ‘biopanned’ on receptor surface to determine which peptides on the coat binds to the surface. Nonbinding phages are washed away while binding phage are amplified and the process repeated with increasingly stringent elution conditions.[45] Ultimately, only those peptides most strongly associated with the substrate remain. Using this technique, peptides have been discovered that bind to a metal or metal oxide surface that can further be used to form nanocluster surfaces.[46–48]

3.4.1 Silver Selected Peptides

Phage display was used to screen peptides for the directed self-assembly of zero-valent nanoclusters in which silver

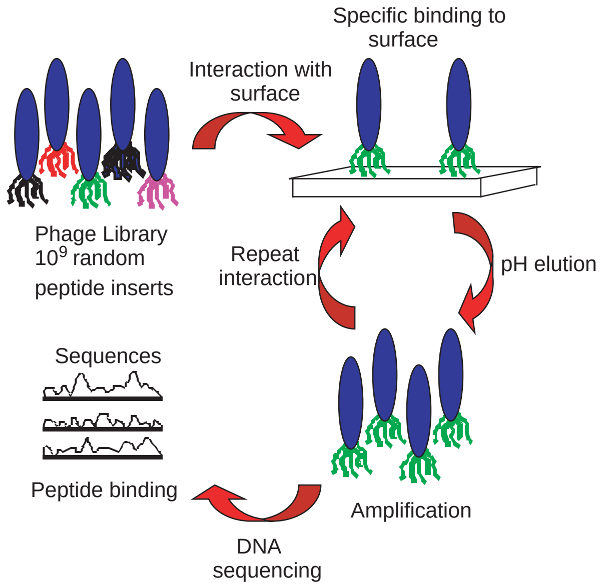

Figure 6 Phage display peptide selection for electronic materials. Random peptides are expressed on the minor phage coat representing 10^9 peptide sequences, peptides are screened for binding affinity to metal surfaces, phages that bind with a specific sequence are eluted from metal surface by lowering pH and amplified by infecting *E. coli* hosts. The amplified phages are reexposed to metal substrate to maximize substrate specificity and binding. This selection process is further repeated to select for the peptide with the highest binding affinity. Finally, the phage DNA is sequenced to reveal the peptide binding sequence

particles were used as the metal substrate surface. From this analysis, three peptides were isolated with the ability to bind to silver surfaces. These peptides (AG3 - AYSSGAPPMPPF, AG4 - NPSSLFRYLPSD, and AG5 - SLATQPPRTPPV) were isolated and further studied for their ability to generate and reduce silver ions to novel zero-valent silver nanoclusters without the addition of any external reductant.[47]

The properties of the isolated peptides were quite similar in nature, whereby each peptide consisted of 12 amino acids in length and possessed a number of residues with functional side groups that could stabilize nanoclusters. In many instances, these side chains were the hydroxyl-terminated side chains of serine, threonine, and tyrosine. In two of the peptides (AG3 and AG4), the location of the hydroxylated amino acids was conserved within two of the peptides. Similarly, one proline amino acid was conserved throughout all three of the sequences.[47]

Upon incubating each peptide in a solution of silver nitrate with *no* exogenous reductant, a clearly observable plasmon resonance peak arose at 440 nm for AG3 and AG4, but not with AG5. The peak was quite broad, indicative of a disperse size and shape distribution.[49] The main difference between the active peptides and inactive AG5 was an overall basic isoelectric point for AG5.[47] The assays were performed at neutral conditions which would modulate the side-chain dynamics under acidic or basic conditions.

TEM analysis of the nanoparticles produced a wide distribution of sizes between 60 and 150 nm in diameter (Figure 7). Also, different morphological structures of Ag^0 particles were observed which included spherical, triangular, and hexagonal shapes.[47] This broad size distribution and variety of shapes concurred with the broad and tailing plasmon peak of the UV.

3.4.2 Silica Precipitating Peptides

In addition to selecting peptides for metal substrates, phage display methods successfully identified peptides capable of forming silica nanospheres. Recently, many groups have isolated proteins and peptides responsible for the *in vivo* production of silica.[50,51] Stone and coworkers have isolated additional novel peptides using phage display that are capable

of yielding similar structures under ambient conditions.[46] The isolated peptides were incubated in monosilicic acid for five minutes at neutral pH conditions using phosphate buffer, and as a result formed large silica nanoparticles on the order of approximately 500 nm.[46] From this assay, Stone *et al*. were able to elucidate the characteristics of the peptides that could produce silica nanospheres (Figure 8). All of the peptides possessed hydroxyl amino acids (mostly serine), basic amino acids (lysine or histidine), and had an overall basic isoelectric point.[46]

3.4.3 *Metal Sulfides*

Belcher *et al*. were able to isolate specific peptides able to direct the synthesis of crystal specific metal sulfide (CdS and ZnS) nanoparticles through phage display.[48] In this study, phages were panned against crystal surfaces, and those which bound were isolated and amplified for further characterization. Two different peptide lengths were studied, a linear 7-mer peptide and a constrained 12-mer. Interestingly, this technique elucidated two different peptide sequences capable of directing the synthesis of CdS and ZnS, one set for each metal sulfide. The peptides specific for CdS did not bind ZnS and vice versa.[48]

The set of 7-mer peptides showed a binding motif in which the arrangements of proline, methionine, and positively charged amino acids (R, H, K) were required for binding to ZnS surfaces. The set of 12 cyclic amino acid peptides (Figure 9) showed similar patterns, positively charged amino

acids/proline, followed by methionine or hydroxyl amino acid residue.[48] This similarity is of interest to note because of the fact that two different phage displayed constructs showed similar binding motifs indicative of the overall understanding of peptide binding to ZnS surfaces.

When specific phages were incubated with nanoparticle reactants, lattice specific ZnS crystals were synthesized. The Z8 phage clone (H_2N-LRRSSEAHNSIV-CO_2H) generated nanoparticles of 4 nm in diameter, while phage A7 peptides (H_2N-CNNPMHQNC-CO_2H) grew crystals of 4 nm by 2 nm in size. Through subsequent characterization, it was elucidated that the A7 clone grew crystals of ZnS with a wurtzite lattice structure, while the phage Z8 produced ZnS nanocrystals with a zinc blend lattice.[48] This characterization gives credence to the biological formation of different crystal structures through different interactions of peptides with metal and metal sulfide surfaces. This specificity is most likely the mechanism through which nature uses to produces intricate structures that are biologically relevant.

4 PROTEIN TEMPLATES

There are a number of physiological functions in organisms that necessitates the biosynthesis of nanoparticles ranging from metal regulation/storage to detoxification to structural assemblies. Consequently, the production of nanoparticles is mediated by various types of protein templates suited to guide nanoparticle formation and function. For instance, they provide a spatially delineated cage which confines nanoparticle synthesis to the physical dimensions of the protein cavity, while encapsulating the newly formed nanoparticle. Additionally, proteins serve as scaffolds for the directed assembly of metal nanostructures. With the current advancements in molecular biology; proteins can be readily expressed, cloned, mutated, and purified, offering an accessible means toward the biomimetic synthesis of inorganic nano-materials. The first protein system shown to mineralize metal nanoparticles was the well known iron storage protein ferritin. By using ferritin as a model template, proteins not typically associated with metals were crafted to mimic ferritin's activity.

4.1 Ferritin Protein

Ferritins are a ubiquitous class of robust proteins involved in the biomineralization of iron oxide particles. Structurally, the protein shell is assembled from 24 peptide subunits (4 helical bundles) of repeating H and L chains which form the fundamental spheroidal shape; provide a large spatially arranged compartment (9.0-nm diameter) for mineralization; and generate hydrophilic and hydrophobic channels with openings of 0.5 nm that lead directly to the cavity

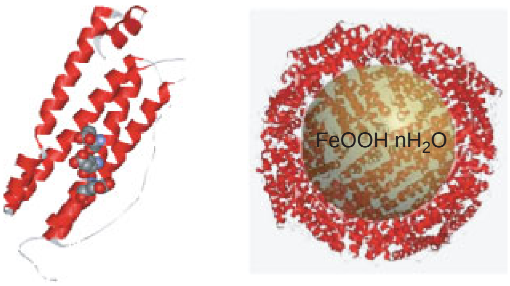

Figure 10 Four helix bundle of the L chain of ferritin showing iron oxide nucleating site (Glu61, Glu64, and Glu67). Quaternary structure of ferritin displaying mineralized ferrihydrite particle

(Figure 10).[52] Besides serving as structural components, each chain performs a complementary function in terms of processing cellular Fe^{II}. Primarily, the H chain catalyzes the oxidation of Fe^{II} to Fe^{III} at a dinuclear ferroxidase site; whereas the L chain contains a putative iron oxide nucleation domain integrated within the 4-helix bundle subunit.[52] This site consists of three glutamic acid residues (Glu 61, 64, and 67) along a helix face directed toward the interior of the protein (Figure 10).[53] As a result, an abundance of iron binding sites with negative charge density is organized within the protein cavity facilitating nucleation of discrete ferric oxyhydroxide mineral cores. Upon forming cores along the protein interior, further mineralization proceeds through an autocatalytic reaction.[52]

Indeed, the protein cage is archetypal in biomineralization by offering a controlled reaction environment that minimizes oxidative hydrolysis anywhere other than within the confines of the protein cavity.[52] Additionally, the soluble protein coat encapsulating the iron mineral prevents the ripening of these particles into larger insoluble aggregates. These inherent properties as well as structural features have prompted an interest in ferritin as a template in the biomimetic synthesis of a collection of various nanoparticles. This collection consists of Fe_3S_4/Fe_2S_3,[54] Fe_3O_4,[55] α-MnOOH,[56] Co(O)OH,[57] UO_2,[58] and CdS[59] nanoparticles.

Ferritin induced nanoparticle synthesis was adapted from a number of different synthetic strategies reliant upon the physical nature of ferritin. For instance, ferritin can readily exist in two stable forms (native ferritin with an intact iron oxide core or apo-ferritin lacking a mineral core) owing to the enhanced structural integrity of the protein shell. As a result, two general reaction schemes were adopted. The first route utilized the iron oxide core of native or reconstituted ferritin as a precursor to different mineral phases and types of iron nanoparticles, while the second invokes mineralization within the empty cavity of apo-ferritin. In the latter approach, the native protein must be demetallated by reductive dissolution with thioglycolic acid to yield apo-ferritin.[58] Ultimately, apo-ferritin provides a widely applicable means to the synthesis of various nanoparticle compositions under many conditions.

Recently, Mann *et al.* have successfully shown the *in situ* biomineralization of iron sulfide nanoparticles from both native and reconstituted iron oxide cores of ferritin by utilizing the permeability of the protein for a sulfur containing source.[54] Basically, a source of aqueous Na_2S was introduced to a de-aerated solution of native (3000 Fe atoms) or reconstituted (500 Fe atoms) horse spleen ferritin under acidic conditions. After 40 min, the iron oxide core had been transformed into an amorphous iron sulfide particle.[54] The particles were characterized by TEM and revealed average sizes of 6.5 nm and <2 nm in diameter for the native and reconstituted ferritin derived reactions. Further analysis by ^{57}Fe Mössbauer spectroscopy indicated some structural and magnetic ordering of the iron sulfide product (effective oxidation state +2.5) from the reconstituted based reaction.[54] In contrast, the native ferritin product was determined to possess a +3 oxidation state, tentatively identified as 'Fe_2S_3'. From these results, it was hypothesized that the reaction of iron oxide with sulfide proceeds according to the following steps: rapid surface adsorption of sulfide, formation of surface bound ferric sulfide, electron transfer, and dissolution of Fe^{II}.

In a parallel reaction, the synthesis of an ancillary magnetic phase of iron oxide, magnetite, was explored as a means to determining structural specificity occurring during mineralization processes.[55] Also, this would provide an alternative synthetic approach to the development of potential contrast agents for magnetic resonance imaging of tissue, cell labeling, and separation techniques. However within the cavity of ferritin under physiological conditions, the antiferromagnetic mineral form of ferrihydrite ($FeOOH{\cdot}nH_2O$) is kinetically favored leading to its preferential mineralization, as it provides a functional source of labile iron for metabolic use.[55] Synthetically, the controlled formation of magnetite was achieved by the slow oxidation of Fe^{II} over ten sequential additions to apo-ferritin at relatively high temperatures (60 °C) and pH (8.5).[55] The resultant encapsulated particles were spherical with diameters of 6.0 ± 1.2 nm. Exposure to air resulted in a phase transition of the core to maghemite (γ-Fe_2O_3). This synthesis was also further optimized to mineralize only magnetic iron oxide phases, magnetite, and maghemite.[60] Mann *et al.* performed the mineralization under purely anaerobic conditions and stoichiometric amounts of an oxidant, trimethylamine-N-oxide.

In an attempt to elucidate the efficacy of non-iron substrates, the biomimetic synthesis of MnOOH was demonstrated with apo-ferritin templates. The reconstitution of ferritin with manganese oxide was performed by addition of $MnCl_2{\cdot}4H_2O$ at an optimal pH of 8.9–9.2 with theoretical loading of between 1000 to 3000 Mn atoms.[56] Consequently, the synthesis showed signs of non-mineralized proteins and a significant degree of nonspecific oxide precipitation of crystalline Mn_3O_4 in the bulk. This was attributed to isolated and sporadic nucleation events, little or no oxidase activity for Mn ions, and an equivalent mineralization rate for Mn ions without ferritin present in the bulk solution.[56]

Additional metal precursors were examined because of the limited mineralization and deposition of MnOOH particles by ferritin. In particular, Co(O)OH particles were synthesized within ferritin from Co^{II} and H_2O_2 as an external oxidizing agent.[57] The reaction was performed via a stepwise synthesis of the mineral core and monitored by a pH-stat autotitration. Results from the autotitration provided mechanistic detail, whereby it was determined that 2.1 protons are released per Co^{II} in the 2 electron reduction of H_2O_2 to Co^{III} which subsequently underwent hydrolysis.[57] The oxidative hydrolysis proceeded rapidly and was confined entirely within the protein cavity as confirmed by the absence of bulk precipitation with the subsequent addition of excess oxidant.

Undoubtedly the most unlikely substrate for ferritin is UO_2^{2+}, however, the implications of biomimetically synthesizing uranium oxide loaded ferritin could have use in neutron capture therapy. The synthetic approach utilized ion binding of $UO_2(O_2CCH_3)_2$ according to a known stoichiometry of 12 ions per ferritin molecule, followed by hydrolytic polymerization of metal ions within apo-ferritin.[58] Characterization by TEM analysis confirmed dense cores of polymerized uranyl oxyhydroxide particles of 6 nm in diameter.

4.2 Ferritin-like Proteins

Interestingly, in the bacterium of *Listeria innocua*, protein systems similar to ferritin have been discovered to possess a cage-like structure.[61] Comparatively, this unusual protein is comprised of only 12 peptide subunits and is substantially smaller in magnitude than native ferritin. As a result, these structural characteristics generate an interior cavity with dimensions of 5 nm capable of holding a maximum of 500 iron atoms (4500 Fe atoms for ferritin). Douglas *et al.* have exploited the smaller cage of this protein in the synthesis of ferromagnetic iron oxide particles following the controlled oxidative hydrolysis method described above.[61] As expected, the mineralized product was 4.4 ± 1.1 nm in diameter according to TEM and identified as the cubic iron oxide phase (γ-Fe_2O_3) by selected area diffraction, consistent with results obtained from the native ferritin system.[61]

Additionally, the *L. innocua* ferritin-like protein served as a template for the controlled mineralization of two cobalt oxide phases Co(O)OH and Co_3O_4 under two reaction temperatures of 23° and 65 °C, respectively.[62] Substantial differences in crystallinity of the cobalt mineral core was observed between the two synthetic routes. The mineralization reaction carried out at higher temperatures yielded more crystalline nanomaterials, while the low-temperature synthesis tended toward amorphous material. The high crystallinity obtained at higher temperatures is most likely due to removal of structural waters present in the protein cavity and the surpassed energy barrier of nucleation at 65 °C.[62]

Synthetic modifications to native ferritin also provided a ferritin-like protein with different intrinisic properties, functions, and mineralization abilities. The exterior protein shell of ferritin was modified by an alkylation reaction using long chain primary amines (C_n, $n = 6$, 9, 12, 14, 18) covalently coupled by nucleophilic substitution at carbodiimide-activated carboxylic acid groups on the protein surface.[63] This resulted in a hydrophobically modified protein that exhibited significant solubility in organic solvents such as dichloromethane. However, reconstitution of the alkylated protein with Fe^{II} was ineffective at *in situ* cavity mineralization of discrete iron oxide cores due to the modified surface chemistry.[63]

4.3 Heat Shock Proteins

Heat shock proteins (Hsp) represent an essential class of proteins which act as molecular chaperones to partially denatured proteins.[64] These proteins are rapidly expressed in all organisms at increased levels in response to cellular stresses such as elevated temperatures, chemical or heavy metal exposure, pH extremes, osmotic variations, and infection or disease state.[65] As a consequence of these external stimuli, normal proteins are then susceptible to unfolding of their native conformational structure. Fortunately, small heat shock proteins favorably interact and stabilize the damaged target protein preventing mutual association, irreversible aggregation, and precipitation of proteinaceous plaques.[65] The Hsp-protein complex forms through the interactions of exposed hydrophobic residues of the damaged protein with the hydrophobic pocket of the heat shock protein. This maintains the solubility of the damaged protein by encompassing it within a structurally defined pore comprised of two supramolecular rings with each ring composed of 7–9 complementary protein subunits with molecular weights of 60 kDa.[65] Conceptually, this pore presents a template conducive toward biomaterials synthesis.

Only recently have heat shock proteins been used in the stabilization of nanoparticles. Aida *et al.* have demonstrated the inclusion of already preformed CdS nanoparticles within the chaperonin proteins of GroEL from *Escherichia coli* and *T.th* cpn from *Thermus thermophilus* HB8.[66] These proteins were chosen as a result of sharing similar structural characteristics: (1) tubular structure measuring 14.6 nm in length, (2) cylindrical cavity with a 4.5-nm diameter, and (3) stability to adverse conditions (pH and temperature). *T.th* cpn, however, contains an additional bowl-shaped capping protein.

The protein-nanoparticle complex was prepared by adding a dimethylformamide (DMF) solution of preformed CdS nanoparticles ranging from 2 to 4 nm to a solution of heat shock protein. As a result, the CdS nanoparticles diffused into the heat shock pore analogous to a damaged protein over a period of 100 h. TEM analysis revealed that as much as 75% of the proteins contained a single discrete nanoparticle core of CdS. Upon subsequent inclusion, the CdS complex displayed intense photoluminescence from 430 to

720 nm for as long as 400 days with GroEL. Additionally, when subjected to heating-cooling cycles over the range of 4–80 °C, the photoluminescence of the *T.th* cpn-CdS complex was quenched at 80 °C but quickly recovered to its original intensity after cooling to 4 °C.[66] In contrast, CdS particles not stabilized by proteins showed an irreversible photoluminescence profile at only 30 °C. The enhanced thermal stability of the *T.th* cpn-CdS complex is entirely dependent on the chaperonin protein.

In an innovative experiment, these protein encapsulated nanoparticles were shown to be responsive to the action of adenosine 5′-triphosphate (ATP) (Figure 11).[66] Inherently, chaperonin proteins react to the binding of ATP in the presence of Mg^{2+} and K^{+} by inducing a comformational change in the protein structure. This mediates the opening of the pore and subsequently releases the guest proteins. By analogy, CdS nanoparticles were released upon ATP binding as monitored by size exclusion chromatography. The SEC elution profile showed a peak corresponding to the *T.th* cpn protein and an additional broad peak attributed to ATP and its hydrolyzed products.[66] More importantly, the fluorescence of CdS was absent, consistent with its release from the protein cavity.

The concept of using heat shock proteins as templates for nanoparticle assembly was further explored by Trent *et al.* through genetic manipulation of the 9 β subunits of a heat shock protein isolated from the thermophillic organism of *Sulfolobus shibatae*.[67] This protein offered numerous benefits which made it an optimal system for study; such as stability to adverse conditions, self-assembly into regular double-ring (each ring contains 9 β subunits) structures driven by ATP and Mg^{2+}, and a propensity to crystallize into higher-order periodic structures of 2-D crystals up to 20 μm in diameter.[67]

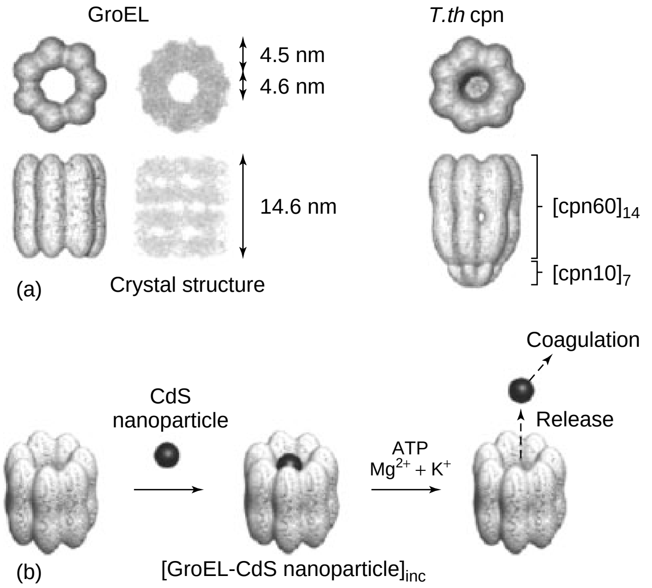

Figure 11 Strategy for nanoparticle inclusion/release by chaperonin protein templates. (a) Structural representation of chaperonin proteins, GroEL, and *T.th* cpn. (b) Scheme depicting inclusion of CdS nanoparticles within chaperonin cavity and their triggered release from the cavity by ATP. (Reproduced by permission of Nature Publishing Group (www.nature.com))

Prior to use as a nanoparticle template, the β subunits were genetically modified by adding cysteine residues at different solvent exposed sites to yield two mutant variations of the β subunits. The two variations consisted of β subunits with exposed 28 amino acid loops and β subunits with these amino acid loops deleted. These β subunits were then assembled into chaperonin proteins upon Mg^{2+}/ATP binding and crystallized into a reactive protein template with a ring of thiol groups that protruded into the protein pore to different extents (3 nm and 9 nm pore diameters).[67]

The two variations of chaperonin proteins containing different pore diameters were used in the size-selective discrimination of Au^0 nanoparticles (5, 10, 15 nm diameters) and CdSe–ZnS quantum dots (4.5 nm). Experimentally, protein samples in hexagonally packed 2-D crystals were applied to formvar coated TEM grids producing a hydrated protein template attached to the TEM substrate. This was followed by additions of aqueous gold nanoparticles passivated with bis(p-sulfonatophenyl)phenylphosphine ligands of a particular size. Dependent on the pore diameter, appropriately sized particles either subsequently bound the interior thiol groups of the protein template or were physically restricted. This was definitively demonstrated by the inclusion of only 5 nm Au^0 particles within the mutant protein possessing a 3-nm pore diameter, and the occlusion of 10 and 15 nm particles.[67] In contrast, the proteins with pores of 9 nm in diameter bound predominantly 10 nm Au^0 particles with partial signs of random binding with the 5-nm and 15-nm gold. Core shell CdSe–ZnS particles of 4.5 nm stabilized by trioctyl phosphine oxide (TOPO) were unevenly distributed on the chaperonin templates with 3 nm pores.

This heat shock protein system was also used as a biomimetic template for the synthesis of metal nanoparticles based on the reduction of protein stabilized metal precursor complexes. Accordingly, a heat shock protein template was designed by Jonathan Trent (NASA Ames Research Center) with small peptide binding sites, histidine-rich peptide epitopes (HRE) of AHHAHHAAD previously reported to stabilize a variety of metal nanoparticles, integrated into the central pore of the ((HRE)-Hsp) protein. This served to potentially revert the natural function and hydrophobicity of the protein pore as well as provide nine selective HRE metal binding domains that project into the cavity (1 HRE peptide per β subunit/9 HRE peptides total per protein). Recently in our lab, we prepared nanoparticle/(HRE)-Hsp complexes by saturating the HRE peptides with metal ions of Au^{3+}, Ag^{+}, or Zn^{2+} that would load the heat shock pore. This was followed by standard borohydride reduction or inorganic sulfide addition resulting in Au^0, Ag^0, or ZnS

nanoparticles confined within the heat shock protein cavity (unpublished).

Consequently, the synthesis of protein encapsulated nanoparticles within the heat shock cavity resulted in $<10\%$ of the proteins associated with a nanoparticle (Figure 12). This suggests that the diffusion of hydrated metal precursor ions into the pore was limited by the hydrophobic environment of the protein pore. Ultimately, the integrated HRE peptides within the protein cavity failed to lessen the hydrophobic barrier, and as a result provided ineffectual binding domains for the hydrated metal ions of Au^{3+}, Ag^{+}, and Zn^{2+}. To compensate for the hydrophobic nature of the protein pore, an insoluble Au^{I} precursor complex of $AuClP(CH_3)_3$ was used. The (HRE)-Hsp template was saturated with $AuClP(CH_3)_3$ through (nonspecific/HRE) binding and adsorption of gold. Association with the protein induced solubilization of the chlorotrimethylphosphinegold (I) compound, and upon reduction with $NaBH_4$ resulted in a gold nanoparticle decorated protein. The TEM micrograph of the Au^0/(HRE)-Hsp structure (Figure 9) reveals a discrete Au^0 particle confined within the heat shock pore and surrounded by gold particles bound to the protein surface at each of the nine HRE modified β subunits through nonspecific interactions.

Analogously, Douglas *et al.* have used a small 24 subunit heat shock protein isolated from the hyperthermophillic archaeon, *Methanococcus jannaschii*, as a biomimetic template for the oxidative mineralization of iron.[68] Both the wild type and a mutant (glycine at position 41 replaced for cysteine) exhibited ferrihydrite mineralization as determined by an increase in the ligand to metal charge transfer absorbance at 400 nm and the presence of discrete iron oxide particles of 9.0 ± 1.2 nm in diameter from TEM.

5 VIRUSES FOR NANOPARTICLE SYNTHESIS

Viruses represent another example of viable nanoparticle templates resulting from their structural polymorphism and defined composition. In general, viruses exist in a variety of sizes and morphologies ranging from 30 nm spherical viruses to 300 nm rod-like structures. Additionally, all viruses are comprised of a compact self-sustaining packet of genetic material enveloped within a functional protein capsid ideally suited for their survival and propagation. The protein capsid functions by protecting the genome, releasing nucleic acids upon host infection, recognition, and reassembly/externalization of progeny virions. Each related function occurs by highly coordinated large scale structural changes to the capsid such as covalent cross-linking between neighboring subunits and modifications in the secondary and tertiary protein structures. Ultimately, these characteristics have inspired the directed synthesis of nanoparticles using numerous viral templates that results in highly ordered nanoparticle arrays or spatially confined particles.

5.1 Mosaic Virus Templates

5.1.1 Tobacco Mosaic Viruses (TMV)

TMV primarily affects tobacco plants by infecting the leaves and roots system of predisposed cultivars. The virulence is manifested in a mottled appearance or mosaic pattern on leaves and inevitably the inhibition of normal growth. TMV is derived from a Japanese strain and attributed to worldwide losses of tobacco crops.[69] In particular, TMV particles contain 95% proteins and 5% nucleic acids. The proteins that compose the viral envelope and genome compartment consist of 2130 identical coat protein molecules in total which follow the right-handed helix of an associated RNA strand. The orientation of identical proteins generates a 300-nm long hollow cylinder defined by an 18-nm outer diameter and 4 nm inner diameter.[69] The dimensions and repeating proteins presented along the viral surface provided a template for the biomineralization of nanoparticle arrays as documented by Mann *et al.*[70]

Exposure of wild-type TMV to $[AuCl_4]^-$, $[PtCl_6]^{2-}$, and Ag^+ precursors, followed by hydrazine reduction and photoreduction yielded viruses decorated with zero-valent nanoparticles. Reduction of $[AuCl_4]^-$ and $[PtCl_6]^{2-}$ by hydrazine at an acidic pH induced nucleation at the positively charged lysine and arginine residues along the outer surface of the viral template. As a result, Au^0 and Pt^0 spheroidal nanoparticles of 8.6 ± 3.0 nm and 2.5–5.0 nm, respectively, were locally externalized at the virus surface with Au^0 TMV surface illustrated in (Figure 13).[70] Under basic conditions, the positive charges on the surface were reduced while the negative charges of glutamate residues lining the 4-nm channel wall increased, thus promoting the binding of positively charged Ag^+ along the channel interior. Upon photoreduction

of Ag^+, linear arrays of Ag^0 nanoparticles less than 5 nm in diameter were spatially organized within the virion channel.

Virion templates of TMV were also used in combination with different synthetic routes for CdS, PbS, and Fe oxide nanoparticles.[71] Nanoparticle-virion tubules were prepared by reacting a buffered solution of TMV in $CdCl_2$ (pH 7) or TMV in $Pb(NO_3)_2$ (pH 5) with H_2S gas. The formation of metal sulfide nanoparticles occurred over 6 hours as observed by a uniform coating of CdS and PbS nanocrystals on the TMV surface from TEM analysis. Selected area electron diffraction of the mineralized products indicated a zinc blende crystal structure for CdS particles and a rock salt structure for single domain PbS nanocrystals. The iron oxide nanoparticles were mineralized by the TMV templates by the oxidative hydrolysis of an Fe^{II}/Fe^{III} acidic solution with NaOH.[71] Consequently, a mineral coating of irregular ferrihydrite particles grew on the surface to a thickness of 2 nm.

5.1.2 Brome Mosaic Viruses (BMV)

Brome mosaic viruses (BMV) readily infect different varieties of grasses and to a minor extent maize. Collectively, BMV is among the smallest viruses with an icosahedral protein capsid of 27 nm in diameter, and in contrast to most other viruses, is cationic at pH below 6.5.[72] The architecture of the capsid portion of the virus is constructed from 180 protein capsomeres that are independently stabilized by weak electrostatic interactions with the negatively charged RNA core (3234, 2865, 2114, and 876 nucleotides).[72] Kao *et al.* have developed an approach to replacing this RNA core with negatively charged citrate stabilized Au^0 particles with the intentions of incorporating a potential spectroscopic probe into the virion cavity for the study of single virus particles.[73]

Kao *et al.* performed the replacement of the RNA core of BMV particles with 2.5–4.5 nm Au^0-(citrate) nanoparticles by sequentially disassembling the BMV virions into individual capsomeres, reassembling the BMV virions in the presence of Au^0 nanoparticles, and purifying the resultant BMV encapsulated Au^0 particles.[73] As determined from TEM micrographs, only 2% of the viral capsids appeared to be functionalized with gold nanoparticles. However, some of the functionalized virions contained a pair of Au^0 particles enclosed within the same capsid. Pairing of Au^0 particles was illustrated by a dark-field optical micrograph (Figure 14), whereby the scattered intensity of the brighter spots indicated a Au^0 nanoparticle pair and the lesser intensity was representative of a single gold particle.[73]

5.2 Cowpea Chlorotic Mottle Viruses (CCMV)

As a close relative to the brome mosaic virus; the cowpea chlorotic mottle virus (CCMV) possesses an outer diameter of 28 nm, is assembled from 180 subunits that create an icosahedral type structure, and contains an RNA core.[72,74] Another similarity is the cationic interior surface of the viral capsid which is formed from subunits with highly basic N-termini (6 positively charged arginine and 3 lysine residues) that project into the cavity and stabilize the RNA core.[75] However as a potential biomineralization template, the electrostatic environment of the virion cavity precludes any cationic metal precursors and thus limits its applicability for nanoparticle synthesis.

Recently, Young *et al.* have designed a CCMV virion cage with an anionic interface that favorably binds Fe^{II} and Fe^{III} ions and then subsequently controls the oxidative hydrolysis to size-constrained iron oxide minerals.[75] The anionic cage was prepared by genetically replacing the 9 basic residues

at the N-terminus with glutamic acid groups yielding a total of 1620 corresponding anionic binding sites. Based on the synthesis of the iron oxides in ferritin, the modified virus was initially loaded with approximately 2000 iron atoms and air oxidized to yield an iron oxide particle size of 8.2 ± 1.6 nm according to TEM. The virion encapsulated particles were further subjected to iron oxide mineralization by additions of 6000 iron atoms per cage which resulted in nanoparticles with an average size of 24.0 ± 3.5 nm that completely occupied the volume of the cavity (CCMV inner diameter 18–24 nm). To establish the significance of the mutations, the wild-type CCMV empty protein cage (cationic interior) was substituted for the mutant virus in iron oxide mineralization experiments. As expected, the wild-type protein exhibited a lack of control in iron oxide mineralization as observed by bulk precipitation, demonstrating the utility of cationic interface.

As described above, protein capsids are inclined toward reversible changes in their overall structure that induce transfer of the nucleic acid contents through virion pores. Synonymously, CCMV was identified to undergo dynamic structural changes correlated to the opening or closing of these viral gated pores. The molecular gating mechanism occurs by pH- dependent swelling/shrinking of the virion by as much as 10% of the virus dimensions. For example, a pH greater than 6.5 causes a volume expansion of the virion cage and the concerted opening of 60 separate pores with a diameter of 2 nm which allows free molecular exchange. Under acidic conditions ($pH < 6.5$), the virion contracts to its original non-swollen form by forcing the pores closed and in turn preventing access to the cavity. This pH-dependent structural control was exploited in the oligomerization reactions of tungstate and vanadate ions into confined paratungstate and decavanadate polyanions. The reaction was performed by first removing the viral RNA, swelling the virion capsid by adjusting the pH to greater than 6.5, incubating the empty swollen virions with metal anions, and then lowering the pH below 6.5 to close the gated pores. As a result, the structural transition from open to closed pores resulted in the spatially selective crystallization and entrapment of the paratungstate and decavanadate ions within the virion.

5.3 Engineered Bacteriophages for Nanoparticle Assembly

Bacteriophages are classified as simple viruses which target and infect bacteria. Their appeal as a biological template results from three compositional elements fundamental to the phage construct; a major protein coat (900 nm in length), minor protein coat, and a genetic factory of single stranded DNA (Figure 15). Particularly, the DNA plasmid serves as a source for phage replication after injection into the host bacteria, whereupon more phages are created. Additionally, the plasmid contains a random DNA insert, with no purposeful function to the phage, that expresses a sequence of amino acids in accordance with the minor protein coat. As a result, the insert provides an exceptional means to genetically displaying large peptide combinatorial libraries 10^9 on the minor protein coat surface of filamentous bacteriophages for the screening of evolutionary selected peptides against desired inorganic substrates as described above. Aside from genetically engineering the minor coat, the major protein coat also can be modified to incorporate binding sites along the viral surface as shown by Belcher *et al.* in the templated assembly of quantum dot nanowires.[76]

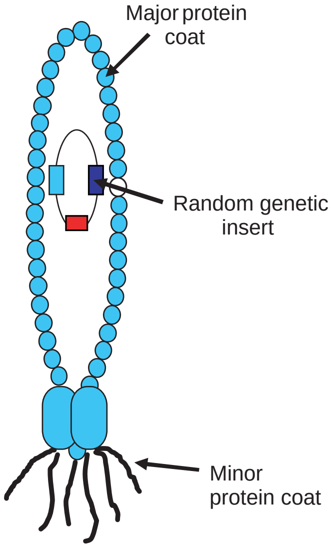

Figure 15 Representation of bacteriophage components

Belcher *et al.* have successfully expressed a group of peptides, that selectively nucleates ZnS and CdS identified from a pIII phage display library, as pVIII fusion proteins into the crystalline helical major coat protein of single M13 phage particles.[76] Subsequently, the integration of nucleating peptides along the viral capsid template was shown to direct the highly oriented, phase specific growth of ZnS or CdS nanocrystals into elaborate nanowires. The viruses were engineered to encode for peptide sequences previously selective for either ZnS or CdS; such as the ZnS peptides of CNNPMHQNC (A7) and VISNHAESSRRL (Z8) or SLTPLTTSHLRS (J140) which recognizes and nucleates CdS.[76] The peptide derivatized templates were added to a solution of $ZnCl_2$ or $CdCl_2$, respectively, for 12 hours to ensure saturation of metal precursor ions at the distinct peptide binding sites. After loading the phage template, Na_2S was introduced into the solution initiating the selective nucleation of metal sulfide nanoparticles at temperatures of 0 °C or −25 °C for 24 h, and then allowed to age at room temperature conditions.

Analysis of the Z8 peptide engineered virus demonstrated preferential growth of ZnS particles oriented in the [001] direction perpendicular to the viral surface.[76] Alternatively, the shorter A7 peptide sequence resulted in high density layers of ZnS (8–16 quantum dots per 10 nm of virus) particles due to

an increased register of peptide copies programmed along the surface (Figure 15).[76] Analogous results were observed with CdS (3–6 quantum dots per 10 nm of virus). Additionally, a CdS and ZnS viral heterostructure was obtained with a dual peptide system that presented two nucleation sites specific for CdS or ZnS.

Liquid crystalline systems based on nanoparticle-bacteriophage conjugates were recently developed by Belcher *et al.* that display novel material properties.[77] They used the innate anisotropic shape of bacteriophages to form well ordered liquid crystals (head to tail vertical alignment) and the potential binding sites of the minor coat protein for templating nanoparticle growth. Specifically, the A7 peptide selective for ZnS was expressed in the minor coat, exposed to $ZnCl_2$ solution, and mineralized with Na_2S, to yield a smectic-like lamellar ZnS viral film.[77] As a result, multiple ZnS nanocrystals bound at the A7 peptide and were aligned in the direction of the bacteriophage (Figure 16). Optical characterization elucidated the different liquid crystalline phases of the ZnS-phage hybrid and their transitions under a magnetic field. Examination by scanning electron microscopy (SEM) indicated a periodic length of 895 nm between the 20 nm aggregates of ZnS nanocrystals and A7 phage layers approximately equivalent to the length of a bacteriophage of 880 nm.[77]

6 PLANT MEDIATED NANOPARTICLE SYNTHESIS

Plants display a well known ability to bio-remediate heavy metals, and as a consequence have been used for nanoparticle synthesis. Presently, Gardea-Torresdey *et al.* demonstrated the first living plant system (*Medicago sativa* alfalfa plant) to bio-reduce Au^{3+} into corresponding Au^0 nanoparticles. In addition to the bio-reduction of gold, live alfalfa plants have exhibited reduction activity with silver, whereby exposure to silver containing media results in reduction to Ag^0, followed by absorption and uptake by the roots system, and finally translocation to the shoots as silver nanoparticles.[78] TEM analysis shows mainly spherical nanoparticle morphologies with diameters of 2–20 nm.

Certain plant species have also been reported to biosynthesize silver nanoparticles analogous to alfalfa. After extensive screening of different plant types for silver reduction, Sastry *et al.* have identified geranium leaf (*Pelargonium graveolens*) extracts as successful candidates in the synthesis of silver nanoparticles.[79] Upon exposure of geranium leaf broth to silver nitrate, silver nanoparticles were quickly formed within nine hours. This was substantially faster in comparison to the 24–120 h required for silver reduction by bacteria or fungi. XRD confirmed the presence of metallic silver, although it most likely occurs as a composite with a bioorganic phase as observed by an additional unassigned diffraction peak. Interestingly, the unexposed leaf broth when cast into a film exhibited intense diffractions attributed to the crystalline phase of the magnesium containing metalloprotein, chlorophyll. This is also supported by EDS measurements, whereby magnesium was detected in the sample indicative of chlorophyll. Further analysis by Fourier transform infrared (FTIR) revealed stretching vibrations at 1640 cm^{-1} for an amide I band in the silver leaf broth sample, suggestive of chlorophyll or terpenoids possibly acting in silver reduction.

Jones *et al.* have described an unusual plant extract in the synthesis and stabilization of metal hydroxide particles consisting of an extracted biopolymer of κ-Carrageenan derived from seaweed.[80] κ-Carrageenan features repeating units of hydroxy and sulfate groups which favorably interact with mineral surfaces and represents an exceptional stabilizing ligand for nanoparticles. Addition of Fe^{3+}, Ni^{2+}, or Co^{2+} to κ-Carrageenan and increases of pH yielded solutions of stabilized metal hydroxides as observed by XRD. According to

TEM, morphologies of iron oxyhydroxide particles stabilized by κ-Carrageenan appeared as a gel 'cage' and colloidally stable.[80] For nickel hydroxide, the biopolymer prevented aggregation by covering the crystal surface as observed by disperse particles. However, cobalt hydroxide revealed superstructures in the TEM composed of 100–200 nm platelets 'glued' together into a 10 μm spherical aggregate. It was determined that κ-Carrageenan interacts with all 3 metal cations through physical cross-linking of the biopolymer by electrostatic interactions of the cations with the ionized sulfate groups initially. At a basic pH of 13, the metal ions are precipitated as the hydroxide resulting in the formation of the colloidal nanoparticles stabilized through reversible electrostatic interactions with the κ-Carrageenan backbone.

7 CONCLUSIONS

Nature has provided a wealth of examples of stabilizing ligands used in the synthesis of various types of nanoparticles ranging in structural diversity from single amino acids to small peptides to large proteins. This structural scale of complexity is best exemplified by small phytochelatin peptides used to detoxify Cd^{2+} and Zn^{2+} into metal sulfide nanoparticles and the iron storage protein ferritin which controls the selective mineralization of iron oxide particles. Conceptually, these biological systems represent exquisite models for biomimetic nanoparticle synthesis by offering functional binding templates, surface passivating agents, and biomolecular recognition elements.

Systematically, a collection of individual amino acids (cysteine, histidine, aspartic acid, and lysine) was shown to stabilize a number of different zero-valent metal and metal sulfide nanoclusters displaying a broad scope of physical properties. These provided a fundamental basis set for nanoparticle synthesis and the further development of higher-order molecules exhibiting protein secondary structure and spatial/structural control over materials synthesis in three-dimensions. Accordingly, the structural and sequence variability of small peptides has had significant implications in nanoparticles synthesis owing to the assembly of nanoparticle-peptide interfaces originating from biomineralization proteins, evolutionary selected by phage displayed peptide libraries, and/or screened from combinatorial peptide libraries. Ultimately, spatial control is highly desired and has recently been achieved with the use of protein and viral templates possessing a defined cavity for the mineralization of atypical nanoparticle substrates. In total, templates derived from biological motifs exhibit control over nanoparticle size, morphology, and crystallinity that mimics the natural function and mineralization activity in nature.

1 INTRODUCTION

The chemical bond has resisted all attempts to provide it with a rigorous definition, yet it is one of the most widely used concepts in chemistry. It relies on the assumption that chemistry can be understood by considering only the nearest neighbors of a given atom and ignoring all interactions between more distant neighbors, an assumption that has never been justified theoretically. In spite of this lack of theoretical underpinning, the chemical bond model (*see Localized Bonding*), which predates the discovery of the electron by half a century, has been remarkably successful.

Many properties have been attributed to the chemical bond, but most of these. such as the bond energy (*see Bond Energies*), are difficult to define in a precise way and even more difficult to measure. The only bond property that can be measured with confidence is its length (*see Bond Length*), and many thousands of accurate bond lengths have been reported in the scientific literature (*see* ***Diffraction Methods in Inorganic Chemistry***).[1]

There are currently three different approaches to understanding chemical bonding. Quantum mechanical calculations (*see Ab Initio Calculations*; ***Molecular Orbital Theory***), even though they give the most complete picture, offer few insights into the nature of chemical bonds themselves because the concept of a bond does not arise naturally from a formalism based on the interactions between nuclei and electrons rather than the interaction between atoms. Even though quantum mechanics gives accurate values for measurable properties, its calculations are computer intensive and it becomes more difficult to use the more complex the chemical system.

A simpler approach that avoids the use of quantum mechanics is the two-body potential model (ionic model) that treats a crystal or molecule as a collection of atoms that interact through an empirical classical potential (*see* ***Solids: Computer Modeling***). This model involves a smaller, though still significant, computational load and is frequently used to predict the physical properties of crystals, but the potentials used are long-range and are inconsistent with a picture of localized chemical bonds.[2]

A third approach, the bond valence model (*see Bond Valence Method*), is related to the two-body potential model but is expressed in terms of the electrostatic field rather than the energy. It assumes that the valence electrons of the atoms can be assigned to individual bonds and that these determine the bond length. In spite of its conceptual and computational simplicity, this model gives good predictions of the bond length and provides useful chemical insights.[3]

Each of the above three models has advantages and limitations, but all can predict interatomic distances to an accuracy of a few picometres. Only the last is expressed in terms of the chemical bond and this model will be reviewed here.[3]

2 EARLY ATTEMPTS TO UNDERSTAND BOND LENGTHS

The earliest attempt to explain the observed lengths of chemical bonds in inorganic solids was the ionic model (*see Ionic Bonds*), in which the valence electrons were all assumed to reside on the more electronegative atoms (anions) leaving the more electropositive atoms (cations) with a positive charge (*see Anion* and *Cation*). The ions themselves were assumed to be hard or soft spheres with a fixed radius. Since the ions are held together by the long-range Coulomb potential, this model belongs to the two-body potential class of models and a quantitative treatment requires the summation over all pairs of atoms in the crystal.

When the interacting atoms have a similar electronegativity (*see Electron Spin Echo Envelope Modulation Spectroscopy*), as in organic compounds, a covalent bond model is usually used. Atoms are assumed to be held together by pairs of valence electrons localized between the two bonded atoms. The localized covalent bonds (*see Covalent Bonds*) and the long-range ionic interactions (*see Lithophiles*) represent two extremes of bond character with real bonds lying on the continuum in between. Unfortunately there is no unique way to locate the position of a given bond on this continuum, which makes it difficult to combine these two viewpoints quantitatively.

3 AN ELECTROSTATIC DESCRIPTION OF THE CHEMICAL BOND

It is, however, possible to derive an electrostatic picture of a localized chemical bond that leads naturally to the bond

valence model. Atoms consist of an inert *core* (nucleus plus the filled inner electron shells), which carries a positive charge equal and opposite to that of the valence electrons that occupy the partially filled outer shell and are used to form chemical bonds.

When two atoms are brought together, the partially filled valence shells overlap first, with the valence electrons of one atom occupying states in the unfilled valence shell of the other. The overlapping electrons lie between the two positively charged cores attracting both, and pulling them together. The closer the atoms get, the larger the number of valence electrons lying in the overlap region and the greater the attractive force between the nuclei. Eventually the two cores start to overlap and, being unable to accommodate electrons from the other atom, they generate a repulsive force. Equilibrium is reached when the attractive and repulsive forces are equal. If the number of overlapping valence electrons is increased, they pull the atoms closer together, increasing the core repulsion until a new equilibrium is reached. The distance between the two atoms is therefore a measure of both the repulsive and the attractive force, hence of the number of valence electron pairs in the overlap region.

The electrostatic field linking the atom cores to the overlapping valence electrons can be used to define a chemical bond. As shown schematically in Figure 1, this field can be represented by lines of field. The total number of lines of field linking the charges is called the electrostatic flux, and it is equal to the charges on which it starts and terminates. Figure 1(a), which gives an electrostatic picture of a covalent bond, shows that the flux in the bond (proportional to the number of lines of field) is equal to the number of valence electron pairs in the overlap region. This picture of a covalent bond can conceptually be converted from a covalent to an ionic bond by moving the overlapping valence electrons onto the more electronegative atom (the anion) as shown in Figure 1(b). As Figure 1 shows, the electrostatic flux linking the A and X atoms depends only on the number of overlapping valence electrons and not on their location. The model therefore gives a quantitative picture of both ionic and covalent bonds.

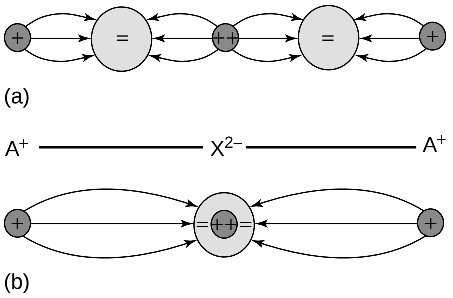

Figure 1 A schematic representation of the electrostatic model of the chemical bonds in a hypothetical $A^{+}-X^{2-}-A^{+}$ molecule: (a) a covalent bond and (b) an ionic bond. The small circles represent the atomic cores, the large circles represent the overlapping valence electrons

4 BOND LENGTHS, BOND FLUXES AND BOND VALENCES

The bond flux is equal to the number of electron pairs associated with the bond, and as expected, this number can be estimated from the bond length, R_{ij}, using equation (1)

$$S_{ij} = \exp\left(\frac{R_0 - R_{ij}}{B}\right) \tag{1}$$

where R_0 and B are empirically determined constants[4–6] (a selection is given in Table 1) that are transferable to all bonds between the same pair of ions. S_{ij} is an estimate of the flux, but as it is subject to the experimental uncertainties associated with R_{ij}, it is not identical to the flux and is conveniently called the *bond valence.* Provided the bond is not sterically strained (see Section 5), the bond valence calculated using equation (1) is a good approximation to the electrostatic flux.[7] The form of equation (1) is shown by the line in Figure 2 for Ca–O bonds. For comparison, the points show the bond fluxes calculated directly from Coulomb's law for a selection of Ca–O bonds in well-determined structures.

According to Gauss' electrostatic theorem, the total bond flux, s_{ij}, leaving the core of atom i is equal to its charge, which is the same as the number of valence electrons, V_i (the formal ionic charge (*see Formal Charge*) or *atomic valence*), that the atom uses in bonding, equation (2).

$$V_i = \sum_j \{s_{ij}\} \tag{2}$$

The constants in equation (1) are fitted for each pair of ion-types to ensure that equation (2) is obeyed when the bond valence, S_{ij}, in equation (1) is substituted for the bond flux, s_{ij}, in equation (2) for a large number of accurately determined coordination environments.[9] While the value of R_0 depends on the sizes of the ions, a value of $B = 0.37$ A is found to work well for many ion pairs.[4] The programs VALENCE and VALIST can be used to determine the bond valence from the bond length.[10,11]

The bond flux can also be calculated by recognizing that in the ionic limit each bond is an electric capacitor (represented by flux linking two opposite charges). The network of atoms and bonds is thus a capacitive electrical circuit, and since in most equilibrium structures all the bond capacitances are empirically found to be equal, the fluxes can be calculated using the Kirchhoff equations (2) and (3) in which the bond capacitances cancel.[12]

$$0 = \sum_{\text{loop}} \{s_{ij}\} \tag{3}$$

where the summation is over any loop in the bond network. The program BONDVAL can be used to solve the Kirchhoff equations.[13]

[a]O–H bonds are conveniently modeled with $R_0 = 0.529$, $B = 0.94$ over the range of distances most commonly encountered, but these values do not give good valences for very short and very long bonds.

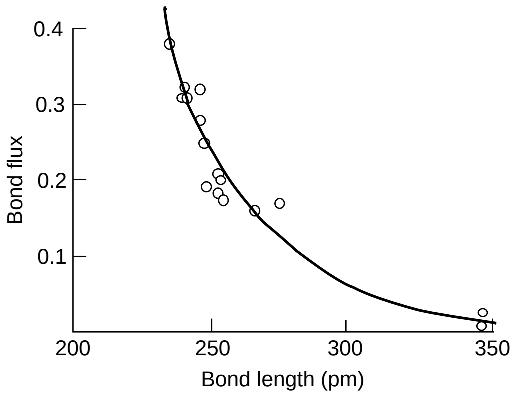

Figure 2 The relation between bond valence and bond length for Ca–O bonds. The line shows equation (1). The points are electrostatic fluxes calculated using Coulomb's law for several different Ca-bearing crystals. (Figure 3.1 from 'The Chemical Bond in Inorganic Chemistry' by Brown, David (2001)). (Ref. 3. Reproduced by permission of Oxford University Press)

5 SOME THEOREMS ABOUT BOND VALENCES

A number of theorems associated with the bond valence model are useful in the analysis of inorganic structures.[14] Equation (2), known as the *valence sum rule,* is central to the model. Since Gauss' theorem is necessarily obeyed by the bond fluxes that terminate at each atom, equation (2) is always obeyed and ensures that if the flux in one bond is changed, the fluxes in all the other bonds in the network will relax, giving rise to the long-range Coulomb effects. However, if bond valences determined from experimental bond lengths are used instead of the fluxes, equation (2) may not be exactly obeyed, particularly if the structure is strained as a result of crowding or incomensurations between its different parts as found, for example, in many perovskites. Important as such deviations are, they are the exception, and equation (2) is widely used to check the chemical validity of a newly determined crystal structure, or to see whether the bonds are strained (*see* ***Diffraction Methods in Inorganic Chemistry***).[15]

The equal valence rule or loop rule equation (3) is less rigorously obeyed, and does not apply to the environments of atoms with electronically driven anisotropies arising from, for example, lone electron pairs (*see Lone Pair*; ***Electronic Structure of Main-group Compounds***) or Jahn–Teller distortions (*see Jahn–Teller Effect*; ***Copper: Inorganic & Coordination Chemistry***).

The concave form of equation (1) shown in Figure 2 leads to the distortion theorem that states that any deviations of the bond lengths in the coordination environment of an atom from their mean causes an increase in the bond valence sum, provided that the average bond length is held constant. A corollary is that any atom located in a cavity that is too large will tend to distort its environment, often by moving away from the center of the cavity, as this will increase the bond valence sum which otherwise would be too small. The best-known example of such a distortion is the O–H···O hydrogen bond (*see* ***Hydrogen Bonding & Dihydrogen Bonding***). The two

O atoms come into contact when the O–O distance is larger that twice the O–H distance expected for a symmetrically two-coordinated H atom. To compensate, the H atom moves off-center until its bond valence sum reaches 1.0 e (electrons), giving rise to the characteristically asymmetric hydrogen bond (*see Hydrogen Bonding*).[16]

6 APPLICATIONS

Before the development of the bond valence model, ionic radii were widely used to predict bond lengths (*see Crystallographic Radius*).[8] Popular listings are provided by Pauling[17] and more recently and comprehensively by Shannon and Prewitt.[18,19] A selection of the latter are given in Table 1. However, since the ionic radii predict that all bonds between a given pair of ions will have the same length, they do not take into account the effects of neighboring atoms and can only reliably predict individual bond lengths in regular cation environments. Nevertheless, they provide a convenient measure of the relative sizes of atoms that can be used for comparative purposes as, for example, in Figure 3. They can also be used to decide whether two cations can substitute for each other, since substitution should be easiest between ions of similar valence and similar size.

For the accurate prediction or analysis of bond lengths a more sophisticated model is needed.[14] If the way in which the atoms are linked by bonds is known, equations (2) and (3) can be used to predict bond fluxes, and equation (1) can then be used to calculate the expected bond distances. Differences between the predicted and observed bond lengths indicate the presence of either electronic or steric strain (or possibly an incorrectly determined structure).[15] Alternatively, using equation (1) experimentally determined bond lengths can be converted to bond valences, which can be checked to see how well equation (2) is obeyed. The root mean square discrepancy between the bond valence sums and the formal valence, V_i, for all the atoms in a crystal, is known as the *global instability index*, (GII). Experimental uncertainties in the bond lengths usually account for GII values of around 0.05 e. Larger values indicate either bond strain or errors in the structure determination. Structures with GII $>$ 0.25 e are unstable and should be checked for possible errors. Figure 3 shows how the GII varies as a function of rare-earth cation radius in Ln_2BaCuO_5. In this series of isostructural crystals, Tm has the least strained structure but the isostructural Nd compound would be so highly strained that Nd_2BaCuO_5 adopts a different structure.[20]

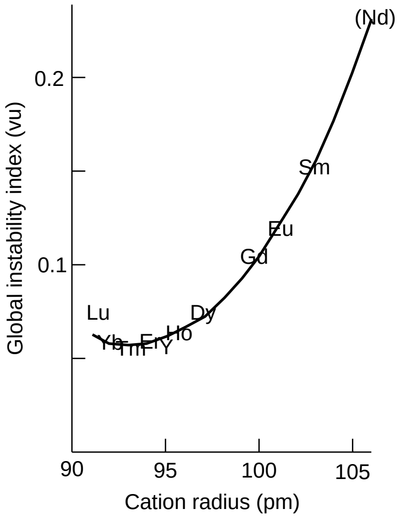

Figure 3 The variation in the Global Instability Index of Ln_2BaCuO_5 as a function of the ionic radius of Ln. The line is a fitted second order equation. Nd adopts a different structure. (Figure 12.3 from 'The Chemical Bond in Inorganic Chemistry' by Brown, David (2001)). (Ref. 3. Reproduced by permission of Oxford University Press)

Other uses for the bond valence sums include the determination of the oxidation states of atoms (*see Oxidation Number*), the examination of the distribution of atoms over different crystallographic sites (*see Crystal Structures*),[21] the location of Ca and Na binding sites in proteins (*see* ***Calcium-binding Proteins***),[22] and the analysis of enzyme mechanisms (*see Protein Determination*; ***Cation-activated Enzymes***).[23] The bond valence model also gives good predictions for chemical properties such as solubility and stability.[24] Compared to other methods of exploring the structure and properties of chemical compounds, the bond valence model, by focussing on localized bonds, is conceptually simple. The insights it provides make it an ideal tool for use in both planning and analyzing the structures of inorganic materials.

1 INTRODUCTION

Mutations in the genes encoding proteins that are involved in normal metal metabolism usually result in severe genetic disorders. Wilson and Menkes diseases are two genetic disorders of copper metabolism. They are caused by mutations in the genes *ATP7B* and *ATP7A*, which encode copper-transporting P-type ATPases. The major genetic disorders affecting iron metabolism are hematochromatosis, thalassemia, and aceruloplasminemia. Genetic disorders of zinc metabolism include acrodermatitis enteropathica. There are several other rare genetic disorders of little known genetic factors. They will be discussed very briefly in this article.

2 COPPER-RELATED DISEASES

2.1 Wilson Disease

2.1.1 Clinical and Biochemical Features

Wilson disease is an autosomal recessive disorder of copper transport (Figure 1).[1] It results in the toxic accumulation of copper in various tissues, but mainly in the liver, kidney, and brain. Wilson disease occurs worldwide with an average prevalence of about 1 in 30 000 in most populations.[2] The age of onset for Wilson disease is variable and can extend from 3–4 years into the mid-50s. There are three phases in the progression of the disease. In the first phase, copper accumulates in the cytoplasm of hepatocytes. As more copper is absorbed, in the second phase the increased concentration of cytoplasmic copper results in the induction of large amounts of metallothionein (*see* ***Metallothioneins***). It causes the chelation and storage of copper in the hepatocytes leading to necrosis and release of copper into the blood stream.[3] In the third phase, copper begins to accumulate in other organs such as the brain, kidney, and cornea. Sudden release of high level of copper in the blood circulation due to oxidative damage to erythrocyte membranes leads to hemolytic anemia.[4] Wilson disease patients fall into three categories: those displaying hepatic symptoms, those displaying neurologic symptoms, and those displaying both (Table 1).

One of the important diagnostic features of Wilson disease is the dull brown Kayser-Fleisher (K-F) rings caused by deposition of copper in the cornea.[5] The majority of Wilson disease patients and all patients displaying neurologic disorder demonstrate K-F rings.[6] Patients with an early age of onset usually display predominantly hepatic symptoms, whereas those with a later age of onset display predominantly neurologic symptoms.[7] Liver dysfunction symptoms include jaundice and fatigue; associated conditions include asymptomatic cirrhosis, subacute hepatitis, and hepatitis resembling autoimmune hepatitis.[8] Symptoms of neurologic disorders in Wilson disease include deteriorating coordination, tremors, dysarthria, drooling, personality changes, dementia, slurring of speech, rigidity, and behavioral problems.[9] It is generally believed that the neurologic symptoms of Wilson disease are due to cerebellar or extrapyramidal involvement or combination of both conditions.

The disturbance of copper excretion, primarily due to a defect in the billiary excretion, is consistent with the biochemical findings in patients with Wilson disease. Urinary copper excretion is increased owing to total body overload of copper. Renal dysfunction includes albuminuria and renal rickets.[9] Incorporation of copper in ceruloplasmin is impaired. Thus, there is a greater proportion of copper bound to albumin and amino acid complexes in the serum. But the overall copper concentration in serum is low. Ceruloplasmin is a multicopper oxidase (*see* ***Copper Proteins: Oxidases***) that

Table 1 Clinical and biochemical features of Wilson and Menkes diseases

Laboratory findings	Menkes disease	Wilson disease
	↓Serum copper levels ↓Liver copper levels ↑Intestinal/kidney copper levels	↓Serum copper levels ↑Liver copper levels ↑Urinary copper levels
Defect	Intestinal copper absorption Deficiency of copper enzyme	Decreased billiary excretion of copper Incorporation of copper into ceruloplasmin
Treatment	Daily Cu-histidine injections	Chelation therapy
Genes	X chromosome/recessive	Chromosome 13/recessive

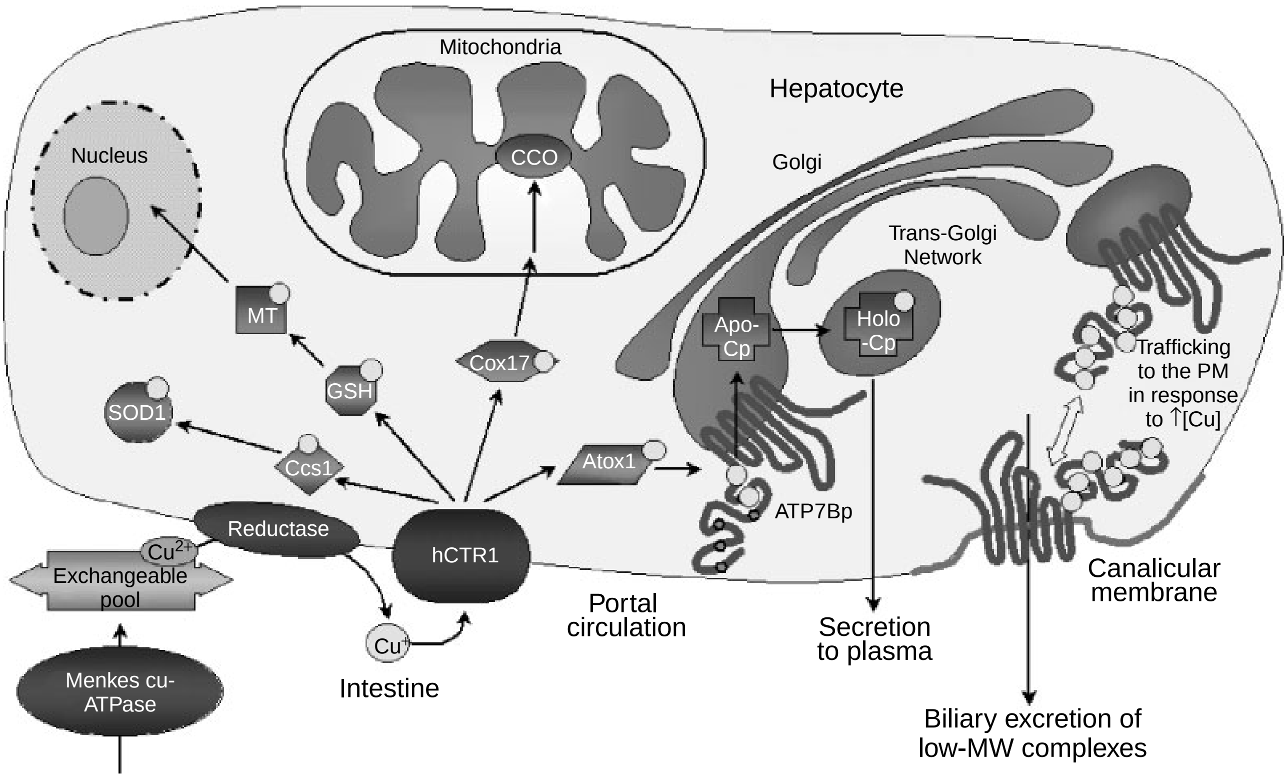

Figure 1 Copper transport pathway. Copper is absorbed in the intestine and becomes bound to amino acids, mainly histidine and albumin. Prior to uptake, Cu(II) is reduced to Cu(I) by a membrane-bound reductase and enters the cell via a passive transporter. Once in the cell, copper becomes bound to copper chaperones responsible for delivering copper to specific proteins. The Wilson/Menkes ATPase accepts copper from these chaperones and pumps it into the Golgi for incorporation into various proteins such as ceruloplasmin (Cp). Ceruloplasmin may also play a role in delivering copper to peripheral tissues via cell-surface receptors that internalize the protein. The Wilson disease ATPase may also play a role in the elimination of copper into the bile

has been implicated in iron metabolism (see section on aceruloplasminemia). The low ceruloplasmin levels in Wilson disease are the result of a disturbance in the transfer of copper to the apoprotein during its synthesis.

2.1.2 Wilson Disease Gene

The Wilson disease gene was first assigned to a single locus by linking to the esterase D gene.[10] Later studies placed the gene close to a cluster of polymorphic markers in the q14.3 hand of chromosome 13.[11–13] The localization studies led to the cloning of the gene independently by two groups designated as *ATP7B*.[14,15] The gene consists of 22 exons out of which 21 are expressed in the liver. Exon 22 is expressed in the kidney.[16–18] The size of the exons ranges from 77 bp to 2355 bp.[16] There is a high level of expression of the gene transcript in the liver and kidney with a lower level in the lung and placenta.[14] One finds a good correlation of the pattern of expression and the observed clinical and biochemical features of the disease.

There are missense mutations in the Wilson disease gene in all the exons and rarely in exons 1–5, which encode the six N-terminal metal-binding motifs, and exon 21, which encodes the C-terminal tail of the protein.[18,19] Several other mutations in the Wilson disease gene, with small insertion/deletions, nonsense, frameshift, and splice-site mutations, have been found and they are discussed elsewhere.[18,20–24] Most common missense mutations in many populations are a change from histidine in position 1069 to glutamine. This mutation is found in about 38% of homozygous Wilson disease patients of North European descent. It occurs in a conserved loop motif (SEHPL) that is adjacent to the conserved phosphorylation motif DKTG. It is not clear what specific function is performed by this motif, but it seems to be necessary for the function of the heavy-metal ATPases, as this motif is conserved between the Wilson disease (ATP7B), Menkes disease (ATP7A), and Cop A (bacterial copper ATPase) proteins.[15,25]

Advantage was taken of the high frequency of the His 1069 Glu for a genotype/phenotype analysis of this mutation. In one case study, patients homozygous for the His 1069 Glu mutation had later age of onset as compared to the heterozygous patients, 20 years versus 15.4 years.[19] This His 1069 Glu was found at high frequency in Mediterranean populations. The data from several studies suggest that the His 1069 Glu mutation is the most common molecular defect

in the Wilson disease protein and it probably arose from an ancient mutational event.[26]

2.1.3 *Wilson Disease Copper-transporting ATPase: ATP7B*

The Wilson disease gene is predicted to encode a copper-transporting P-type ATPase, having many features in common with other cation-transporting P-type ATPases including bacterial heavy-metal transporters shown in Figure 2.[27] The predicted structure of the Wilson disease copper-transporting ATPase contains general features conserved among members of the P-type ATPase family. There are the TGEA motif (actuator domain), DKTG motif (phosphorylation domain), and the sequence MXGDGXNDXP found in the hinge region that connects the phosphorylation domain to the transmembrane segment. ATP7B is further classified as a heavy-metal transporting P-type ATPase since it contains six metal-binding motifs, GMTCXXC at the N-terminus of the molecule, the CPC motif in the sixth transmembrane region (TM6), the SEHPL motif in the nucleotide-binding domain and eight transmembrane segments.

Structural Studies of ATP7B. A complete structural description of ATP7B remains unsolved. However, major advances have been made to characterize the N-terminal copper-binding domain of ATP7B. The ATP7B copper-binding N-terminal domain binds copper with the stoichiometry of one copper per metal-binding repeat and this binding occurs through a cooperative mechanism.[28–30] The bound copper is in the +1 oxidation state and is coordinated by two cysteines in a distorted linear geometry. CD experiments have shown that the N-terminal domain undergoes secondary and tertiary conformational changes in response to copper binding. It has been suggested that the conformational changes observed in the ATP7B N-terminal domain induced by copper-binding may signal the protein to traffic between the trans-Golgi network (TGN) and the plasma membrane in a copper-dependent manner.[31] Interestingly, the N-terminal copper-binding domain has the ability to bind different transition metals with varying affinities

(a) The predicted structure contains domains that are similar to other cation-transporting ATPases as well as other heavy-metal transporters. Cu1-6, N-terminal copper-binding motifs; TGEA, transduction motif; CPC, transmembrane motif present in heavy-metal transporters; DKTG, phosphorylation motif; SEHPL, conserved motif found in all heavy-metal transporting ATPases of unknown function. (b) Sequence alignment of metal-binding motifs from the Wilson disease protein (WDCu1-6) and other heavy-metal binding/transporting proteins. ATX1, copper chaperone from *S. cerevisiae*; ATOX1, human copper chaperone; CopA, copper-transporting ATPase from *E. hirae*; MerP, mercury-binding protein from E. coli; CadA, cadmium-transporting ATPase from *S. aureus*

as follows: Cu(II) ≫ Zn(II) > Ni(II) > Co(II). Zinc binds mostly to nitrogen atoms in the N-terminus and not to the copper-binding motif having cysteine residues. The conformational changes induced by zinc binding are completely different from those of copper-binding.[32]

The experimental determination of the 3D structure of the entire ATP7B poses many technical challenges. However, studies have been carried out by homology modeling using gapped-BLAST analysis. The sequence of ATP7B was aligned representing the copper-transporting ATPases with the SERCA1a sequence.[33,34] This sequence alignment generated a structural alignment of homologous regions of ATP7B (Figure 3).

Functional Aspects of ATP7B. Since the discovery of the Menkes and Wilson disease genes, the studies of many research groups revealed various aspects of how these copper-ATPases work. The unique metal-binding cytosolic N-terminal domain of copper ATPases has been the focus of much research. In copper ATPases with multiple copper-binding domains, the closest to the transmembrane region appears to be functionally more important than the ones closest to the amino terminus.[35] Therefore, the role of the N-terminal copper-binding domains may be to increase the overall catalytic rate of the transporter. Conformational studies have shown that the N-terminal domains undergo secondary and tertiary conformational changes in response to copper-binding.[31] It is not known just how the conformational changes in the N-terminal copper-binding domain affect the function of the ATPase. It has been suggested that the conformational changes observed in the ATP7B N-terminal domain induced by copper binding may signal the protein to traffic between the trans Golgi network and the plasma membrane. In addition to its role in trafficking, a regulatory role has also been suggested for the N-terminal domain. Results have shown that the nucleotide/phosphorylation domains interact with the N-terminus and the copper-bound N-terminal domain induces a conformational change in the nucleotide/phosphorylation domain, altering the protein–protein interaction.[36] The copper chaperone ATOX1 was shown to interact with some, but not all, the N-terminal copper-binding repeats.[37,38] Structural homology modeling of the six repeats of ATP7B reveals that they have different electrostatic surfaces from one another and thus not all are equally capable of interacting with the chaperone.[39] Copper binding to the N-terminus weakens its interaction with the nucleotide-binding domain thereby causing them to dissociate.[40] The dissociation of the N-terminus from the nucleotide-binding domain restores the nucleotide-binding affinity of this domain thereby allowing the binding of ATP to the nucleotide-binding site. The successive conformational changes are transmitted to the translocation domain. The transmembrane domains are associated with the transduction channel and contain residues critical to cation binding. The conserved proline residue in the ATPase transmembrane domain 6 is flanked by a pair of cysteine residues to form the highly conserved CPC motif, which is predicted to be one of the copper-binding sites within the channel.[41–43] The hydrolysis of the phosphoenzyme requires the release of copper from the channel to the lumen. The release of cation may cause the movement of the activator domain and allow water to access and hydrolyze the phosphoenzyme.

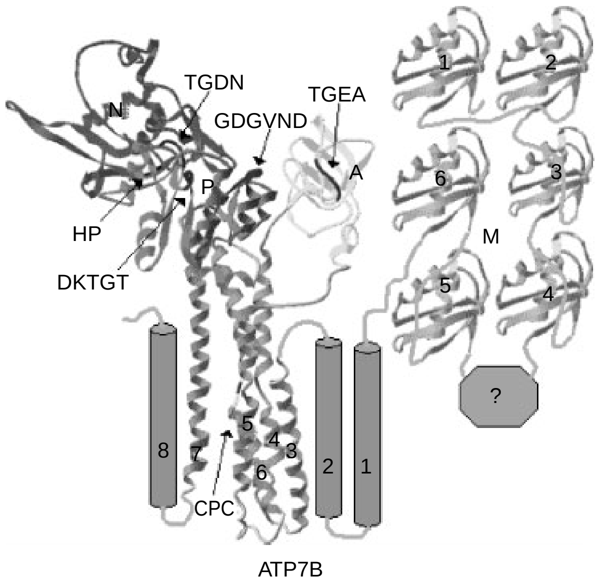

Figure 3 Homology modeling of ATP7B based on the known structure of calcium ATPase. The core of ATP7B encompassing the regions between TM3 and TM7 can be successfully modeled. Actuator domain (A); N-terminal metal-binding domain (M); nucleotide-binding domain (N); phosphorylation domain (P). The important and conserved residues are marked on ATP7B. TM1, TM2, and TM8 do not correspond to any of the transmembrane helices in calcium ATPase and were not modeled. The six copper-binding domains in the N-terminal region of ATP7B each adopt a ferredoxin-like fold found in other metal-binding domains. The region between the 4th and 5th copper-binding domains may contain a domain whose function is yet to be discovered[33]

2.1.4 *Treatment of Wilson Disease*

For almost 50 years following the description of Wilson disease, there was no effective treatment for this progressive fatal disorder. The damage to vital organs (liver, brain, kidney) in Wilson disease is caused by the toxic action exerted by excessive amounts of copper deposited primarily in these organs. There are several pharmacologic regimens and therapeutic modalities available for the treatment of Wilson disease (Table 2).

It should be pointed out that failure to comply with lifelong therapy led to recurrent symptoms and liver failure, the latter requiring liver transplantation for survival.[44] Treatments used for Wilson disease are described below.

Table 2 Agents for the treatment of Wilson disease

Agent	Mechanism of Action	Daily Adult Dosage
D-Penicillamine[a]	Reduction and chelation of copper. Urinary excretion of copper by mobilizing copper from organs	1–2 g orally in divided doses
Triethylenetetramine (Trientine)	Copper chelator and urinary excretion	0.75–1.5 g orally in divided doses
Zinc salts	Inhibits intestinal absorption of copper by induction of intestinal cell metallothionein; may also induce hepatic metallothionein	150–200 mg of elemental zinc orally in divided doses
British anti-Lewisite (BAL)[b]	Copper chelator	3 mL of 10% BAL in peanut oil IM
Tetrathiomolybdate[c]	Blocking the intestinal absorption of copper and a copper chelator	Up to 2 mg/kg orally in divided doses

[a]Administered with supplementation of 25 mg pyridoxine orally daily; [b]Rarely used. [c]Experimental.

a. BAL (2,3-Dimercaptopropanol)

It was the first agent used to treat Wilson disease as a decoppering agent.[45,46] It must be administered by intramuscular injection; its use was all but abandoned in favor of orally available chelating agents.

b. D-Penicillamine

D-Penicillamine was first introduced in the treatment of Wilson disease in 1956.[47,48] The usual recommended adult dose is 1 g/day. D-Penicillamine acts by reductive chelation.[49,50] It reduces copper bound to protein, which in turn causes the reduction of affinity of the protein for copper and allows D-penicillamine to bind the copper. The immediate and dramatic result of the administration of D-penicillamine is a marked increase in urinary copper excretion. Removal of copper from the liver remains incomplete and hepatic copper levels may remain elevated even after years of therapy.[49] The major problem with D-penicillamine is its high level of toxicity. Approximately 30% of patients are hypersensitive to the drug, which may cause its discontinuation. It has been shown that a significant number of patients with neurologic aspects of the disease may become worse after they are started with this drug.[51] Most of the long-term side effects involve either the immune system or connective tissues.[52] The deleterious effects on connective tissues are a direct result of reaction with D-penicillamine itself. This could also result from an interaction with the enzyme lysyl oxidase, which is a copper enzyme and is responsible for the cross-linking of collagen.

c. Trientine

Trientine (triethylenetetramine) was used in 1982 to treat Wilson disease as an alternative to D-penicillamine.[52] It is also a chelator of copper and increases urinary excretion of copper. There is less experience with the use of trientine compared to D-penicillamine. Its toxicity is relatively unexplored. The initial effect of this treatment is large cupriuresis but its rate diminishes more rapidly than with D-penicillamine. However, it should be pointed out that this treatment is effective especially in situations for which D-penicillamine must be stopped because of adverse side effects. Trientine appears to compete effectively for the copper bound to serum proteins but is not able to do so in the liver.[53]

d. Zinc

Zinc was known to produce copper deficiency in experimental animals. The first report of zinc treatment for Wilson disease was published in 1979.[54] Zinc causes induction of metallothionein in the intestinal cells, which binds copper with high affinity and holds it with high affinity until the intestinal cells are sloughed off. Thus, zinc inhibits absorption of copper from the intestine and increases the fecal excretion of copper. Zinc also blocks the reabsorption of endogenously secreted copper from saliva and gastric juice. A major advantage of zinc treatment is its low toxicity.

e. Tetrathiomolybdate

Molybdate is known to induce copper deficiency. It was found that the administration of molybdenum compounds, particularly with added sulfate, impaired copper metabolism in ruminants.[55] Tetrathiomolybdate has been used to treat patients who were intolerant to D-penicillamine, trientine, and zinc. Tetrathiomolybdate seems to act both by blocking the intestinal absorption of copper and keeping it in a metabolically inert chelated form, which is not taken up by the liver. However, it induces only a modest cupriuresis.[56] There are also known toxic effects of tetrathiomolybdate on the skeletal system of growing animals.[57] Thus one should be extremely careful in administering this compound. It should be considered as an experimental drug.

2.2 Menkes Disease

2.2.1 Clinical and Biochemical Features

Menkes disease is another genetic disorder of copper metabolism characterized by an impairment in the absorption of dietary copper and severe disturbance in the intracellular

transport of copper.[58] The disease was first characterized by John Menkes and coworkers in 1962 during the course of study of five patients from the same family who died before the age of three.[59] In their original study, they noticed that the disease seemed to be confined to males and was inherited in a sex-linked recessive manner.

Menkes disease patients are unable to absorb copper and hence suffer from the effect of copper deficiency. The disease has a very early age of onset and affected children suffer from neurodegeneration and die before the age of three years. All patients gain very little weight following birth. Several gross abnormalities are noted with hair. They are coarse and brittle and either twisted or fractured at various intervals. This abnormality of hair in Menkes disease led to the disorder to be referred to as kinky hair syndrome.

The clinical features of the disease include hypothermia, arterial rupture, and bone changes. Patients are found to have extremely low levels of copper in the liver, brain, and serum as well as having very low ceruloplasmin levels. These all are due to the basic biochemical defect of severely reduced ability to absorb copper from the intestine and a disturbance in the intracellular transport of copper.[58,60]

The clinical symptoms of classical Menkes disease can be traced back to developmentally important copper enzymes such as lysyl oxidase, tyrosinase (*see* ***Copper: Hemocyanin/Tyrosinase Models***), cytochrome *c* oxidase (*see* ***Cytochrome Oxidase***), dopamine β-hydroxylase, superoxide dismutase, and amine oxidase (*see Superoxide Dismutase*).[6,61] Lysyl oxidase is needed for the cross-linking of connective tissue; a deficiency in this enzyme causes weakened connective tissue and connective tissue disorder such as arterial ruptures as observed in these patients.[6] Low levels of cytochrome c oxidase cause temperature instability and the absence of tyrosinase explains the hair depigmentation observed in affected individuals.[62]

2.2.2 Menkes Disease Gene

Early genetic work on Menkes disease had mapped the disease locus to band xq13.3.[63–65] Following this road map, the Menkes disease gene (*ATP7A*) was isolated and independently identified by three groups using positional cloning.[66–68] The gene contains 23 exons and spans a genomic region of approximately 150 kb.[69,70] The exons are in the 77 to 726 bp range with introns ranging from 196 bp to 60 kb. After the exon coding for the fifth metal-binding domain (exon five in *ATP7A* and exon 3 in *ATP7B*), the coding region for both the Wilson disease gene (*ATP7B*) and Menkes disease gene (*ATP7A*) are virtually identical.

In the Menkes disease gene, approximately 20% of the mutations are insertion/deletion mutation of varying sizes. In a study of 41 unrelated patients presenting the severe form of Menkes disease, 19 mutations were due to insertion or deletion.[71] The two largest of the deletions are 14 bp deletion in exon 10 and 10 bp deletion in exon 22. These deletions, as well as the others would be predicted to alter the reading frame of the gene, leading to the introduction of a stop codon and premature truncation of the protein. Alternatively, these mutations may lead to the skipping of subsequent mutation-bearing exons, which may result in an internally deleted protein that may still retain some function of the *ATP7A*.[72] Exon 8 codes for the region between metal-binding 6 and the first transmembrane segment of the protein. The exact role this region plays in the function of the ATPase remains unknown but it could play a role in the precise localization of the metal-binding domain relative to the ATPase core. The importance of this region of the protein is exemplified by the finding that individuals carrying mutations in exon 8 present the most severe form of Menkes disease.[71] In the Wilson disease protein, only two mutations have been found in the corresponding region.[26] These findings may indicate that these domains play somewhat different roles in the Wilson and Menkes ATPases, despite their high degree of sequence homology.

2.2.3 Menkes Disease Copper-transporting ATPase: ATP7A

The Menkes disease gene encodes a 1500 amino acid protein, which is predicted to be a copper-transporting P-type ATPase with a high degree of homology with the Wilson disease protein (Figure 4).[68] The overall identity between these two proteins is 57% and this rises to 79% and higher in the phosphatase, transduction-phosphorylation and ATP-binding domains.[14] Although these two proteins have a significant similarity, there are some significant differences, most notably a 78-amino acid insertion between metal-binding domains 1 and 2 in the Menkes protein, which is not the case in Wilson protein. The importance of this insertion is not yet known.

2.2.4 Structure and Function of Menkes Disease Protein

Copper-binding properties of the N-terminal metal-binding domain are similar to that in Wilson disease ATPase. This protein also binds copper in a 1:6 protein to copper ratio.[29]

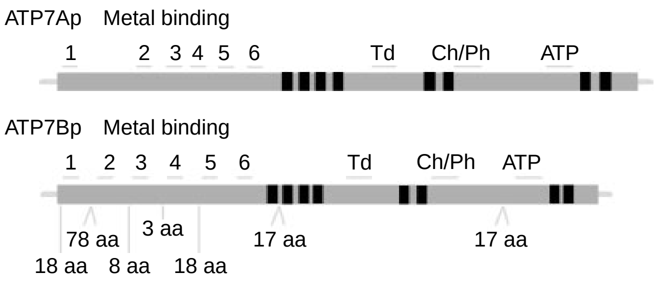

Figure 4 Comparison of Menkes (ATP7A) and Wilson (ATP7B) ATPases. ■ – Transmembrane segments, Td – Transduction, Ch – Channel, Ph – Phosphorylation, ATP – ATP binding, | – Insertion relative to ATP7A, Λ – Deletions relative to ATP7A

The geometry of the copper-binding site is digonal as seen in the case of Wilson protein.[73] Binding of Ag to the fourth domain of the metal-binding segment has been characterized by NMR studies.[74]

The mechanisms of catalysis and copper-dependent trafficking of the Menkes protein have been summarized in a recent review.[75] Biochemical studies indicated that mutation of six metal-binding sites did not abolish the catalytic activity of Menkes ATPase and hence it was considered that these motifs were not essential for copper translocation. However, the binding of copper to these sites increased the affinity of the protein for copper translocation, which would involve the interaction between the binding sites and the cytosolic ATP-binding domain of ATP7A. Much further work is necessary to delineate the mechanism of this process.

2.2.5 *Treatment of Menkes Disease*

Treatment of Menkes patients have concentrated on restoring normal copper levels in the body by administering copper. Since the intestinal absorption of copper is very low in Menkes patients, copper must be administered parenterally. Copper has been administered in various forms including copper chloride, copper sulfate, copper EDTA, and copper-albumin. But none of these copper compounds is able to produce significant clinical improvement, especially in regard to neurodegeneration.[76] The only currently available treatment for Menkes patients is subcutaneous injections of copper-histidine. This complex was originally discovered in human blood and was shown to transport copper across the cell membrane.[1] The structure of copper-histidine has recently been solved by X-ray crystallography.[77] Patients treated with copper-histidine soon after birth have shown significant clinical and biochemical improvements and can achieve normal levels of ceruloplasmin, dopamine β-hydroxylase, norepinephrine, and serum copper.[78–81] A long-term clinical follow-up of copper-histidine treated patients over 10–20 years has been reported (Table 3).[82] Despite the favorable effects on the neurologic symptoms, the residual abnormalities such as connective tissue abnormality can become more severe later in life. Therefore, this treatment should still be regarded as experimental.

3 IRON-RELATED DISEASES

3.1 Hereditary Hemochromatosis

3.1.1 *Clinical and Biochemical Features*

Hereditary hemochromatosis is a disorder of iron metabolism in which the uptake of iron from the digestive

Abbreviations: NE, not estimated; Cu-his, copper-histidine.

system is not downregulated, resulting in excessive iron uptake. The body continues to absorb high levels of dietary iron regardless of the levels of stored iron in the body (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). Excess iron is slowly deposited in the liver as hemosiderin with a simultaneous increase in plasma iron and saturation of plasma transferrin.[83] Tissue damage becomes evident when the iron store reaches 20 to 50 times normal values. Hence, the age of onset of the disease is late between 40 and 60 years. However, neonatal hemochromatosis and juvenile hemochromatosis have also been described;[84] these are not the same as hereditary hemochromatosis pathophysiologically. Hereditary hemochromatosis seems to be more prevalent in males than in females owing to differences in the rate of iron absorption and loss.[83]

The classic clinical and pathological findings include weakness and lethargy, abdominal pain, diabetes mellitus, amenorrhea, dyspnea, and various neurologic symptoms. The onset of the clinical symptoms of the disease is greatly affected by both genetic and environmental factors. Patients demonstrate asymptomatic elevation of serum alanine aminotransferase and aspartate aminotransferase. Iron is stored in the liver, thyroid, and heart in the form of hemosiderin. An early diagnostic test is to monitor the level of iron and transferrin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***) saturation in plasma. Measurement of transferrin saturation in the 70% range is usually diagnostic with typical hereditary hemochromatosis patients having values in the 90% range.

Iron being a redox-active metal, it most likely exerts its toxic effects through the generation of hydroxyl radical or by generation of ferryl ion.[85–87] In iron loaded condition, there is generation of radical species leading to lipid peroxidation. Lipid peroxidation of cellular membrane would have deleterious effects on their function and hence on the function of the cell. There is also irreversible oxidation of ascorbic acid. Deficiency of ascorbic acid can lead to a reduction in the amount of iron available for erythropoiesis.

3.1.2 Genetic Aspects of Hemochromatosis

Hereditary hemochromatosis is an autosomal recessive disorder of iron metabolism. The frequency of the homozygous genotype is 1 out of 250 persons, with 1 in 9 being a carrier.[88,89] The disease is most common in European descent and it is the most common genetic disorder in Caucasians known in the United States. Early studies indicated that the gene responsible for hereditary hemochromatosis was linked to the human leukocyte antigen. In 1996, the gene was identified near the major histocompatibility complex (MHC) on chromosome 6, which contained a mutation present in 83% of individual homozygous for hereditary hemochromatosis.[90] The gene, termed HFE, encodes a 343-amino acid protein, which is very similar to MHC class 1 molecules.

3.1.3 HFE protein

Although concrete evidence as to the exact function of the HFE protein is as yet unavailable, many interesting theories have been proposed. A proposed model for the HFE protein is shown in Figure 5.[90] β_2-microglobulin is a protein that is usually found complexed to MHC class 1 proteins on the surface of most cells. If β_2-microglobulin is absent, the complex is destabilized and cell-surface quantities of HLAs are reduced. The Cys 282 Tyr mutation common in hemochromatosis patients is very close to the expected site of β_2-microglobulin binding and would be expected to diminish this interaction. Immunohistochemical studies have localized the HFE protein to various portions of the gastrointestinal tract. These findings correlate well with observation that primary site of iron absorption is affected.[91,92] Based on these observations, it has been proposed that HFE protein is involved in the downregulation of the iron absorption process. There are three proposals regarding the possible role of HFE protein. First, the HFE protein may act as a ‘sensor’ of body iron concentration by some form of iron chelate. This would in turn tell the enterocyte that iron stores are high and that iron uptake should be downregulated. Secondly, the HFE protein would act as part of a signal transduction pathways, as has been demonstrated in the epidermal growth factor (EGF) receptor systems.[90] Third, it has been suggested that HFE may interact with members of the immune system and indirectly affect iron metabolism. Much further work is necessary to know the exact function of this protein.

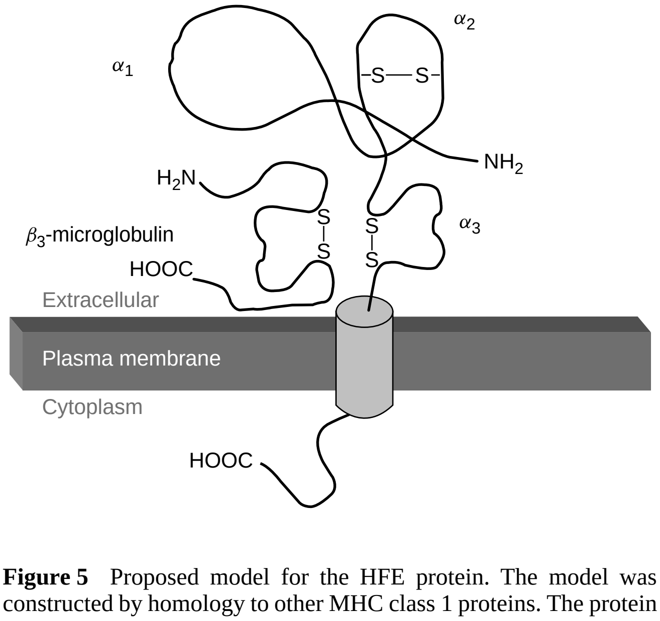

Figure 5 Proposed model for the HFE protein. The model was constructed by homology to other MHC class 1 proteins. The protein has three extracellular domains, which are homologous to the α_1, α_2, and α_3 domains of other MHC class 1 proteins. The protein also has a site for noncovalent interaction with β_2 microglobulin, which is a separate protein. In addition, the protein has a single transmembrane segment and a short cytoplasmic tail

3.1.4 Treatment for Hereditary Hemochromatosis

Once diagnosed hereditary hemochromatosis can be treated by weekly venesection of approximately 0.5 L of blood. The amount of iron removed in this way is usually around 250 mg per 0.5 L of blood.[93] The intensive therapy lasts for 2–3 years depending on the iron present. A recent study reported patient compliance with this form of treatment.[93] Another treatment option is chelation therapy by deferoxamine but this is an expensive treatment and the iron removal is slower; its main use is with non-HFE hemochromatosis.

3.2 Thalassemia

3.2.1 Clinical and Biochemical Features

Thalassemias are technically not disorders of iron metabolism or iron transport but the severe iron overload is usually the major complication of the disease. The most clinically important forms of thalassemia are α and β-thalassemia caused by the decreased or absent production of one or more globin proteins (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***) and those where some chains are synthesized but at greatly reduced rate. Patients with the severe form of the disease suffer from iron overload as a side effect of regular blood transfusion to treat the disorder. The β-globin production in homozygous forms of β-thalassemia is either nonexistent or very low, leading to an excess of α-globin chains in red-cell precursors. Since the α-globins are not able to form a viable tetramer, they precipitate and form inclusion bodies, which leads to the destruction of red-cell precursor and subsequent ineffective erythropoiesis. The end result is hemolysis and general state of anemia and tissue hypoxia. The hypoxic condition stimulates the release of erythropoietin, which, in turn, leads to the increased absorption of intestinal iron and expansion of the bone marrow. Iron loading is further compounded by the fact that blood transfusion is needed to relieve anemia. It causes decrease of intestinal iron but the additional input of iron through transfusion continues to accumulate.

The continued absorption of iron causes its deposition in various tissues starting with liver and spleen and followed by myocardium. Deposition of iron in the myocardium usually results in death by intractable cardiac failure.[94] Patients suffer from hypoparathyroidism and hypogonadism. Patients with the severe form of thalassemia are more susceptible to bacterial infection, possibly due to the increase in serum iron, which may favor bacterial growth. Iron overload is less common in the adult forms of α-thalassemia. This is most likely the result of a fundamental difference between α and β-thalassemia. As mentioned, the excess of α-globin chains cannot form viable tetramers and causes red-cell destruction. The excess β-chains present in α-thalassemia are able to form soluble homodimers and do not precipitate in the bone marrow. This is paralleled in the fetal state when excess γ-chains form soluble homodimers. Hence, α-thalassemia is characterized by a severe degree of inefficient erythropoiesis and a milder degree of anemia.

3.2.2 Genetic Aspects of Thalassemia

The underlying cause of the disease is a disturbance in the synthesis of one or more of the globin chains of hemoglobin. There are several different types of hemoglobins, all of which are tetrameric, containing two pairs of different polypeptide chains, and are developmentally regulated. The structure of human hemoglobin shows that each α-chain makes contact with two β-chains creating an α, β and $\alpha_2\beta_2$ interface.[95,96] The six globin genes are divided into two clusters found on two different chromosomes. The α-like gene cluster is located on chromosome 16 while the β-like gene cluster resides on chromosome 11. However, no protein product has yet been isolated and its function remains unknown. Rearrangements within the α and β gene clusters are fairly common and in most cases have no associated clinical condition.

3.2.3 Treatment of Thalassemia

The treatment of thalassemia, as in other metal overload disorder, is chelation therapy. The chelating agent most widely used is deferoxamine administered subcutaneously. The search for an orally administered iron chelator has intensified in recent years, leading to clinical trials of many potential new iron chelators such as deferiprone(L1). However, many issues regarding the use of these drugs, such as dose-related toxicity and recommended age of initiation, remain unresolved.[97–101]

3.3 Aceruloplasminemia

3.3.1 Clinical and Biochemical Features

In aceruloplasminemia, iron accumulates in various tissues including liver, brain, and in the islets of Langerhans, which causes loss of pancreatic β-cells. There is an increase in iron level in the basal ganglia. Iron also deposits in the microglia and neurons.[102] These findings are consistent with biochemical studies, which suggested direct involvement of ceruloplasmin in the iron metabolism pathway. The ferroxidase activity of ceruloplasmin has been proposed since the 1960s.[103–105] The clinical features of aceruloplasminemia includes neurologic disease, diabetes mellitus, and retinal degeneration.[106] The age of onset of neurologic disorders varies from 38 to 65 years. Patients show involuntary movements such as ataxic gait or slurred speech initially. Patients also develop mental disturbances and intellectual impairment. Once the disease is full-blown, various degrees of neurologic symptoms are observed. All these observations suggest that ceruloplasmin is playing a critical role in the metabolism of iron in brain implying that ceruloplasmin is unable to cross the blood-brain barrier. Thus, the ceruloplasmin gene must occur in the brain. Under normal conditions, iron in the brain is oxidized by astrocyte-secreted ceruloplasmin, followed by incorporating into transferrin, which is synthesized in oligodendrocytes.[102]

Without ceruloplasmin activity the ferrous iron is taken up by brain cells leading to iron overload and cell death. A similar situation occurs in peripheral tissues. This is supported by studies indicating a significant increase in plasma lipid peroxidation in patients with aceruloplasminemia.[107]

3.3.2 Ceruloplasmin Gene

The ceruloplasmin gene is located on chromosome 3, spanning approximately 36 kb and consisting of 19 exons.[108] Mutations in this gene lead to aceruloplasminemia demonstrating progressive neurodegeneration of the retinal and basal ganglia.[102] The disorder is inherited in an autosomal recessive manner. Most of the mutations in this gene result in a shift in the reading frame, such that the amino acid residues at the carboxy terminus essential for the trinuclear copper cluster responsible for oxidase activity are eliminated. This is consistent with the observation of little or no oxidase activity in the plasma of affected individuals. Gene mutations found are heterogeneous in patients with the same ethnic background, though mutation has been shown to be shared by two unrelated Japanese families.[108] All mutations are predicted to produce truncated ceruloplasmin by premature termination in translation.[109]

3.3.3 Ceruloplasmin

Ceruloplasmin is a secreted blue copper protein, which carries 95% of the circulating copper in the body.[110] Copper in ceruloplasmin is not exchangeable. The crystal structure shows that the holoprotein contains six copper atoms, three of which are in a trinuclear copper cluster.[111] The protein is synthesized in the hepatocytes and copper incorporation takes place in the secretory pathway most likely in the Golgi or rough endoplasmic reticulum with N-glycosylation not being required for copper incorporation.[112] The synthesis and secretion of the protein is not dependent on copper incorporation, but apoceruloplasmin lacking oxidase activity is unstable and is rapidly degraded once secreted.[113] Analysis of copper incorporation into apoceruloplasmin in vitro reveals that this process is cooperative and that the failure of copper incorporation into copper-binding site is intrinsic to the mutant proteins.[114] The trinuclear copper cluster is responsible for activating oxygen during the catalytic cycle of the protein. The ligands for the trinuclear cluster originate from both the amino and carboxy termini of the protein. Ceruloplasmin plays a key role in the mobilization and oxidation of iron stores and their incorporation into transferrin.

Human ceruloplasmin is composed of a single polypeptide chain of 1046 amino acid residues.[115] The protein shows a threefold internal homology of amino acid sequence and each homology unit contains 340–350 amino acids. From these data, it is suggested that ceruloplasmin is an evolutionary product of a tandem triplication of ancestral gene.

3.3.4 Treatment

Currently there is no effective treatment for aceruloplasminemia. It is interesting that Wilson disease patients rarely show the symptoms of aceruloplasminemia despite very low levels of ceruloplasmin. It appears that extrahepatic production of ceruloplasmin is enough to carry out iron metabolism. Treatment of aceruloplasminemia involves chelating agent to mobilize and remove iron from various tissues. D-penicillamine therapy was initiated but no clinical effect was demonstrated.[116] Deferoxamine has been used to treat this condition.[117] This chelator has been shown earlier to cross the blood-brain barrier. Initial trials using deferoxamine to treat aceruloplasminemia patients have shown a decrease in neurologic symptoms. But further studies are necessary to provide the basis for treating individuals suffering from aceruloplasminemia.

4 ZINC-RELATED DISEASE

4.1 Acrodermatitis Enteropathica

4.1.1 Clinical and Biochemical Features

Acrodermatitis enteropathica is a rare autosomal recessive disease.[118] It was demonstrated that the disorder was caused by the inability to absorb sufficient zinc.[119] This disease is not present at birth but usually develops in the early months of life soon after weaning from breastfeeding. It causes classic symptoms of zinc deficiency, such as dermatological lesions, changes in the gastric mucosa, associated digestive system problems, lack of weight gain, and immune, and reproductive problems. Neuropsychiatric signs include irritability, emotional disorders, tremors, and occasional cerebellar ataxia.

4.1.2 Genetic Aspects

The linkage analysis revealed that the acrodermatitis enteropathica gene is located on chromosome 8q24.3 and the SLC39A4 gene has been found to be the cause for this disorder.[120–123] The SLC39A4 gene encodes one member of a human zinc–iron regulated transporter-like protein (hZIP) family, hZIP4. The gene consists of a total of 12 exons. Mutations in hZIP4 were found in patients, which strongly suggested that the disorder is caused by a defect in this gene.

4.1.3 Protein Encoded by the Gene

The gene encodes a polypeptide of 647 amino acids, having eight transmembrane domains organized in two blocks of three and five. A histidine-rich region, which is considered

to be the zinc-binding site, resides between the two blocks of transmembrane domains.[121,122,124] This gene is expressed abundantly in the small intestine, stomach, colon, and kidney. The presumed zinc-uptake protein is localized in the apical membrane of the enterocyte.

Little is known, however, about the function of hZIP4, although three other members of the ZIP family (hZIP1, hZIP2, and hZIP3) have been shown to transport zinc into the cytoplasm.[125,126]

4.1.4 Treatment

The symptoms of the disease can be ameliorated by dietary zinc supplementation. The differential diagnosis of the disease includes acquired zinc deficiency condition owing to low-zinc level in mother's milk because both conditions are very similar in terms of onset and clinical features. As soon as the low-zinc breastfed infants are weaned, they no longer require supplemental zinc, but acrodermatitis enteropathica patients experience recurrence of symptoms if they discontinue oral zinc therapy.

5 OTHER RARE GENETIC DISORDERS OF METAL METABOLISM

There are several less common genetic disorders of metal metabolism.[127] Occipital Horn Syndrome is a mild allelic form of Menkes disease causing skeletal dysplasia but with little neurologic impairment except developmental delay. The genetic basis is mutation in *ATP7A*. Serum copper, ceruloplasmin, and lysyl oxidase activity in this disease are low. TFR2-deficiency is a rare form of hemochromatosis caused by mutations in transferrin receptor-2 gene, which maps to chromosome 7q22. Clinical features are related to mutations in HFE.[128] Ferroportin deficiency is related to hereditary hemochromatosis not related to the HFE locus. Ferroportin is the main iron export pump in macrophages and hepatocytes. Mutations are found in the gene *SLC11A3* in chromosome 2q32.[129] Tricho-hepatic-enteric syndrome is a combination of hair abnormality, hepatic dysfunction with iron overload, and diarrhea. This disorder may be related to perinatal hemochromatosis but the basis of the disease is unknown. GRACILE Syndrome (Fellman Syndrome) is caused by mutations in *BCS1L* gene, which encodes a protein in the mitochondrial inner membrane required for assembly of complex III in the mitochondrial respiratory chain.[130] Accumulation of iron in this disorder may be a secondary feature. Iron accumulation becomes less severe as the affected child gets older. There is no effective treatment for this condition. Congenital cholestasis with hepatic zinc accumulation is an extremely rare disease. The pathogenesis of this zinc overload liver disease is not yet determined.

1 HARD AND SOFT DEFINITIONS

Almost 50 years ago, metal ions were divided into two groups: a majority labeled class (a), for which the anion binding strength in aqueous solutions is greatest for F^- and generally follows the order F > Cl > Br > I, and a minority class (b), in which F^- binding is weaker than at least one of the heavier anions and that generally follows the order F < Cl < Br < I (in the gas phase all metal ions follow the first order).[1] The same trends occur in other columns in the periodic table; for example, class (a) metal ions tend to favor binding to oxygen and class (b) metal ions to sulfur ligands. Subsequently Pearson extended the application and changed the terminology so that class (b) metal ions became soft and class (a) metal ions were subdivided into hard and borderline groups.[2] The greater popularity of the altered nomenclature is partly because it is easier to say harder or softer than more (a) character or more (b) character. Thus fluoride and chloride are described as hard, bromide as borderline, and iodide as soft.

The proposal by Pearson that hard acids prefer to coordinate with hard bases, and soft acids to soft bases, has become well known. All alkali, alkaline earth, and lanthanide metal ions are classified as hard as are the five small metal ions Be^{2+}, Al^{3+}, Cr^{3+}, Ga^{3+}, and Fe^{3+}, and also Mn^{2+}, Sc^{3+}, and In^{3+}. Borderline metal ions include the last five dipositive ions of the first transition row and Sn^{2+}, Pb^{2+}, and Bi^{3+}. Soft metal ions include Pd^{2+}, Ag^+, Cd^{2+}, Hg^{2+}, CH_3Hg^+, Tl^+, and Tl^{3+}. In addition to the assignments of the halides already mentioned, hard ligands include most oxygen donor ligands and aliphatic amines, while aromatic amines are borderline. Soft ligands include sulfhydryl groups and CN^-, SCN^-, and $S_2O_3{}^{2-}$. Despite the popularity of the hard–soft designation, a quarter of a century elapsed before Pearson proposed a quantitative scale. Pearson defined softness as the reciprocal of hardness and presented quantitative absolute hardness values for metal ions and ligands (in which the hardness of an atom and an anion such as F and F^- are surprisingly identical).[3] Subsequently Pearson disavowed his quantitative hardness scales for at least some cations and anions.[4] In any case, the hardness values for metal ions do not correlate at all with the stability constants of complexes, which are correlated best by the electron affinity of the metal ion.[5] Though often spoken of by chemists as if it is the determining factor in complex stability, the contribution of hardness or softness may pale compared to the intrinsic stability, which often dominates the binding strength.[4,5]

2 SUBSTITUTION REACTIONS

Just what does the typical chemist imply when she/he uses the terms hard and soft? To few if any does it correspond to Pearson's quantitative scale derived from gas-phase parameters and where hardness is the reciprocal of softness. More likely it expresses features of stabilities where, for example, though Cu^{2+} binds NH_3 more avidly than Mg^{2+}, the latter metal ion interacts more strongly with F^- than does Cu^{2+}. Comparisons of this kind and the stability orders of halide complexes of various metal ions mentioned at the beginning are equivalent to describing the extent of substitution reactions. If M and N are two different metal ions and X and Y two different ligands, we may compare the hardness of a metal ion by considering the substitution on the metal ion of one ligand by another

$$MX + Y \rightleftharpoons X + MY \quad (1)$$

for which the free energy change is proportional to $\log K_{MY} - \log K_{MX}$, where K_{MY} and K_{MX} are the stability constants for complexes MY and MX, respectively. An advantage of such a comparison is that it greatly reduces the overlooked effect of a reduction in coordination number from the aqueous ion for several soft metal ions in augmenting stability constants by powers of 10.[6] Similarly, we may compare the hardness of a ligand by considering the substitution on the ligand of one metal ion for another

$$MX + N \rightleftharpoons M + NX \quad (2)$$

for which the free energy change is proportional to the stability constant difference: $\log K_{NX} - \log K_{MX}$. By considering such substitution reactions one gains consistency in application of the principle of hard and soft acids and bases. The scales presented below are practical scales dependent only upon experimental stability constants determined in aqueous solutions, and they do not involve any other quantities such as electron affinities and other parameters from gas-phase reactions, heats of hydration, or heats of reaction.

Nor do the scales assume a model or rely on derived parameters with arbitrary scaling. These other factors have been discussed many times.[7,8] The scales probably represent what most investigators imply when they use the terms hardness and softness.

3 METAL ION SCALES

To avoid influence of chelate ring bite size on complex stabilities unidentate ligands are emphasized. Extensive stability constant values are available for four unidentate hard ligands: F^-, OH^-, acetate, NH_3, and borderline Br^-. Though somewhat limited in scope, the ligands encompass donor atoms of interest to many chemists. From a careful tabulation of stability constants for 28 metal ions with the five unidentate ligands, stability constant differences for a single metal ion with two different ligands yield the ordering in the following metal ion scales.[9] The number in parentheses following a metal ion is the log stability constant difference.

3.1 Fluoride Minus Bromide: Halide Scale

Among the common halides, iodide is the softest member but a limited number of stability constants have been published. For this reason we employ the more extensive values for bromide. Ordering of metal ion stabilities with soft I^- is virtually identical to that of borderline Br^-. Differences in the stability constant logarithms for a metal ion with F^- minus that for the same metal ion with Br^- give the halide scale. These differences are ordered in the following halide scale where after each of the 22 metal ions the difference appears in parentheses, and a greater than sign (>) indicates a factor of about 10. Not considering the proton at the beginning of the scale, the span of differences is 14.3 log units, and there are 14 greater than signs among the metal ions.

$$\begin{aligned}&\mathrm{H^+}(11.9) \gg\gg\gg \mathrm{Sc}(6.3) > \mathrm{Be}(5.5),\\ &\mathrm{Fe(III)}(5.5) > \mathrm{Ga}(4.5), \mathrm{Y}(4.1), \mathbf{Sn}(3.8),\\ &\mathrm{Lu}(3.7) > \mathrm{Ce}(3.3), \mathrm{La}(3.0) > \mathrm{Mg}(2.7), \mathbf{Bi}(2.4) > \mathrm{In}(1.7),\\ &\mathbf{Zn}(1.4), \mathrm{Mn}(1.0), \mathbf{Cu}(0.9), \mathbf{Ni}(0.9),\\ &\mathbf{Co}(0.8) > \mathbf{Pb}(0.3) > \mathit{Cd}(-0.8) \gg\gg \mathit{Ag}(-4.6),\\ &\mathit{CH_3Hg}(-5.0) \gg> \mathit{Hg}(-8.0).\end{aligned}$$

Halide scale

The only change required by considering iodide instead of bromide is to reverse the order of Bi^{3+}, In^{3+}, and Zn^{2+}. The change from positive to negative signs occurs after Pb^{2+} for either bromide or iodide ligands. This sign change corresponds to the class (a) and class (b) division mentioned in the first sentence of the Introduction. Metal ions assigned by Pearson as hard appear in normal type, borderline in bold, and soft in italics.

Metal ions favoring fluoride appear at the beginning of the scale and those favoring bromide (and iodide) at the end. The ordering in the halide scale corresponds closely to the three categories described by Pearson: nine hard metal ions and borderline Sn^{2+}, are followed by six borderline metal ions and also hard In^{3+} and Mn^{2+}, and completed by four soft metal ions. As the multiple greater than signs indicate, the last three cases involving Ag^+ and Hg(II) are much softer than all others in the list. The above halide scale serves as a quantitative guide to the relative hardness and softness of 22 metal ions toward halide ions in aqueous solutions.

3.2 Hydroxide Minus Ammonia: OH–N scale

More relevant to many investigators than differences among halide stability constants are comparisons involving oxygen and nitrogen donor atoms. These differences are ordered in the following hydroxide–ammonia (OH–N) scale, where after each of the 25 metal ions the difference between stability constant logs appears in parentheses, and a greater than sign indicates a factor of about 10. The span is 10.3 log units and there are 10 greater than signs.

$$\begin{aligned}&\mathrm{Sc}(9.0) > \mathrm{Ga}(8.4), \mathrm{Fe(III)}(8.0) > \mathrm{Al}(6.7),\\ &\mathrm{H^+}(6.5) > \mathrm{In}(6.0), \mathrm{Y}(5.9), \mathrm{Lu}(5.7), \mathrm{Ce}(5.3),\\ &\mathrm{La}(5.3) > \mathbf{Pb}(4.7), \mathit{Tl(III)}(4.3) > \mathit{Pd}(3.4) > \mathbf{Zn}(2.7),\\ &\mathbf{Cu}(2.4), \mathrm{Mg}(2.3), \mathbf{Co}(2.3), \mathit{CH_3Hg}(2.3),\\ &\mathrm{Mn}(2.2) > \mathit{Hg}(1.8), \mathit{Tl(I)}(1.7), \mathrm{Ca}(1.4),\\ &\mathbf{Ni}(1.4), \mathit{Cd}(1.3) > \mathrm{Li}(0.7) \gg \mathit{Ag}(-1.3).\end{aligned}$$

OH–N scale

Again, metal ions assigned by Pearson as hard appear in normal type, borderline in bold, and soft in italics.

Metal ions favoring hydroxide appear at the beginning of the OH–N scale and those favoring ammonia at the end. The OH–N scale begins with nine hard metal ions, followed by nine metal ions with an intermingling of all three types, and finally concluding with four soft metal ions, but also with hard Ca^{2+} and Li^+ and borderline Ni^{2+} embedded therein.

3.3 Acetate Minus Ammonia: O–N Scale

As an oxygen donor ligand, hydroxide may not be typical, and for some applications acetate may offer a more representative oxygen donor ligand than hydroxide. For acetate–ammonia, 22 log stability constant differences yield the following acetate–ammonia (O–N) scale. The scale spans 8.0 log units and each of the eight greater than signs indicates a factor of near 10.

$$\begin{aligned}&\mathrm{Sc}(2.8) > \mathrm{La}(1.6), \mathrm{Ce}(1.5), \mathrm{Y}(1.3), \mathrm{Lu}(1.2) > \mathit{Tl(I)}(0.8),\\ &\mathrm{Ca}(0.7), \mathrm{Li}(0.6), \mathbf{Pb}(0.6), \mathrm{Mg}(0.3) > \mathrm{Fe(III)}(-0.4),\\ &\mathrm{Mn}(-0.4), \mathrm{In}(-0.5) > \mathbf{Co}(-1.0), \mathit{Cd}(-1.1),\\ &\mathbf{Zn}(-1.2) > \mathbf{Ni}(-2.0), \mathbf{Cu}(-2.3) > \mathit{Ag}(-2.9),\\ &\mathit{Tl(III)}(-2.9) > \mathit{CH_3Hg^+}(-4.1), \mathrm{H^+}(-4.5) > \mathit{Hg}(-5.2).\end{aligned}$$

O–N scale

Once again Pearson's hard metal ions appear in normal type, borderline in bold, and soft in italics.

Metal ions favoring acetate appear at the beginning of the O–N scale and those favoring ammonia at the end. Of the first 13 metal ions, 11 are hard, but in this group there is one soft (Tl^+) and one borderline (Pb^{2+}) metal ion. Next a group of four borderline metal ions also contains one soft metal ion (Cd^{2+}). The scale ends with four soft metal ions, but also with the hard proton.

3.4 Carboxylate Minus Sulfhydryl: O–S Scale

Unfortunately, it is impossible to develop a comparable hardness scale with unidentate sulfur donor ligands as so few reliable experimentally determined stability constants are available. Polymerization has gone unrecognized in many of the determinations. Many of the constants involve chelate rings that introduce the additional variable of chelate ring bite size. Ag^+ and Hg^{2+} prefer linear coordination, making formation of five- and even six-membered chelate rings highly strained.[6]

Nonetheless, by relaxing the requirement for unidentate ligands, we may compare the tendency of some metal ions to bind to oxygen or sulfhydryl donor atoms. Stability constants have been tabulated for binding to substituted iminodiacetates, $R–N(CH_2COO^-)_2$.[10] For $R = –CH_2COO^-$ (nitrilotriacetate) and $R = –CH_2CH_2S^-$, the difference in stability constant logs for the former minus the latter tridentate ligand is given in parentheses, in sequence, after each dipositive metal ion.

Ca(1.5), Sr(1.4), Ba(1.3), Mg(1.1)⋙
Mn(−1.9), **Ni**(−2.2), **Fe**(−2.9)≫
Zn(−5.3), **Pb**(−5.6), *Cd*(−6.9), *Hg*(< −8).

O–S scale

Similar differences and sequence are obtained with $R = –CH_2CH_2OH$ as the oxygen donor, with the addition of poorly chelating Hg^{2+}, still with the greatest negative value.[10] Metal ions in the O–S scale falls distinctly into three groups: alkaline earths with differences from +1.5 to +1.1, transition metal ions from −1.9 to −2.9, and filled d orbital ions from −5.3 to <−8. The spans within the first two groups are narrower than the gaps between the three groups. For oxygen–sulfhydryl binding, the alkaline earths may be designated as hard, the three transition metal ions as borderline, and the four filled d shell metal ions as soft. The recognized avidity of Zn^{2+} for sulfhydryl donors is confirmed. Though assigned as hard by Pearson, by this grouping, Mn^{2+} is emphatically borderline. This borderline designation for Mn^{2+} is also more consistent with other scales presented above.

4 LIGAND SCALE

To create a ligand scale, corresponding to the second substitution reaction of Section 2, we consider the differences between stability constant logarithms for soft and hard metal ions for several ligands. Hg^{2+} stands as the preeminent soft metal ion. Sc^{3+} is the hardest metal ion in all three of the above scales, but results are limited. More ligands may be included if results for the smaller and heavier lanthanides are considered for the hard metal ion. For 16 ligands, the difference between the stability constant logarithms for Hg^{2+} minus a lanthanide in parentheses is as follows.

F^-(−3), H_2O(0), acetate(2), HCO_3^-(4), CO_3^{2-}(5),
OH^-(5) > **pyridine**(6), **benzimidazole**(6), **imidazole**(7),
Cl^-(7), NH_3(8), *SCN*$^-$(9), **Br**$^-$(9) > *I*$^-$(13),
CN$^-$(13), *S*$_2$*O*$_3^{2-}$(14).

Ligand scale

Ligands assigned by Pearson as hard appear in normal type, borderline in bold, and soft in italics. For Pearson, aliphatic amines are hard and aromatic amines borderline. Since imidazole binds metal ions through a borderline pyridine-type nitrogen,[11] imidazole is also classed as borderline in the ligand scale. Use of CH_3Hg^+ in place of Hg^{2+} yields a virtually identical ordering with a lesser span of 13 log units.

The hardest ligands appear at the beginning of the ligand scale, which spans 17 log units. Cyanide and thiocyanate are ambivalent ligands; virtually all metal ions bind to CN^- through the carbon atom. Even upon binding the first CN^-, Cu^+, Ag^+, and Hg^{2+} undergo a reduction to two-coordination. A reduction to four-coordination occurs upon binding of the second CN^- to Ni^{2+} and Zn^{2+}.[6] A reduction in coordination number strengthens binding.

Log stability constant plots of the four amines against one another correlate tightly ($R^2 > 0.98$) for seven metal ions. With the values for ammonia on the x-axis, straight lines produced by plotting on the y-axis give slopes of 0.71 for pyridine, 0.77 for benzimidazole, and 0.88 for imidazole. These slopes provide factors that yield quantitative hardness values on the ligand scale from ammonia(8): $0.71 \times 8 = 6$ for pyridine, $0.77 \times 8 = 6$ for benzimidazole, and $0.88 \times 8 = 7$ for imidazole. Thus the order of increasing softness is pyridine(6) < benzimidazole(6) < imidazole(7) < ammonia(8); the aliphatic amine is softer than all three aromatic amines, opposite to the Pearson assignment. The new order is confirmed by quantitatively considering exchange reactions between ammonia and pyridine (or imidazole) with soft CH_3Hg^+ (or Ag^+) and any borderline or hard metal ion: ammonia always pairs preferentially with the soft metal ion.

The above order of increasing softness of the amines is also the order of increasing basicity. The influence of greater basicity in yielding increasing softness is also illustrated by two other comparisons in the ligand scale: H_2O(0) < OH^-(5) and HCO_3^-(4) < CO_3^{2-} (5). These sequences point up a

general feature of metal ion stabilities: greater basicity yields greater metal ion stability, which in turn provides greater discrimination among metal ions, which in turn gives rise to softness. Often, however, other factors overwhelm the influence of basicity: among the halides fluoride is both the strongest base and the hardest.

The ligand scale serves as a quantitative indication of the relative hardness and softness of ligands. Wide applicability of the ligand scale is supported by ordering identical to the above for the seven common ligands in a scale derived from heats of formation of solid compounds of identically charged and similarly sized Ca^{2+} and Cd^{2+}.[7] In the ligand scale, the first six ligands are assigned as hard by Pearson; of the next closely spaced seven ligands, two are hard, four borderline, and one soft. The ligand scale ends with three soft ligands. In the ligand scale, the relative softness of the presumably hard ammonia(8), comparable to borderline bromide(9) and soft thiocyanate(9), emerged unexpectedly. Based on the quantitative results of the ligand scale, previously hard ammonia and chloride and soft thiocyanate are more appropriately switched into the borderline group. These switches more consistently place all amines, aliphatic, and aromatic, in the same borderline group. The recommended designations lead to a consistent sequence of six hard, seven borderline, and three soft ligands, as indicated by the two inequality signs between the three groups. Thus all oxygen donor ligands are designated hard and now all nitrogen donors borderline. Within the borderline group, aliphatic amines are softer than aromatic amines.

5 COMPARISONS OF METAL ION SCALES

5.1 Correlations

Though there is a wide measure of sequence agreement among the three metal ion scales, there are also differences. For example, of the three scales, in only the OH–N scale is Ag^{+} the softest metal ion, in the other two scales it is Hg^{2+}. Departures from an identical ordering demonstrate that the degree of metal ion hardness and softness depends on the ligands considered, and that finding absolute values applicable to all cases in aqueous solutions is not possible. Thus one uses the scales applicable to ligands being considered: for example, the O–N scale for many biological systems.

5.2 Pb^{2+}

Lead (Pb^{2+}) presents a case that demonstrates limitations in the hard-soft concept. The first stability constant logarithms for lead and the halide ions, all at 25° C and 1.0 M ionic strength, appear in parentheses: F(1.44) $>$ Cl(0.90) $<$ Br(1.10) $<$ I(1.26).[12] The increasing trend for the last three halides describes class (b) behavior, while the greatest value for F^{-} characterizes a class (a) metal ion. Pb^{2+} interacts relatively strongly with both oxygen (hard) and sulfur (soft) donor ligands, and relatively weakly with nitrogen donor ligands, as illustrated in the stability ruler (see Section 5 in ***Metal Ion Toxicity***). Despite the presence of a free sulfhydryl group on the proteins, Pb^{2+} binding occurs exclusively at the Ca^{2+} sites, composed solely of O donors, of oncomodulin and chick vitamin D induced intestinal calcium-binding protein.[13] Pb^{2+} also combines with the components of nucleic acids.[14] In many examples, Pb^{2+} eschews borderline (is antiborderline) and opts for either hard or soft behavior, making the simple hard–soft concept ineffective for use with this metal ion. In contrast, compared to other metal ions, Ni^{2+} exhibits a tendency to prefer nitrogen over oxygen or sulfur donors (except when two or more sulfur donors promote a diamagnetic complex).

6 CONCLUSIONS

Note again that the quantitative values associated with hardness and softness in this article are based wholly on experimentally determined log stability constant differences determined in aqueous solutions at room temperature. The values are not absolute; addition of more metal ions might extend the scales in either direction. Small differences between metal ions should not be overinterpreted. The relative difference scales are linear in log stability constant, stretching from very hard at one end to very soft at the other. As hardness decreases, softness correspondingly increases, and vice versa. These practical scales are difficult to relate to that of Pearson, where absolute hardness values are derived from gas-phase parameters, and softness is the reciprocal of hardness.[3]

In practice, the principle of hard and soft acids and bases is often contorted so as to provide nonfalsifiable explanations for almost any observation.[5] The limitations of the principle need greater exposure. The very hard Sc^{3+} and the very soft CH_3Hg^{+} both bind strongly and nearly equally to the hard ligands hydroxide on one hand and acetate on the other.[9] Though both metal ions are considered as very soft, Hg^{2+} is among the strongest binders to hydroxide and acetate, and Ag^{+} among the weakest. With the exception only of Ag^{+}, hydroxide forms stronger complexes with all metal ions than do ammonia or bromide. It is only when differences of stability constant logs are compared that one finds some quantitative justification for the principle of hard and soft acids and bases. Such differences are sequenced in the scales of this article. The principle of hard and soft acids and bases finds its most consistent application, not in direct stability constant comparisons, but rather in the free energy or log stability constant differences of the substitution reactions of Section 2.

1 INTRODUCTION

Electron-transfer (ET) reactions, the simplest chemical transformations, play vital roles in a diverse ensemble of biological processes. Biological electron transfer is an extraordinarily vibrant field of inquiry, responsible for thousands of original research articles during the past decade. This chapter will focus on studies of ET in chemically modified proteins, protein–protein complexes, and two key biological energy transduction pathways, photosynthesis (*see* ***Photosynthesis***) and respiration (*see* ***Cytochrome Oxidase***).

Aerobic organisms derive most of the energy needed for life processes by the burning of foodstuffs with molecular oxygen in air.[1] In the first part of the respiratory process, hydrogen atoms are extracted from organic molecules. The hydrogen carriers provide reducing equivalents to the respiratory chain located in cell organelles (mitochondria) or, in bacteria, in the cell membrane. These chains consist of a series of membrane-bound protein complexes in which the hydrogen atoms are split into protons and electrons. The electrons are passed down the chain and reduce molecular oxygen to water, whereas protons are left behind on one specific side of the membrane. In addition, the electron current through the chain is coupled to the pumping of additional protons from water to the same side of the membrane.[2] The two proton currents lead to an increased positive charge and decreased pH on this side. The resulting electrochemical potential across the membrane drives the synthesis of ATP, the universal energy currency of living cells.

Photosynthesis is the natural complement to respiration. Photons from the sun induce charge separation in a membrane-bound redox chain, ultimately producing a transmembrane potential for ATP synthesis. In green plants, algae, and cyanobacteria, the photogenerated holes oxidize water to oxygen. The photochemically generated reducing equivalents produce NADPH that, along with ATP, is used in carbon dioxide fixation.

Highly optimized ET reactions are essential for the operation of these biochemical machines. Much of the research on biological electron transfer aims to define the electronic and structural factors that regulate the rates and efficiencies of these essential transformations. This chapter will focus on studies of ET through proteins, particularly metalloproteins. ET processes involving DNA molecules have been the subject of extensive research as well,[3–6] but this work is beyond the scope of this chapter.

2 ELECTRON-TRANSFER THEORY

The unique simplicity of ET reactions has fostered the development of a powerful theoretical formalism that describes the rates of these processes in terms of a small number of parameters.[7] The conceptual breakthrough that led to the development of ET theory involved the recognition of the pivotal role played by the Franck–Condon principle.[8,9] Owing to the much higher electron velocities, nuclei remain fixed during the actual electron transfer from donor to acceptor. The transition state for this reaction must lie at a point in nuclear-configuration space where the reactant and product states are degenerate (Figure 1). Hence, through fluctuations of the reacting molecules and their surroundings, the transition-state configuration will be reached and an electron can transfer.

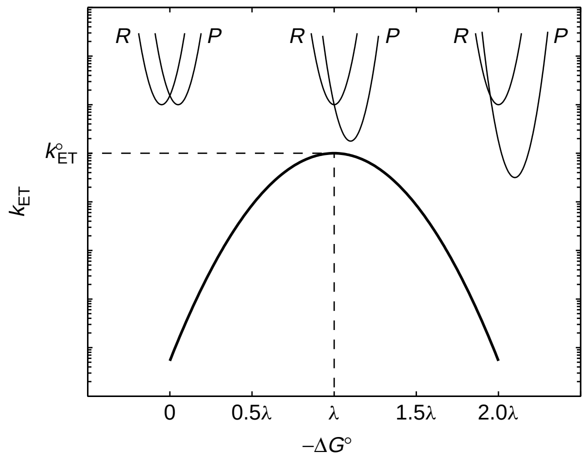

Figure 1 Driving-force dependence of ET rates predicted by semiclassical theory (equation 1). Rates increase with driving force until they reach a maximum value (k°_{ET}) at $-\Delta G^{\circ} = \lambda$. Rates then decrease at higher driving forces (inverted effect)

2.1 Activation Barriers

According to classical (Marcus) theory, the activation barrier for an adiabatic ET reaction depends on two parameters, the driving force ($-\Delta G^\circ$) and the reorganization energy (λ).[7] The reorganization parameter reflects the extent of outer-sphere (λ_{OUT}) and inner-sphere (λ_{IN}) nuclear rearrangement that accompanies charge transfer. The λ values for a cross reaction between two different reagents can be estimated from the average of the electron self-exchange reorganization energies for each redox partner (i.e. $\lambda_{12} \approx \lambda_{11}/2 + \lambda_{22}/2$). The unique prediction from Marcus theory is that rates reach a maximum when the driving force equals the reorganization energy. At higher driving forces, rates are predicted to decline (inverted effect) owing to less favorable Franck–Condon factors for the electron transfer. The central lesson of classical theory is that nuclear rearrangements accompanying ET must be compensated by reaction driving force (Figure 1). The balance between ΔG° and λ is a direct consequence of protein structure.

Electron transfer in proteins generally involves redox centers separated by long distances. The electronic interaction between redox sites is relatively weak and the transition state for the ET reaction must be formed many times before there is a successful conversion from reactants to products; the process is electronically nonadiabatic. A Landau–Zener treatment of the reactant-product transition probability produces the familiar semiclassical expression for the rate of nonadiabatic electron transfer between a donor (**D**) and acceptor (**A**) held at fixed distance (equation 1).[7] Biological electron flow over long distances with a relatively small release of free energy is possible because the protein fold creates a suitable balance between ΔG° and λ as well as adequate electronic coupling between distant redox centers.

$$k_{ET} = \sqrt{\frac{4\pi^3}{h^2 \lambda RT}} H_{AB}^2 \exp\left\{-\frac{(\Delta G^\circ + \lambda)^2}{4\lambda RT}\right\} \qquad (1)$$

2.1.1 Redox Potentials

The reduction potentials of redox-active proteins are exquisitely sensitive to the structure of the polypeptide.[10–13] It is well known that homologous proteins from different organisms can have quite disparate amino acid sequences yet nearly identical three-dimensional structures.[14,15] Nevertheless, single-point mutations can destroy redox function without disrupting structure. Indeed, substitution of a single amino acid in myoglobin can shift the Fe(III/II) reduction potential by as much as 200 mV, effecting greater than a thousand-fold change in the equilibrium constant for reaction with a redox partner.[16]

The secondary and tertiary structures of a protein can modulate the reduction potential of a single cofactor by more than 500 mV. The Fe(III/II) reduction potential of a free heme in aqueous solution is approximately −200 mV versus the normal hydrogen electrode (NHE), the potential of cytochrome *c* is 260 mV, and that of cytochrome *f* reaches 450 mV.[17] The shift in reduction potential is reflected in a differential folding free energy of the oxidized and reduced proteins.[18] In the case of cytochrome *f*, the Fe(II) protein is more stable toward unfolding than the oxidized protein;[19] the redox potential indicates a stability differential of some 650 meV (63 kJ mol^{-1}). In order for cytochrome *f* to be a viable redox protein, the folding free energy of the oxidized form must be at least 2 k_BT (~5 kJ mol^{-1} at 298 K), requiring that the folding free energy of the reduced protein be greater than 68 kJ mol^{-1} (700 meV).

2.1.2 Reorganization Energy

The protein fold plays a central role in lowering the reorganization energy of a biological ET reaction.[10] A large part of the λ-reduction results from sequestering a redox center from the aqueous solvent environment. Continuum models suggest that embedding a redox center inside a low dielectric cavity can lower the outer-sphere reorganization energy by as much as 50%.[20] Moreover, by constraining the coordination environment around metal centers, inner-sphere reorganization energy can be reduced as well.[10] Indeed, metals that are typically poor redox reagents because of large reorganization barriers can be extremely efficient when embedded in protein interiors. The reorganization energy for electron self-exchange in $Cu(phen)_2^{2+/+}$, for example, is ~2.4 eV; the value for Cu(II/I) in *Pseudomonas aeruginosa* azurin is 0.7 eV. The 1.7-eV reduction in λ reflects the transition-state stabilization imposed by the azurin fold.[10,21]

It is important to remember that the reorganization energy is a composite parameter rather than a fundamental physical quantity. Refinements to the semiclassical theory usually arise from quantum mechanical treatments of vibrational motions.[22] The increased rigor associated with these models, however, is rarely accompanied by the extra data required to cope with the influx of new parameters. The approximations involved in its definition, and the errors associated with its measurement dictate that λ should never be expressed with great precision.

2.2 Electronic Coupling

The ability to control redox potentials and reorganization energies in proteins comes at a price: ET partners buried within insulating polypeptides cannot come into close contact to exchange electrons. The essential electronic interaction between redox cofactors must be mediated by the polypeptide matrix. Extensive experimental and theoretical efforts have been aimed at elucidating the factors that regulate distant electronic couplings between redox sites in proteins.[21,23,24]

The electronic coupling matrix element (H_{AB}) reflects the strength of the interaction between reactants and products at the nuclear configuration of the transition state. Square-barrier ET tunneling models predict that the coupling will

depend exponentially on the distance (r) between redox centers (equation 2).[25] A square tunneling barrier implies that a homogeneous medium separates the donor and acceptor. This model is appropriate for electron tunneling across a vacuum ($\beta = 3{-}5\,\text{Å}^{-1}$) and is a reasonable

$$H_{AB}(r) = H_{AB}(r_o)\exp\left\{-\tfrac{1}{2}\beta(r - r_o)\right\} \quad (2)$$

approximation for tunneling through glassy solvents (H_2O, $\beta = 1.65\,\text{Å}^{-1}$;[26] 2-methyltetrahydrofuran, $\beta = 1.2\,\text{Å}^{-1}$[27]). Superexchange models are better suited to the description of tunneling through inhomogeneous media. In 1961, McConnell described a superexchange model for electron tunneling from a donor to an acceptor across a bridge composed of n identical repeat units.[28] The electronic coupling matrix element is a function of the couplings between redox sites and the bridge (h_{Ab}, h_{bB}), the coupling between bridge elements (h_{bb}), and the gap ($\Delta\varepsilon$) between the energy of tunneling electron (or hole) and reduced (or oxidized) bridge states (equation 3).

$$H_{AB} = \frac{h_{Ab}}{\Delta\varepsilon}\left(\frac{h_{bb}}{\Delta\varepsilon}\right)^{n-1} h_{bB} \quad (3)$$

The medium separating redox sites in proteins is comprised of a complex array of bonded and nonbonded contacts and an *ab initio* calculation of coupling strengths is a formidable challenge.[29] The homologous-bridge superexchange model (equation 3) is not suitable because of the diverse interactions in proteins. Beratan and Onuchic developed a generalization of the McConnell superexchange coupling model that accommodates the structural complexity of a protein matrix.[30] In this tunneling-pathway model, the medium between **D** and **A** is decomposed into smaller subunits linked by covalent bonds, hydrogen bonds, or through-space jumps. Each link is assigned a coupling decay (ε_C, ε_H, ε_S), and a structure-dependent searching algorithm is used to identify the optimum coupling pathway between the two redox sites. The total coupling of a single pathway is given as a repeated product of the couplings for the individual links (equation 4). The variation of ET rates with r depends upon the coupling-decay factors

$$H_{AB} = \Pi\varepsilon_C\Pi\varepsilon_H\Pi\varepsilon_S \quad (4)$$

for hydrogen bonds (ε_H), van der Waals contacts (ε_S), and single covalent bonds (ε_C). Equation (3) suggests that the magnitude of ε_C should depend critically upon the energy of the tunneling electron relative to the energies of the bridge hole and electron states. Clear demonstrations of this energy dependence in the tunneling regime have been elusive. Studies, however, have shown that electron transport over exceptionally long distances is possible when hole or electron states of the bridge can be populated as real intermediates.[31,32] In comparing ET data from different protein systems, then, it is important to consider the tunneling-energy gap and the possibility of forming oxidized or reduced intermediates in the bridging medium.

The tunneling-pathway model has proven to be one of the most useful methods for estimating distant electronic couplings.[21,23,30,33] The original tunneling-pathway model successfully described the distance dependence of protein ET reactions when a single pathway dominated the coupling.[30] The model was less successful when multiple pathways contributed to the overall coupling. More elaborate computational protocols have since been developed to describe in greater detail the factors that determine distant couplings in proteins.[29,33–38]

3 CHEMICALLY MODIFIED PROTEINS

3.1 Ru-modified Proteins

Semiclassical theory provides a framework for understanding biological electron flow; what is necessary on the experimental front are systematic investigations of the response of rates to variations in ET parameters ($\Delta G°$, λ, r). Early efforts involving studies of bimolecular ET reactions were frustrated by the effects of diffusion. A simple bimolecular ET reaction can be broken into a sequence of three steps: diffusive formation of an encounter or precursor complex (**DA**); ET from donor to acceptor within the precursor complex (**DA** → **D**$^+$**A**$^-$); and dissociation of the successor

$$k_{obs} = \frac{k_{+D}k_{ET}}{k_{-D} + k_{ET}} \quad (5)$$

complex to give products. The precursor and successor complexes are rarely observed in ET reactions; it is reasonable to employ a steady-state approximation to describe the time dependence of the [**DA**] concentration (i.e. $\partial[\mathbf{DA}]/\partial t = 0$). Within the limits of this approximation, the observed second-order rate constant for a bimolecular ET reaction (equation 5) depends on the rates of formation and dissociation of the precursor complex (k_{+D} and k_{-D}, respectively) and the ET rate within the complex (k_{ET}, equation 1). Below the diffusion limit (i.e. $k_{ET} \ll k_{-D}$), k_{obs} is equal to $K_{[DA]}k_{ET}$ (where $K_{[DA]} = k_{+D}/k_{-D}$ is the equilibrium constant for precursor-complex formation). Since the value of $K_{[DA]}$ is usually not known, it is quite difficult to extract accurate values of λ and H_{AB} from low-driving-force bimolecular ET rates. At high driving forces, reaction rates become masked by diffusion (i.e. $k_{ET} \gg k_{-D}, k_{obs} = k_{+D}$), frustrating efforts to observe inverted driving-force behavior.

In order to circumvent these difficulties, experimentalists developed methods to study the rates of intraprotein ET reactions.[21,23,24,39] One early approach involved metalloproteins that had been surface-labeled with redox-active metal complexes.[40,41]

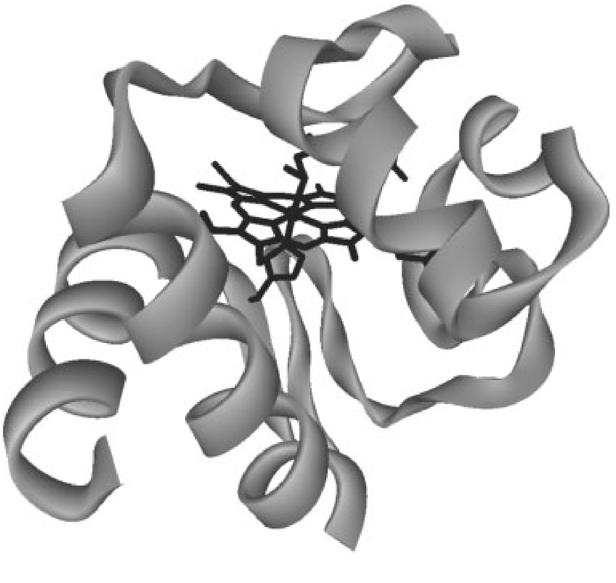

Figure 2 Ribbon representation of the peptide backbone in horse heart cytochrome *c*. The heme and its axial ligands are shown in black

3.2 Reorganization Energy

3.2.1 Cytochrome c

Investigations of intramolecular ET in heme proteins have focused on cytochrome *c* (104 amino acids in the horse protein; 12.5 kDa; $E° = 0.26$ V *vs.* NHE) (*see* ***Iron: Heme Proteins & Electron Transport***) (Figure 2).[14,15] Early work with the Ru–ammine modified protein involved the replacement of the native Fe center with Zn. Long-range ET reactions were initiated by visible-light excitation of the resulting Zn-porphyrin (ZnPor) to its long-lived (>10 ms), strongly reducing ($E° \sim -0.8$ V *vs.* NHE) triplet-excited state. A driving-force study of ET rates in $Ru(NH_3)_4L$(His33)-modified Zn-substituted cytochrome *c* (L = NH_3, pyridine, isonicotinamide) was consistent with $\lambda_{12} = 1.2$ eV.[23,42] The self-exchange reorganization energies for Ru-ammine complexes (λ_{11}) are in the vicinity of 1.6 eV. Intramolecular ET kinetics, then, suggest that $\lambda_{22} = 0.8$ eV for Zn-cytochrome *c*.[42]

Studies of high-driving-force ET in heme and nonheme proteins were made possible by Ru-diimine labeling protocols and the ‘flash-quench’ triggering method.[43] The driving-force dependence of ET in $Ru(diimine)_2$(im)(His33)-modified Fe-cytochrome *c* (im = imidazole) is best described by $\lambda_{12} = 0.8$ eV.[21,23] This value is lower than that found for Ru-ammine-modified Zn-cytochrome *c* because the diimine ligands coordinated to the Ru center are larger and more hydrophobic than ammines. Consequently, the self-exchange reorganization energy for $Ru(diimine)_2(im)(His)^{3+/2+}$ is substantially smaller ($\lambda_{11} = 0.8$ eV) than that of the ammine.[23,42] The combined results from ET measurements in the Ru–ammine and Ru–diimine proteins suggest that the reorganization energy for electron exchange between Fe(II)- and Fe(III)-cytochrome *c* is 0.8(1) eV.

3.2.2 Azurin

The flash-quench method made it possible to examine high-driving-force ET in labeled copper proteins. *P. aeruginosa* azurin (Figure 3) has a Cu(II/I) reduction potential of 0.31 V *vs.* NHE.[24] Analysis of the driving-force dependence of Cu(I) → M(III) (M = Ru, Os) ET in $M(diimine)_2$(im)(His83)-azurin gives a reorganization energy of 0.8 eV.[44] In accord with this finding, the temperature independence (240–300 K) of Cu(I) → Ru(III) ET in $Ru(bpy)_2$(im)(His83)-azurin can be described by $\lambda_{12} = 0.7 \pm 0.1$ eV, although the observed twofold increase in rate constant as the temperature is lowered to 160 K cannot be explained by changes in the exponential term of the semiclassical rate expression.[45] It is more likely

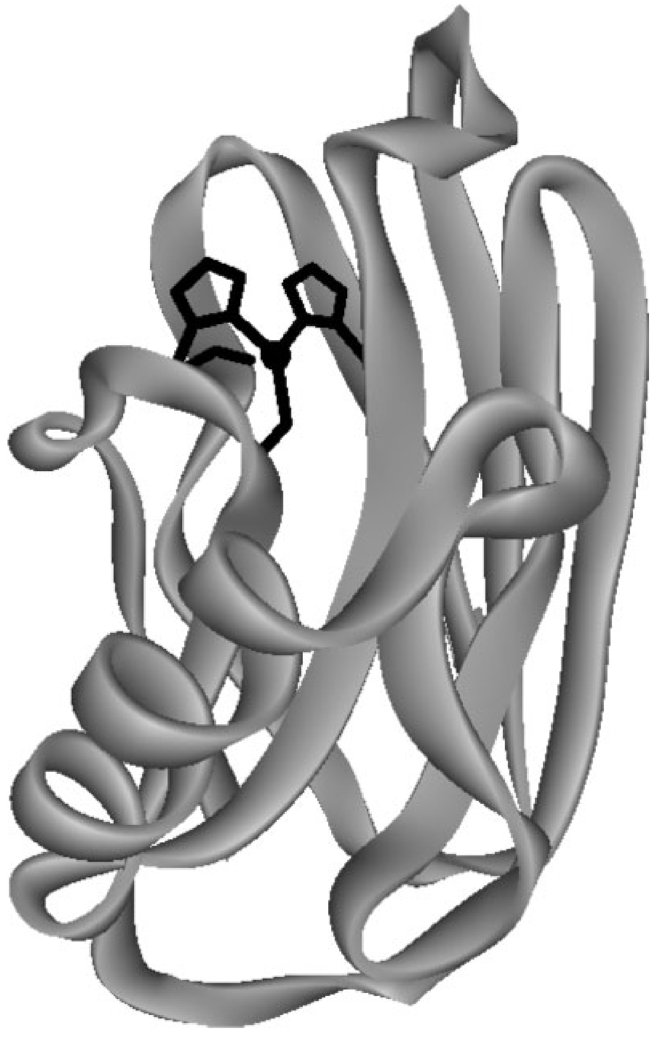

Figure 3 Ribbon representation of the peptide backbone in *P. aeruginosa* azurin. The Cu cofactor and its ligands are shown in black

that the Ru–Cu electronic coupling increases as the protein is cooled to 170 K.

Rates of Ru(III) and Os(III) reduction by Cu(I) have been measured in single crystals of *P. aeruginosa* M(diimine)$_2$(im)(His83)-azurin. In these cases, protein conformation and surface solvation are precisely defined by high-resolution X-ray structure determinations.[46] The time constants for electron tunneling in crystals are roughly the same as those measured in solution, indicating very similar protein structures in the two states. High-resolution structures of the oxidized (1.5 Å) and reduced (1.4 Å) forms of Ru(tpy)(bpy)(im)(His83)-azurin (tpy = 2,2′:6,2″-terpyridine; bpy = 2,2′-bipyridine) establish that very small changes in copper coordination accompany reduction.[46] Although Ru(bpy)$_2$(im)(His83)-azurin is less solvated in the crystal lattice, the reorganization energy for Cu(I) → Ru(III) electron transfer falls in the same range (0.6–0.8 eV) determined experimentally for the reaction in solution. It is striking that driving forces, reorganization energies, and rates of Cu(I) → M(III) (M = Ru, Os) ET are virtually unchanged when labeled azurins lose one-third of their solvent-accessible surface upon transfer from dilute solutions to crystal lattices with just 40% water. These observations suggest that bulk water plays a minor role in azurin ET reactions; what little solvent reorganization occurs is likely to involve only the ordered waters of hydration.

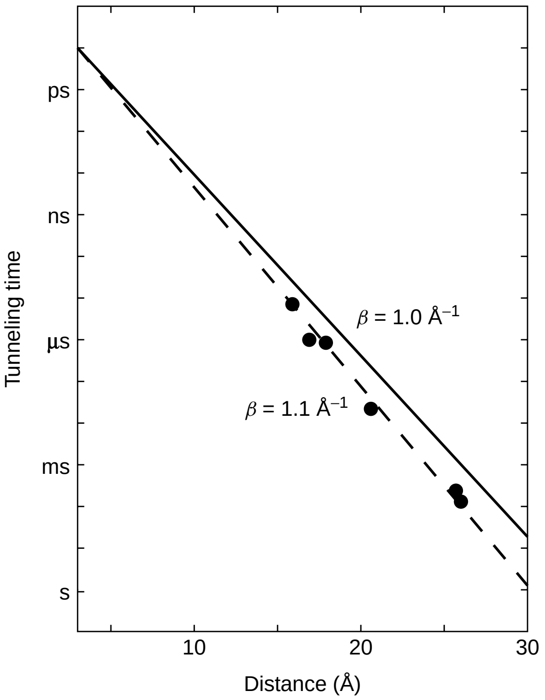

Figure 4 Distance dependence of driving-force-optimized electron tunneling times in Ru-labeled *P. aeruginosa* azurin. The solid line is the distance decay predicted by the tunneling-pathway model for ET along an ideal β-strand ($\beta = 1.0$ Å^{-1}). The dashed line is the best fit to the data ($\beta = 1.1$ Å^{-1})[23]

3.3 Tunneling Timetables

Theoretical analyses of coupling pathways in proteins suggest that the efficiency of long-range electron tunneling depends on the secondary structure of the polypeptide between the redox centers.[47] The distance dependence of ET in azurin provides insight into the efficiency of coupling across β-sheet structures.[23] The copper center in azurin is situated at one end of an eight-stranded β-barrel, ligated in a trigonal plane by two imidazoles (His46, His117) and a thiolate (Cys112); in addition, there are weak axial interactions (Met121 thioether sulfur, Gly45 carbonyl oxygen) (Figure 3).[48] The azurin from *P. aeruginosa* has two additional His residues, one of which (His83) reacts readily with Ru-labeling reagents. An H83Q base mutant was prepared and individual mutant His residues were introduced at five locations on β-strands extending from the Cys112 and Met121 ligands (K122H, T124H, T126H, Q107H, M109H). Measurements of Cu(I) → Ru(bpy)$_2$(im)(HisX)$^{3+}$ ET ($-\Delta G° = 0.7$ eV) provide a calibration for the distance dependence of ET along β-strands (Figure 4). The driving-force-optimized electron tunneling timetable for azurin reveals an exponential distance dependence, with a decay constant (β) of 1.1 Å^{-1}, and an intercept at close contact ($r_o = 3$ Å) of 10^{13} s^{-1}. This decay constant is quite similar to that found for superexchange-mediated tunneling across saturated alkane bridges ($\beta \approx 1.0$ Å^{-1}),[49] strongly indicating that a similar coupling mechanism is operative in the polypeptide.

The validity of the azurin tunneling timetable rests on the assumption that Ru-azurin structures are not very different in crystals and aqueous solutions. Measurements of ET kinetics on crystalline samples of labeled azurins directly test this assumption;[46] the rate constants for oxidation of Cu(I) by Ru(III) and Os(III) in solutions and crystals are nearly identical for each donor–acceptor pair. It follows that the crystal structures of reduced and oxidized azurin are the relevant reactant and product states for solution ET.

It is important to distinguish between superexchange-mediated electron tunneling and multistep mechanisms that also can move charge over large molecular distances.[31,32] In tunneling processes, quantum mechanical mixing of localized donor and acceptor states with oxidized (and/or reduced) bridge states couples the reactant and product states, producing an avoided crossing between the free-energy surfaces at the transition state. Neither oxidized nor reduced bridge states are populated in tunneling reactions; ET occurs in a single elementary reaction step. There is a practical upper limit to the separation distance between redox sites; if charges must be transferred farther than this range, then multiple tunneling steps are required. Long-range ET can proceed by either single or multistep tunneling, but each mechanism has distinct energetic and coupling requirements, and can respond quite differently to changes in reaction parameters (e.g. T, $\Delta G°$).

The energy gap between the donor/acceptor redox levels and those of oxidized or reduced intermediate states is the primary criterion in determining when multistep tunneling becomes important. In proteins with a single redox cofactor, the opportunities for multistep tunneling are limited. Extreme redox potentials are necessary to oxidize and reduce polypeptide backbones; thus multistep tunneling via backbone states will not contribute to observed ET kinetics under most solution conditions. The side chains of certain amino acids (e.g. Tyr, Trp) have redox potentials that are more accessible than those of the peptide backbone.[50,51] Oxidized Trp and Tyr residues have been characterized spectroscopically in a large number of proteins, although direct evidence for their involvement in multistep tunneling reactions is hard to come by.[52]

The $Ru(bpy)_2(im)(His)^{3+/2+}$ reduction potential ($E° = 1.0$ V *vs.* NHE) is not high enough to oxidize Trp or Tyr residues in Ru-azurin; photogenerated holes in $Ru(bpy)_2(im)(HisX)^{3+}$ complexes remain localized on the Ru center. The energy gap between the Ru(III) hole state and oxidized bridge states must therefore be greater than 75 meV ($3k_B$T at 295 K). The fact that oxidized bridge states lie at higher energy than the Ru(III) hole does not rule out multistep tunneling; endergonic steps can be compensated by favorable reactions later in a sequence.[32] Endergonic reactions, however, become less effective as the temperature decreases, so that multistep tunneling with highly endergonic steps will exhibit a strong dependence on temperature. The finding that the rate of Cu(I) → Ru(III) ET in $Ru(bpy)_2(im)(HisX)$-azurin is nearly independent of temperature between 240 and 300 K, coupled with the observation that decreasing the temperature to 160 K produces a twofold increase in the ET rate, demonstrate that multistep tunneling cannot explain long-range ET in Ru-azurin.[45] Instead, the data shown in Figure 4 provide a calibration standard for superexchange-mediated electron tunneling in proteins.

The rates of high-driving-force ET reactions have been measured for more than 30 Ru(diimine)-labeled metalloproteins.[21,23,24] Only modest corrections are required to scale these rates to driving-force-optimized values, permitting comparisons of ET in different proteins. The results are summarized in the electron tunneling timetable of Figure 5. The reported distances are all metal-to-metal measures; in the case of metal clusters, the closest metal was chosen. Tunneling times range from a few nanoseconds (12.2-Å ET in the high-potential iron–sulfur protein from *C. vinosum*) to 10 milliseconds (26-Å ET in *P. aeruginosa* azurin).

The Ru–protein data points are scattered around the Ru–azurin $\beta = 1.1$ Å^{-1} exponential distance decay. More than three-fourths of the Ru–protein ET rates fall in a 1.0 to 1.3 Å^{-1} β-value zone. The data in Figure 5 suggest that a canonical distance decay constant will not describe long-range electron tunneling in proteins. Rates at a single distance can differ by as much as a factor of 10^3 and **D/A** distances that differ by as much as 5 Å can produce identical rates. The

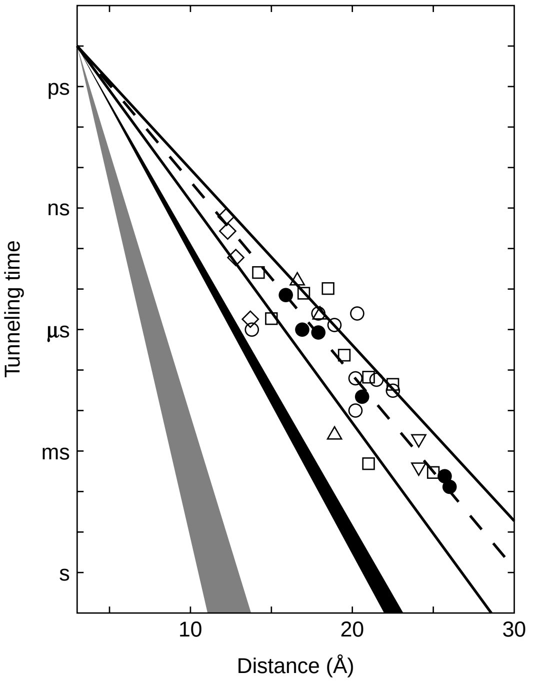

Figure 5 Tunneling timetable for ET in Ru-modified proteins: azurin (●); cytochrome *c* (○); myoglobin (△); cytochrome b_{562} (□); HiPIP (◇); and Fe:Zn-cytochrome *c* crystals (▽). The solid lines illustrate the tunneling-pathway predictions for coupling along β-strands ($\beta = 1.0$ Å^{-1}) and α-helices ($\beta = 1.3$ Å^{-1}); the dashed line illustrates a 1.1-Å^{-1} distance decay. Distance decay for electron tunneling through water is shown as a black wedge. Estimated distance dependence for tunneling through vacuum is shown as the grey wedge[21,23]

absence of a simple exponential distance dependence in the Ru–protein rate data is likely a reflection of the heterogeneity of the coupling medium. The efficiency of the coupling between redox centers is determined by the three-dimensional structure of the intervening polypeptide. While the azurin β-barrel structure supports a relatively uniform distance decay, highly helical proteins (myoglobin, cytochrome b_{562})[21,24] exhibit far more heterogeneous behavior. The protein fold is the key determinant of biological ET rates: it establishes the driving force, the reorganization energy, and the electronic coupling.

4 PROTEIN–PROTEIN REACTIONS

In low ionic-strength buffers, many proteins of opposite charge will form relatively tightly bound complexes.[53,54] With the aid of rapid triggering methods, it is possible to measure rates of long-range ET between redox sites in protein–protein complexes.[55,56] In many complexes, there are multiple binding sites and it is not uncommon to find that the ET kinetics often are regulated by the dynamics of conformational

changes in the complex.[54] The usual interpretation is that surface diffusion of the two proteins produces a transient complex with significantly better electronic coupling and faster electron transfer. Consequently, rates depend strongly on solvent viscosity rather than intrinsic ET parameters ($\Delta G°$, λ, r). A further complication associated with studies of protein–protein ET in solution is that binding sites and, hence, locations of redox cofactors, often are unknown. Issues of conformational change and structural ambiguity have been addressed recently with measurements of protein–protein ET kinetics in protein crystals.

4.1 Hemoglobin Hybrids

Kinetics measurements on crystallographically characterized metal-substituted hemoglobin (Hb) hybrids provided some of the earliest insights into interprotein ET rates.[57] Because Hb is a very strongly bound complex of four polypeptide subunits, ET measurements are not complicated by the dynamical problems that plague interpretation of rates in more weakly bound complexes. Replacement of the native Fe center in the β-subunits of Hb with Zn or Mg creates the opportunity for photoinitiated ET reactions. The reacting metal centers in the Hb hybrids are separated by 25 Å so that rates are relatively slow even at high driving forces. The time constant for ET from a triplet-excited ZnPor in the β-subunit to an Fe(III) center in the α-subunit is about 16 ms. Extensive studies of temperature dependences of hybrid Hb ET rates led to the conclusion that the reorganization energy for these reactions ($\lambda \sim 1$ eV) is dominated by outer-sphere contributions.[58] Measurements of ET rates in cryogenic glasses suggest that the polypeptide is the primary outer-sphere medium for the reaction and that bulk solvent reorganization does not play an important role in the reaction. Moreover, it was suggested that even at room temperature, the protein medium in Hb acts like a frozen glass. Results from measurements on Ru-azurin crystals also indicate that bulk solvent makes only a minor contribution to protein ET reorganization energies.[46]

4.2 Cytochrome *c*/cytochrome b_5 Complexes

The ET reaction between cytochrome *c* and cytochrome b_5 has been the subject of experimental and theoretical investigations for more than forty years.[59,60] Modeling both bimolecular and intracomplex ET between these proteins has been an active field of study. The detailed structural model proposed by Salemme in 1976 for the precursor complex of this protein pair stimulated a great deal of experimental work.[61] Careful spectroscopic studies revealed that these oppositely charged proteins form a stable 1:1 complex at low ionic strength.[59]

McLendon and Miller employed a combination of photochemical and pulse-radiolytic methods to probe the driving-force dependence of heme–heme ET in this complex.[53] The ET rates exhibit a near-Gaussian free-energy dependence, in excellent agreement with a 0.8-eV reorganization energy. The significance of this result is that, although this is a relatively low value of λ for ET between transition metal complexes in aqueous solution, it is by no means optimized. Most biological ET processes release less than 0.3 eV of free energy; with a 0.8-eV reorganization energy, rates will be 1–2 orders of magnitude below their maximum values.

Evidence for more complex ET processes came from studies in which photochemically generated reductants injected electrons into preformed Fe-cytochrome b_5/Fe-cytochrome *c* complexes. In one study, the rate of $b_5 \rightarrow c$ ET ($1.7 \times 10^3\ s^{-1}$) was reported to depend on viscosity and surface mutations.[62] A later laser-flash photolysis study found a rate-limiting second-order reduction of Fe-cytochrome b_5/Fe-cytochrome *c* complexes and no sign of saturation, suggesting that the intracomplex ET rate was greater than $10^4\ s^{-1}$.[59]

Ru-modified cytochrome b_5 and photochemical triggering methods were used to examine the kinetics of ET in cytochrome b_5/c complexes.[60] Rapid intraprotein reduction (<100 ns) of Fe(III)-cytochrome b_5 by excited $Ru(bpy)_3{}^{2+}$ made it possible to probe $b_5 \rightarrow c$ ET kinetics. Two concentration-independent ET rates ($4 \times 10^5\ s^{-1}$, $3.4 \times 10^4\ s^{-1}$) were observed, suggesting that two cytochrome b_5/c species are present in solution. Studies of ionic-strength dependences and the effects of mutations suggest that the slower Fe(III)-cytochrome *c* reduction phase may be limited by conformational changes within one of the complexes.[60]

4.3 Cytochrome *c*/cytochrome *c* Peroxidase Complexes

Cytochrome *c* peroxidase (C*c*P) catalyzes the two-electron reduction of H_2O_2 by ferrocytochrome *c*. Hydrogen peroxide reacts rapidly with the resting ferric form of C*c*P to produce a species referred to as compound I, which contains a ferryl ($Fe(IV)O^{2+}$) heme and a protein radical located on Trp191. The ET reactions involving these physiological redox partners have been studied in great detail.[54] At low ionic strength, acidic C*c*P and basic cytochrome *c* form a stable complex. A model of a 1:1 complex, based on the crystal structures of the two independent proteins, was proposed by Poulos and Kraut in 1980.[63] Twelve years later, Pelletier and Kraut reported the crystal structure of a 1:1 complex of the two yeast proteins.[64] Interestingly, the complex between yeast C*c*P and horse cytochrome *c* exhibited a slightly different structure. Analysis of the yeast/yeast complex suggested an electronic coupling pathway from the cytochrome *c* heme to the C*c*P heme via Trp191. On the basis of these crystallographic results, Pelletier and Kraut argued that C*c*P and cytochrome *c* form a highly specific 1:1 ET complex.

Hoffman and coworkers have employed metal-substituted C*c*P and cytochrome *c* to explore the ET kinetics between these two proteins.[54] Results from four-dimensional quenching studies, temperature and ionic-strength dependences, species variations, and electrostatic modeling provide compelling

evidence for two distinct cytochrome *c* binding sites on C*c*P. The higher affinity binding site is the locus for Trp191 radical reduction by cytochrome *c*. Heme (C*c*P) reduction by cytochrome *c* can occur from either the high or low affinity binding site but, when exchange between the two is rapid, reduction from the low affinity site dominates.[54] These studies of C*c*P/cytochrome *c* ET, as well as those of cytochrome b_5/c, reveal the considerable mechanistic complexity of protein–protein ET processes.

4.4 Zn-cytochrome *c*/Fe-cytochrome *c* Crystals

Studies of C*c*P/cytochrome *c* and cytochrome b_5/c reactions highlight the difficulty of extracting ET parameters when donors and acceptors are not held at fixed distances and orientations. Crystals containing photoactivatable donors and acceptors at specific lattice sites are ideal media for investigating tunneling between proteins. In crystal lattices of tuna cytochrome *c*, chains of cytochrome *c* molecules form helices with a 24.1-Å separation between neighboring metal centers.[65] All other metal–metal distances in the lattice are greater than 30 Å. Thus, the heme groups can be treated as ordered in a one-dimensional chain, separated by identical protein and solvent media. By doping Zn-cytochrome *c* into this lattice, interprotein ET was probed using laser-flash transient spectroscopy. ET from the triplet-excited Zn-porphyrin to a neighboring Fe(III)-cytochrome *c* proceeded with a rate constant of $4(1) \times 10^2\ s^{-1}$; the rate of charge recombination was about four times faster ($2.0(5) \times 10^3\ s^{-1}$).[65]

Rapid relay of electrons involving at least one soluble redox enzyme requires the formation of short-lived, weakly bound protein–protein complexes. The recognition sites between proteins in such complexes tend to be smaller (<1200 Å^2) and include more water molecules than the interfaces between subunits in oligomeric proteins. The interprotein interactions in crystals of tuna cytochrome *c* involve relatively few contacts: 760 Å^2 of surface area is buried in an interface with 31 van der Waals contacts ($3.2 \leq d \leq 3.9$ Å) and 16 water molecules (3 of which form bridging hydrogen bonds across the interface) but only one direct hydrogen bond bridging the two proteins. Indeed, the cytochrome *c* – cytochrome *c* interface is reminiscent of that between the natural redox partners, cytochrome *c* and cytochrome *c* peroxidase (770 Å^2),[64] and may be typical of the interaction zones for soluble redox proteins. The Zn–Fe separation in doped tuna cytochrome *c* crystals is similar to that in Zn–Fe–hemoglobin hybrids (24.7 Å, T-state), although the tetrameric heme protein has many more contacts between subunits and a greater atom density at the interface. Nevertheless, *ZnPor → Fe(III) and Fe(II) → $ZnPor^{+\bullet}$ ET rates in Hb hybrids[57] and Zn-doped tuna cytochrome *c* crystal are quite similar and fall well within the range that has been established in studies of Ru-modified proteins.[21,23,24] The protein crystal ET data demonstrate that small interaction zones of low density are quite effective in mediating interprotein redox reactions.

5 PHOTOSYNTHESIS AND RESPIRATION

5.1 Photosynthetic Reaction Centers

Bacterial photosynthetic reaction centers (PRC) have been among the most actively studied ET proteins since DeVault and Chance first measured *C. vinosum* tunneling rates in the early 1960s.[66,67] In many cases, measurements of ET kinetics preceded determination of the three-dimensional structure of the membrane-bound protein assembly. It was not until the X-ray crystal-structure determinations of the *Rhodopseudomonas (Rps.) viridus*[68] and *Rhodobacter (Rb.) sphaeroides*[69] PRCs that distances could be assigned to specific rate constants. The recent crystal structures of photosystems I[70,71] and II[72,73] from cyanobacteria promise to clarify critical aspects of the ET mechanisms in oxygenic PRC.[74,75]

Photosynthetic reaction centers are ideal substrates for investigations of long-range electron transfer.[76–78] Charge separation in anoxygenic bacterial PRCs arises from a series of highly optimized ET processes (Figure 6). The primary photochemical event involves 2-ps ET over 17.8 Å from an electronically excited chlorophyll special pair (*$(Bchl)_2$) to a pheophytin (Bphe) acceptor.[79] The rate of this reaction increases by about a factor of two as the temperature is lowered from 295 to 4 K. The absence of thermal activation indicates that the reorganization energy for *$(Bchl)_2$ → Bphe ET must be close to the driving force (0.2 eV). The reduced pheophytin delivers an electron to a quinone (Q_A) 14.5 Å away in 100 ps. This productive reaction is 500 times faster than charge recombination with the hole in the bacteriochlorophyll special pair ($(Bchl)_2^{\bullet+}$). In 100 ps, approximately half of the 1.3 eV excitation

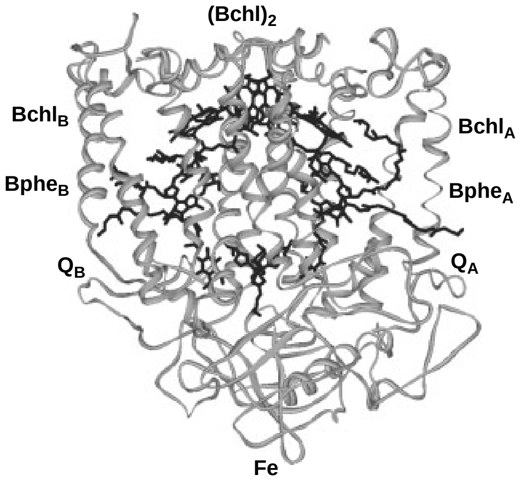

Figure 6 Model of the X-ray crystal structure of the photosynthetic reaction center from *Rb. sphaeroides*.[69] The bacteriochlorophyll special pair ($(Bchl)_2$), accessory bacteriochlorophylls (Bchl), bacteropheophytins (Bphe), quinones (Q), and iron complex (Fe) are shown in black. Electron transfer proceeds primarily along the A branch

energy of *$(Bchl)_2$ has been used to produce a 28.7 Å charge separation.[80] The charge on Q_A is subsequently transferred to a second quinone (Q_B) in a proton-coupled ET step.[81,82]

The hole in the bacteriochlorophyll special pair is filled by electron transfer from a cytochrome. In *Rps. viridis,* the cytochrome donor is tightly bound to the PRC at the membrane surface. This subunit contains four hemes in a nearly linear array oriented perpendicular to the membrane.[68] The reduction potentials of the hemes alternate from high ($\geq$250 mV *vs.* NHE) to low ($\leq$50 mV) as the distance from $(Bchl)_2$ increases.[83] The heme closest to the special pair, cytochrome c_{559}, has the highest potential and fills the $(Bchl)_2^{\bullet+}$ hole in about $\sim$200 ns.[84] The next well-characterized process is ET from cytochrome c_{556} to cytochrome c_{559} in $\sim$2 µs over a distance of 27.9 Å.[84]

In *Rb. sphaeroides,* $(Bchl)_2^{\bullet+}$ is reduced by a soluble single heme protein, cytochrome c_2. Several *Rb. sphaeroides* PRC mutants with altered $(Bchl)_2^{\bullet+/0}$ potentials have been prepared. In all, $E°((Bchl)_2^{\bullet+/0})$ values range from a low of 0.410 V to a high of 0.765 V *vs.* NHE (the wild-type value is 0.505 V).[85] A driving-force study of Fe(II) → $(Bchl)_2^{\bullet+}$ ET in cytochrome c_2/PRC complexes gave $\lambda = 0.5$ eV.[86] Global analysis of temperature and driving-force dependences of these ET rates indicated that $\lambda = 0.96 \pm 0.07$ eV, and H_{AB} values were not constant for all of the mutants.[87] The kinetics of ET from cytochrome c_2 to $(Bchl)_2^{\bullet+}$ in the PRC from *Rb. sphaeroides* have been measured in structurally characterized crystals.[88] The rate ($1.1 \times 10^6\,s^{-1}$), driving force (0.16 eV), and donor–acceptor distance (21.2 Å) are quite similar to those for ET from cytochrome c_{559} to $(Bchl)_2^{\bullet+}$ in *Rps. viridis.*

Photosynthesis works because charge separation is more efficient than energy-wasting charge recombination. By blocking appropriate steps in the charge-separation sequence, it has been possible to determine the rates of PRC charge-recombination reactions. The near-linear arrangement of redox cofactors forms a redox potential gradient that favors short-range charge-separation reactions. In all cases, charge recombinations are many orders of magnitude slower than competing charge-separation reactions.[80]

Many of the PRC ET reactions exhibit only modest variations with temperature. The rate of the primary photochemical event increases at cryogenic temperature.[79] Several other reaction rates decrease by only small factors when temperatures are lowered.[87] For charge separation, this behavior can be attributed to driving-force-optimized reactions.

5.2 Cytochrome *c* Oxidase

In the terminal reaction of the respiratory chain, membrane-bound cytochrome *c* oxidase (C*c*O) receives electrons from soluble cytochrome *c* and passes them on to O_2.[1] C*c*O is a multisubunit membrane-bound enzyme with four redox cofactors (Cu_A, cytochrome *a*, cytochrome a_3, Cu_B). The locations of these metal complexes in C*c*O were revealed in the 1990s by the X-ray crystal structures of bacterial[89] and bovine enzymes (Figure 7).[90,91] The ET reactions of C*c*O have been the subjects of extensive investigation.[92,93] Cu_A, a binuclear Cu site with bridging S(Cys) atoms, is the primary electron acceptor from soluble cytochrome *c*.[94] Studies with Ru-modified cytochrome *c* reveal rapid ($6 \times 10^4\,s^{-1}$)[95] electron injection from Fe(II) into Cu_A at low driving force ($\Delta G° = -0.03$ eV).[96] Modeling suggests that cytochrome *c* binds to the bovine enzyme at an acidic patch on subunit II with an Fe–Cu distance of 17.8 Å.[97] The cytochrome *c* heme in the model is within 3.3 Å of the Trp104 (subunit II) indole ring, a residue that appears from mutagenesis experiments to be critical for rapid cytochrome *c*/Cu_A ET. A possible electron tunneling path from this cytochrome *c* binding site through Trp104 to the bridging S(Cys200) ligand on Cu_A has been identified.[98]

The 19.6-Å electron transfer from Cu_A to cytochrome *a* proceeds rapidly at low driving force ($1.8 \times 10^4\,s^{-1}$; $\Delta G° = -0.05$ eV).[95] Multiple electronic coupling pathways

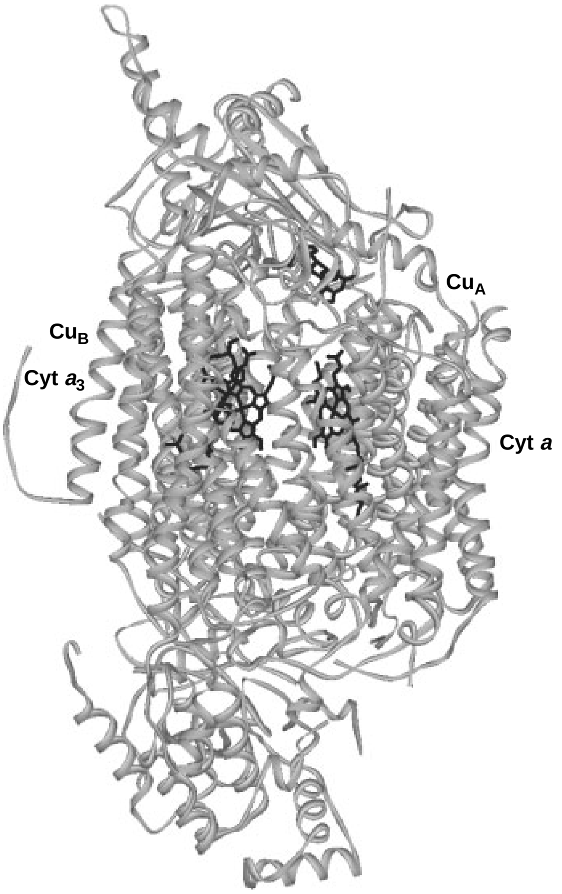

Figure 7 Model of the X-ray crystal structure of the bovine cytochrome *c* oxidase.[90,91] The dimeric Cu_A site, cytochromes *a* and a_3, and the Cu_B center are shown in black. Electrons enter the enzyme through Cu_A and oxygen is activated at the cytochrome a_3/Cu_B active site

have been proposed for this reaction. One postulated coupling route proceeds from Cu_A ligand His204 (subunit II) across one hydrogen bond to Arg438 (subunit I) (H204(Nε)-R438(O), 3.36 Å), and another H– bond (2.95 Å) from the Arg438 N–amide to the cytochrome *a* heme-propionate.[1,99–101] A tunneling-currents analysis suggested a slightly different Cu_A-cytochrome *a* coupling route through His204.[102] More recent work suggests that, owing to strong Cu–S(Cys) electronic interactions, pathways involving the bridging Cys residues are important for mediating coupling even though they involve more bonds than do routes through His204. Two independent analyses indicated that the sequence Cys200/Ile199/Arg439/heme-propionate (cytochrome *a*) is the dominant coupling route between Cu_A and cytochrome *a*.[101,102]

The coupling between cytochrome *a* and cytochrome a_3 has also been examined.[99,102] Nearly equivalent coupling routes between the two hemes involving the axial His residues (His378(cytochrome *a*), His376(cytochrome a_3)) were identified. One pathway proceeds through the intervening Phe377 residue; the other two involve a hydrogen bond between His378 and Val374. From Ala375, one pathway goes directly to His376 and the other involves a hydrogen bond to Tyr372 (which is hydrogen bonded to His376). A second study identified three major cytochrome *a*/cytochrome a_3 pathways: one is the direct jump from heme *a* to heme a_3; one has the aromatic ring of Phe377 as the only intermediate group; and the third involves His378 and the Phe377 aromatic ring. In spite of the similarity in Cu_A-cytochrome *a* (19.6 Å) and Cu_A-cytochrome a_3 (22.4 Å) distances, pathway analyses do not find important coupling pathways between the Cu_A center and cytochrome a_3.[99,102]

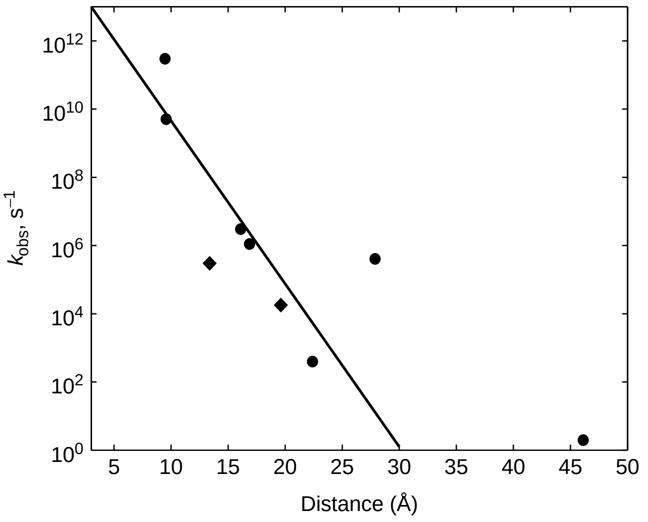

Figure 8 Distance dependence of observed ET rates in C*c*O (♦) and the PRC (•).[92,104] The solid line shows the average distance dependence found for driving-force-optimized ET in Ru-modified proteins ($\beta = 1.1$ Å^{-1})

6 CONCLUDING REMARKS

It is interesting to compare rates of electron tunneling in C*c*O and PRC with results from Ru-modified proteins (Figure 8).[80,92] The solid line in the figure corresponds to the average distance dependence of driving-force-optimized ET rates in Ru-proteins ($\beta = 1.1$ Å^{-1}; 10^{13} s^{-1} intercept). Most of the observed tunneling rates in C*c*O and the PRC lie near or *above* this line, indicating that the natural ET reactions are highly optimized, both in terms of reorganization energy and electronic coupling. Three of the *Rps. viridis* PRC reactions are at least two orders of magnitude faster than would be expected for activationless ET: the initial charge-separation event; ET from cytochrome c_{556} to cytochrome c_{559}; and charge recombination from reduced Q_A to cytochrome c_{559}. These unusually high ET rates may signal the presence of multistep tunneling processes.[79,88,103] It is interesting that neither the $Q_A^- \rightarrow (Bchl)_2^{\bullet +}$ nor the $Q_A^- \rightarrow$ cytochrome c_{559} charge-recombination reaction is unusually slow. This contrasts with the $Bphe^- \rightarrow (Bchl)_2^{\bullet +}$ reaction, which is 10^3 times slower than expected for a driving-force-optimized process at the same distance.[80] Inverted driving-force behavior may be responsible for retarding $Bphe^- \rightarrow (Bchl)_2^{\bullet +}$ ET, but multistep tunneling may nullify its effects in the longer-range reactions. The rate of ET from Cu_A to cytochrome *a* in C*c*O is close to that expected for an optimized reaction, yet the reaction driving force is just 50 meV. Clearly, both reorganization energies and electronic coupling pathways in C*c*O have been finely tuned to achieve a high level of electron transport efficiency.

1 INTRODUCTION

The fluorescence (*see Fluorescence*) properties of organic compounds are well known and extensively studied. Many compounds, especially the polyaromatics, exhibit intense

fluorescence with tunable energy upon variation in electronic and structural factors. The emission origin is usually limited to $^1(\pi \rightarrow \pi^*)$, $^1(n \rightarrow \pi^*)$, or intramolecular charge-transfer (*see Charge Transfer*) although in many cases excimer and exciplex formation has been observed. The synthesis, structures, and chemical reactivity of a number of organotransition metal compounds have received much attention over the past decades. Factors such as a wide choice of carbon-containing ligands, the flexible bonding modes of these ligands, and the diversity of molecular structures, can result in the formation of novel organometallic compounds with characteristic physical and chemical properties. In particular, the luminescence and photochemical studies of organotransition metal compounds contribute to an important aspect of modern photochemistry.

Incorporation of transition metal centers to organic ligands enables efficient spin-orbit coupling, leading to the population of excited states (*see Excited State*) of triplet (*see Triplet State*) character and enhancement of the phosphorescence of organic compounds or phosphorescence (*see Phosphorescence*) characteristic of the organometallic compounds. Basically, coordination of transition metal centers to organic compounds can enrich the emission properties by providing new excited-state character that is unable to achieve otherwise. For example, metal-to-ligand charge-transfer transitions are commonly observed in transition metal complexes containing d electrons and organic ligands with low-lying empty π^* orbitals. Ligand-to-metal charge-transfer transitions are also common for electron-rich organic ligands and electron-deficient (*see Electron Deficient Compound*), high-valent transition metal centers. In addition, short metal–metal separations, which could be an implication of weak metal–metal interactions, have been observed in many polynuclear organotransition metal systems (*see* ***Polynuclear Organometallic Cluster Complexes*** and ***Dinuclear Organometallic Cluster Complexes***), especially those with a d^8 and d^{10} electronic configuration. The metal–metal interaction can destabilize the filled d_{z^2} orbitals (due to the formation of $d\sigma^*$) and stabilize the empty p_z orbitals (due to the formation of $p\sigma$ orbitals). Thus, the HOMO-LUMO gap (*see HOMO–LUMO Gap*) can be reduced, leading to low-energy $(d\sigma^* \rightarrow p\sigma)$ transitions.

In this article, a number of selected d-block organotransition metal compounds are introduced and their remarkable luminescence and photochemical properties are described and discussed. Emphasis is placed on the interrelationship between the nature of the transition metal centers, identity and bonding mode of the organic ligands, the photophysical and photochemical properties, and the character of the emissive states. Novel luminescent organotransition metal complexes with potential application values in different areas are also included here. Meanwhile, readers are referred to a selection of book chapters and review articles on the photophysics and photochemistry of transition metal complexes.[1–7]

2 CARBONYL, ISOCYANIDE, AND CYANIDE SYSTEMS

2.1 Carbonyl Systems (*See Carbonyl Complexes of the Transition Metals*)

2.1.1 Luminescence Properties

Hexacarbonyl complexes $[M(CO)_6]$ (M = Cr, Mo, W) can react with a diimine ligand (N–N) to form highly colored complexes $[M(CO)_4(N–N)]$.[8] The photophysical properties of these complexes have received much interest. The electronic absorption spectra of $[M(CO)_4(N–N)]$ (M = Cr, Mo, W) displayed two bands in the visible region. The absorption band at higher energy (ca. 400 nm) was proposed to be an admixture of ^{1}MLCT and d-d transitions, while the lower energy one at ca. 460–600 nm was assigned to an ^{1}MLCT $(d\pi(M) \rightarrow \pi^*(N–N))$ transition. Excitation of the complexes $[M(CO)_4(N–N)]$ (M = Mo, W) in degassed benzene at room temperature resulted in dual luminescence with emission bands at ca. 606 and 739 nm. The origin of both bands has been assigned to an ^{3}MLCT excited state, with the higher-energy band perturbed by a nearby ^{3}LF state.[3]

There have been many photophysical and photochemical studies of the rhenium(I) carbonyl diimine complexes $[Re(CO)_3(N–N)X]$ (N–N = diimine ligands, X = monodentate ligands such as carbonyl, halides, pyridines, and phosphines).[1–4,8] In the presence of the diimine ligand, relatively intense ^{1}MLCT $(d\pi(Re) \rightarrow \pi^*(N–N))$ absorption bands appear in the visible region. In most cases, excitation of the complexes gives rise to intense and long-lived emission in the visible region. The lifetime falls into the submicrosecond to microsecond timescales, and the emission is phosphorescence in nature. An excited state of ^{3}MLCT $(d\pi(Re) \rightarrow \pi^*(N–N))$ character has been assigned to many complexes of this type.[1–4,8]

The ^{3}MLCT emission properties of many rhenium(I) carbonyl diimine complexes have been used to demonstrate the energy-gap law. For example, the complexes $[Re(N–N)(CO)_3(L)]$ (N–N = bpy, phen, 5-Ph-phen; L = substituted pyridines or quinoline) displayed ^{3}MLCT $(d\pi(Re) \rightarrow \pi^*(N–N))$ phosphorescence at room temperature.[9] The radiationless decay-rate constants depended on the emission energy as described in the energy-gap law $(\ln k_{nr} \approx A - B\,E_{em})$. From the Hammett constant of the substituent, both the emission energy and lifetime of related complexes can be predicted.[9]

A special property of these luminescent carbonyl diimine complexes is their solvatochromic behavior.[1–4,8] The MLCT absorption bands exhibit a noticeable red shift when the polarity of the solvents decreases (negative solvatochromism). For example, the ^{1}MLCT transition of $[Re(CO)_3(bpy)Cl]$ occurred at 370 and 400 nm in CH_3CN and benzene respectively.[3] Similar solvatochromism was also observed for the charge-transfer bands of other carbonyl complexes

$[M(CO)_4(N–N)]$ (M = Cr, Mo, W).[1–4,8] The hypsochromic shift of the MLCT absorption band with increasing solvent polarity has been accounted for by assuming that the charge transfer in the MLCT excited state occurs antiparallel to the ground-state dipole moment. The higher transition energy in more polar solvents may be due to dominating ground-state stabilization. The ^{3}MLCT emission of these complexes displays a small blue shift with an increase in emission lifetimes in more non-polar solvents. For example, the complex $[Re(CO)_3(bpy)Cl]$ showed ^{3}MLCT emission in CH_3CN at 622 nm ($\tau_o = 25$ ns) while the emission occurred at 615 nm ($\tau_o = 70$ ns) in benzene.[3] These solvent effects have also been interpreted mainly on the basis of the energy-gap law.[10]

These luminescent carbonyl diimine MLCT emitters also display interesting luminescence rigidochromism.[1–4,8,10,11] The emission maxima of these complexes exhibit a distinct shift to higher energy upon cooling the sample solutions from room temperature to glass at low temperature. This phenomenon is associated with the rigidity change in the medium rather than simply a temperature effect because it was found that even at room temperature, significant hypsochromic shifts were noticed when these MLCT emitters were incorporated in a rigid polyester resin.[11] The blue shift was a consequence of the destabilization of the excited state of the complex since the solvent molecules cannot freely reorient themselves around the excited complex in a rigid environment. As an example, the complex $[W(CO)_4(4\text{-Me-phen})]$ displayed a weaker emission band at 553 nm and a stronger one at 765 nm in EPA at 293 K.[11] Upon lowering the temperature from 293 to 80 K, the overall emission intensity increased by 100 fold, and the higher-energy band became more dominant. Both bands displayed significant hypsochromic shifts to ca. 533 and 647 nm, respectively, at 80 K. On the basis of the sensitivity of the luminescence properties of these organometallic complexes on the rigidity of their local environment, these complexes have been exploited as spectroscopic probes in the cross-linking polymerization of photosensitive thin films.[11] To illustrate this, the luminescent rhenium(I) complex $[Re(CO)_3(4,7\text{-}Ph_2\text{-phen})Cl]$ has been used to monitor the acrylate cross-linking reaction. The ^{3}MLCT emission of the complex added to a TMPTA/PMMA system containing the photoinitiator 2,2-dimethoxy-2-phenylacetophenone experienced a blue shift (from 576 to 562 nm) with an increase in emission intensity and lifetime when polymerization proceeded. The change in the emission intensity and lifetimes essentially resulted from the increased rigidity of the polymer environment and the corresponding decrease of the matrix free volume. This rhenium(I) complex and its analogues such as $[Re(CO)_3(phen)Cl]$ and $[Re(CO)_3(4,7\text{-}Ph_2\text{-phen})I]$ were also used as probes in the curing of photosensitive epoxy-based materials.[11]

The emission properties of rhenium(I) polypyridine complexes have been utilized in biological studies. Activation of the coordinated isonicotinic acid of the complex $[Re(CO)_3(2,9\text{-}Me_2\text{-}4,7\text{-}Ph_2\text{-phen})(py\text{-}4\text{-COOH})]^+$ by N-hydroxysuccinimide allowed the conjugation of the complex to biomolecules such as human serum albumin.[12] The HSA conjugate displayed intense emission at 550 nm ($\tau_{average} = 2.7\,\mu s$) in oxygenated aqueous solution. The emission polarization of the rhenium-HSA conjugate was sensitive to the binding of anti-HSA due to the increase in molecular weight and a substantial enhancement in anisotropy. This luminescent conjugate was employed in a competition immunoassay for HSA.

Schanze and coworkers connected an anthracene unit to a rhenium(I)-bpy chromophore via a flexible tether to give complexes such as $[Re(CO)_3(bpy)(py\text{-}4\text{-}CH_2NHCO(CH_2)_3NHCH_2\text{-9-anthracene})]^+$.[13] In an aqueous solution, the rhenium(I)-bpy unit interacted with the hydrophobic anthracene and the ^{3}MLCT luminescence was significantly quenched by exchange triplet–triplet energy transfer. However, in the presence of double-stranded DNA molecules, anthracene intercalated strongly into the double-helix, leading to an increased separation between the rhenium(I)-bpy and anthracene units. The efficiency of the intramolecular energy transfer quenching was lowered and the ^{3}MLCT emission was thus resumed (Figure 1).

The ^{3}MLCT emission properties of a series of rhenium(I) polypyridine complexes attached with a biotin moiety $[Re(CO)_3(N–N)(py\text{-}CH_2NH\text{-biotin})](PF_6)$ have been studied.[14] While common organic fluorescent biotin conjugates suffer from significant self-quenching due to resonance-energy transfer upon binding to the protein avidin, these rhenium(I) biotin complexes displayed luminescence enhancement and lifetime elongation upon binding to avidin. These

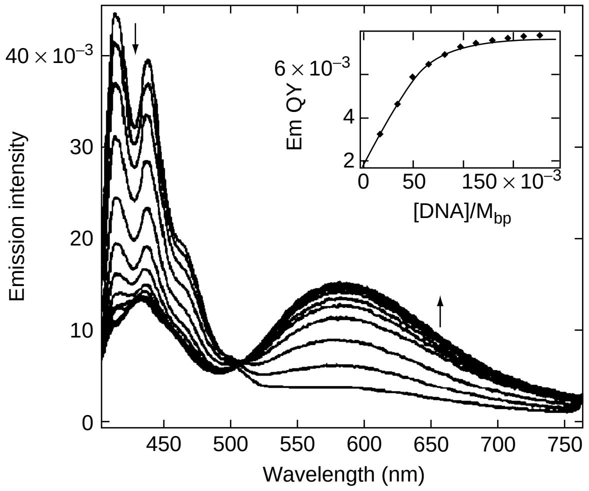

Figure 1 Corrected emission spectra of $[Re(CO)_3(bpy)(py\text{-}4\text{-}CH_2NHCO(CH_2)_3NHCH_2\text{-9-anthracene})]^+$ as a function of [DNA]/[Re]. [DNA]/[Re] ratios: 0, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, and 5.5. Inset shows a plot of Φ_{em}^{MLCT} versus [DNA] for the same emission titration experiment. Conditions: Tris buffer; pH = 7.0; [Re] = 33 μM. (Reprinted with permission from Ref. 13. © 1993 American Chemical Society)

observations suggested that the complexes could be exploited as a new class of a luminescent probe for avidin, biotin, and biotinylated species.

2.1.2 Nature of Excited States

It is noteworthy that the excited-state lifetimes of $[Re(CO)_3(N–N)X]$ increased significantly upon changing the axial ligand X from Cl to Br and then to I, while the emission energy did not change.[15] The transient absorption difference spectra of $[Re(CO)_3(bpy)X]$ revealed the absorption of the bpy$\cdot^-$ anion radical at ca. 375 and 470 nm together with an absorption band associated with the halide ligand. For X = Cl, it occurred as a very weak red tail of the bpy$\cdot^-$ anion radical band, and for X = Br, it became a distinct low-energy shoulder. However, for X = I, a separate and intense band occurred at 780 nm. Time-resolved IR spectra showed that the carbonyl stretching frequencies shifted to higher values upon irradiation, an observation due to the reduced π-back bonding (*see Back Bonding*) of the rhenium center to the carbonyl in the charge-transfer excited state. The force constants of the CO bonds decreased in the order: X = Cl ($82\,N\,m^{-1}$) > X = Br ($76\,N\,m^{-1}$) ≫ X = I ($55\,N\,m^{-1}$), suggesting that the HOMO of the complexes contained substantial Re–X ($d\pi$-$p\pi$) antibonding character (Figure 2). The halide participation in the HOMO increased in the order Cl < Br ≪ I because of its better electronegativity from Cl to I, and the excited state of the iodo complex $[Re(CO)_3(bpy)I]$ should be best described as XLCT in character.

The dinuclear rhenium(I) thiolate complexes $[\{Re(N–N)(CO)_3\}_2(\mu\text{-S-}C_6H_4\text{-X-p})](CF_3SO_3)$ showed low-energy ^{1}MLCT ($d\pi$(Re) → π^*(N–N)) absorption bands at ca. 430 nm in CH_2Cl_2.[16] Excitation of the complexes resulted in intense yellow–green luminescence at ca. 606–615 nm (τ_o = 100–140 ns). On the basis of the relatively small dependence of the emission energy on the nature of the thiolate ligands, the emission was assigned to an ^{3}MLCT ($d\pi$(Re) → π^*(N–N)) excited state, mixed with some ^{3}LLCT (p(S) → π^*(N–N)) character. Related mixed-metal rhenium(I) thiolate and selenolate complexes $[\{Re(N–N)(CO)_3(\mu\text{-E-}C_6H_4\text{-X-}p)\}_2M(bpy)_2]^{2+}$ (M = Zn(II), Cd(II)) were also studied.[17]

When more conjugated diimine or pyridine ligands are used, the excited states of rhenium(I) carbonyl complexes can have substantial ^{3}IL character.[18] While the ^{3}MLCT emission is often broad, with a lifetime in the submicrosecond to microsecond timescale, the ^{3}IL emission usually has noticeable structural features, even in fluid solutions at ambient temperature. The emission lifetime is usually very long. A simple and widely applicable approach is to evaluate the ratio of the emission quantum yield and the emission lifetime (the product of the intersystem crossing efficiency and radiative decay-rate constant).[18] Experimental values of

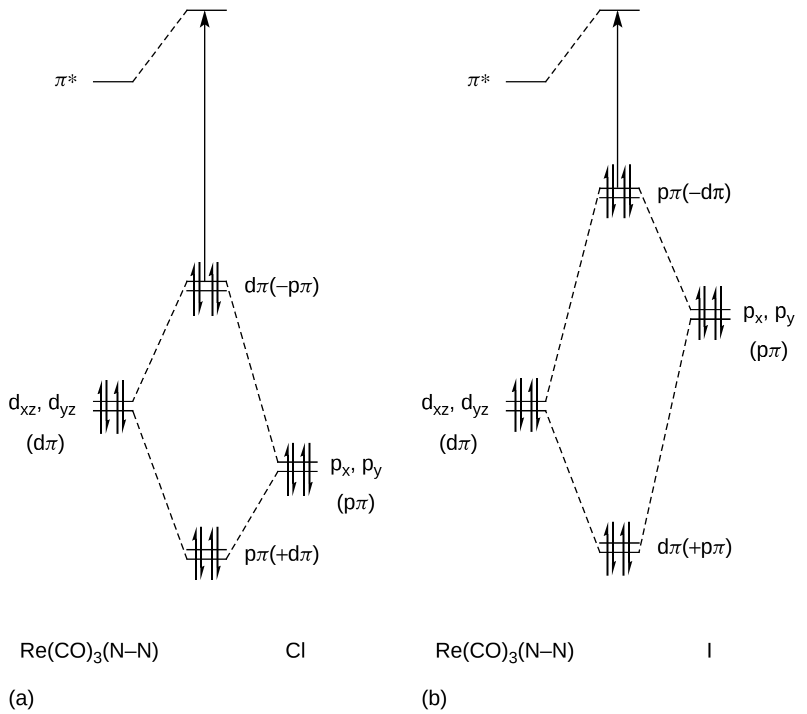

Figure 2 Simplified MO schemes showing the effect of π-interaction between the rhenium atom and the halide axial ligand on the character of the lowest electronic transition of $[Re(CO)_3(N–N)X]$. The two highest-occupied molecular orbitals of the chloro (a) and iodo (b) complexes were predominantly of metal $d\pi$(Re) and iodo $p\pi$ character, respectively, giving rise to essentially ($d\pi$(Re) → π^*(N–N)) MLCT and (p(I) → π^*(N–N)) LLCT lowest transitions, respectively. (Reprinted from Ref. 15, © 1998, with permission from Elsevier)

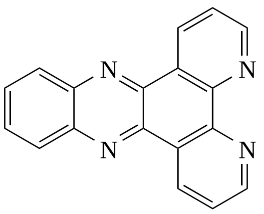
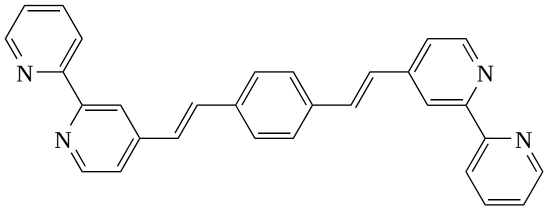
this ratio being $<10^4\,s^{-1}$ suggest that the intersystem crossing (*see Intersystem Crossing*) efficiency to populate the ^{3}MLCT state is less than unity, implying the population of ^{3}IL or other triplet states such as an LF state directly from the ^{1}MLCT state: for example, the products ($\eta_{ISC} \cdot k_{nr}$) for the dppz (**1**) and bpy-dvb-bpy (**2**) complexes of rhenium(I), $[Re(CO)_3(dppz)(py\text{-}4\text{-}Me)]^+$, and $[Re(CO)_3(bpy\text{-}dvb\text{-}bpy)(CH_3CN)]^+$, were 11 and $<20\,s^{-1}$, respectively, reflecting significant ^{3}IL character in their emissive states. In addition, the transient absorption difference spectra of these complexes showed remarkable difference to those of common rhenium(I) diimine ^{3}MLCT emitters, but resembled those of the free ligands dppz and bpy-dvb-bpy, respectively.



dppz

(**1**)

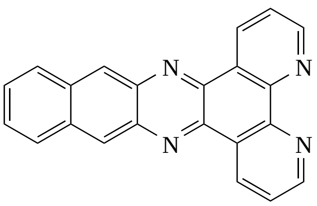


bpy-dvb-bpy

(**2**)

Time-resolved, step-scan FT-IR spectroscopy has been used to monitor the ν(CO) frequencies of rhenium(I) carbonyl polypyridine complexes and hence to study the excited-state electronic structures of these systems.[19] The MLCT and IL character in the emissive states of $[Re(CO)_3(phen)(py\text{-}4\text{-}Me)]^+$ and $[Re(CO)_3(dppz)(PPh_3)]^+$, respectively, has been studied by this technique. The presence of two close-lying states of MLCT and IL character for the complex $[Re(CO)_3(4,4'\text{-}\{NH_2\}_2\text{-}bpy)(py\text{-}4\text{-}Et)]^+$ was also confirmed.

The complexes $[Re(CO)_3(N\text{–}N)(L)]^+$ (N–N = dppz or dppn (**3**), L = pyridine or 4-methylpyridine) have been prepared and their luminescence properties studied.[20,21] Luminescence and transient absorption spectroscopy indicated that this class of complexes exhibited a triplet IL excited state. The intercalative binding of the complexes to double-stranded calf thymus DNA and synthetic oligonucleotides was investigated, and cleavage of the plasmid pBR322 upon visible light irradiation was observed. It appeared that the excited complex $[Re(CO)_3(dppz)(py)]^{+*}$ directly oxidized the DNA molecule. However, in the case of the dppn analogue, the reactive species responsible for the cleavage was identified to be superoxide radicals and hydroxyl radicals, both of which were produced from the reduction of dioxygen by the excited complex. In a related study, the ^{3}IL (dppz) nature of the excited state of the complex $[Re(CO)_3(dppz)(py)]^+$ has been investigated using visible and infrared transient absorption and resonance Raman spectroscopy (*see Resonance Raman Spectroscopy*) on the picosecond and nanosecond timescales.[22]



dppn

(**3**)

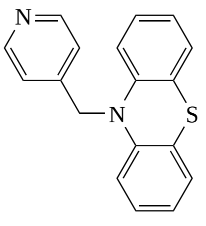
The emission properties of another class of complexes $[Re(CO)_3(N\text{–}N)(py)]^+$ containing alkyl and aryl-substituted phenanthroline ligands (N–N) (3,4,7,8-Me_4-phen, 2,9-Me_2-4,7-Ph_2-phen, 4,7-Me_2-phen, 5,6-Me_2-phen, 5-Ph-phen, 2,9-Me_2-phen and phen), have been investigated.[23] In particular, the temperature dependence of the solution emission was studied. Most of the complexes showed a steady increase in the observed decay-rate constant with temperature from 150 to 320 K, which can be rationalized by the thermal population of a short-lived ^{1}MLCT or d-d state, which was higher in energy than the usual ^{3}MLCT state. Interestingly, the rate constant of the 3,4,7,8-Me_4-phen complex first decreased from 150 to 230 K before rising from 230 to 320 K. Fitting of the data suggested the presence of a longer-lived state lying about $130\,cm^{-1}$ above the ^{3}MLCT state. For this particular complex, the long-lived state was assigned to an ^{3}IL state associated with the 3,4,7,8-Me_4-phen ligand. The presence of IL character in the solution emission of this complex can be revealed by its extraordinarily long emission lifetime (13 µs in CH_2Cl_2 at 298 K) and structured emission spectra.

The intriguing luminescence properties of the platinum(II) carbonyl biphenyl complex $[Pt(bph)(CO)_2]$ have been studied.[24] The low-energy absorption bands at ca. 301 and 330 nm were assigned to ^{1}MLCT (d(Pt) $\rightarrow \pi^*$(bph)) transitions. In the solid state, the crystals were green and absorbed at ca. 650 nm. The absorption band was assigned to a $^1(d\sigma^* \rightarrow \pi^*$(bph)) transition. The complex showed excitation wavelength-dependence and structured emission bands in low-temperature glass. Such multiple emission behavior is characteristic of the presence of more than one emitting species. The emission bands that occurred at ca. 525 and 660 nm were related to the presence of dimeric species and higher-nuclearity aggregates formed as the solution cooled. The solid sample showed an intense emission band at 726 nm, which was proposed to be related to the columnar structure

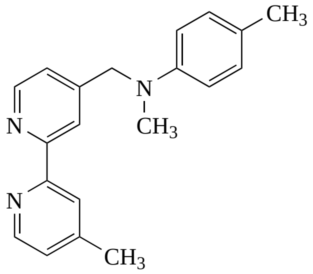
of the solid in which the complex molecules were stacked alternatively with a Pt–Pt distance of ca. 3.24 Å.

2.1.3 *Photochemical Properties*

The photoredox properties of rhenium(I) polypyridine complexes have been well studied. Reductive quenching of luminescent rhenium(I) systems by amines, and oxidative quenching by pyridinium ions have been described.[1–4,8] When these quenchers are linked covalently to a rhenium(I) center, photoinduced intramolecular electron transfer reactions are anticipated. The intramolecular electron transfer chemistry of rhenium(I) polypyridine complexes has been investigated in detail by Meyer and coworkers.[25] The complex $[Re(CO)_3(bpy)(py\text{-}PTZ)]^+$ contained a reductive quencher ligand py-PTZ (**4**). In 77-K alcohol glass, the photophysical properties of the complex were essentially the same as that of its pyridine counterpart. However, in CH_3CN at room temperature, excitation of the ^{1}MLCT chromophore was followed by rapid appearance of transient absorption features at 350 and 500 nm, consistent with the formation of charge-separated states $[Re(CO)_3(bpy^{\bullet -})\ (py\text{-}PTZ^{\bullet +})]^+$. Kinetic measurements revealed that this charge-separated transient species decayed to the ground state with a rate constant that was three orders of magnitude smaller than that of the back-electron-transfer within the model association complex $\{[Re(CO)_3(bpy^{\bullet -})\ (py\text{-}4\text{-}Et)]^0$, $10\text{-}MePTZ^{\bullet +}\}$. The relatively small decay-rate constant for the intramolecular electron transfer was accounted for by the restricted relative orientation of the electron donor and acceptor. The photophysical properties of a related complex $[Re(CO)_3(dmb\text{-}tol)Cl]$ containing the quencher dmb-tol (**5**) were also investigated.[26]



py-PTZ
(**4**)



dmb-tol
(**5**)

In view of the strong photooxidizing properties of $[Re(CO)_3(phen)(im)]^+$,[27] azurin from *Pseudomonas aeruginosa* has been modified with a rhenium(I) diimine unit via a histidine residue to give the derivative $[Re(CO)_3(phen)(His83)]^+\text{-}AzCu^+$. Direct photoinduced oxidation of Cu(I) to Cu(II) was observed.[27] In a related study, the photogeneration of tryptophan and tyrosyl radicals by rhenium(I) complexes conjugated to azurin involving the flash-quench technique has been demonstrated.[28] The EPR spectra of frozen solutions of irradiated $[Re(CO)_3(phen)(H83)]^+\text{-}AzZn^{2+}/[Co(NH_3)_5Cl]^{2+}$ and $[Re(CO)_3(phen)(H107)]^+\text{-}AzZn^{2+}/[Co(NH_3)_5Cl]^{2+}$ (Y72F mutant, leaving only one tyrosin, Y108, in the protein) revealed the presence of W48• and Y108• radicals, respectively, formed by the oxidizing rhenium(II) species.

Transient FTIR and UV-vis spectroscopy have been used to study the excited-state properties of mononuclear $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)(CH_3CN)](PF_6)$ and dinuclear $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)]_2$ in CH_3CN or THF.[29] The one-electron reduced monomer $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)(Sol)]$ (Sol = CH_3CN or THF), formed from (1) the reductive quenching of the excited states of $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)(CH_3CN)](PF_6)$ by triethylamine or (2) the homolysis of $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)]_2$, underwent dimerization slowly in THF. The reaction of $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)(Sol)]$ with CO_2 was slow and competed with the dimerization. Photolysis of $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)]_2$ in the presence of CO_2 produced CO with a 25–50% yield based on [Re]. A CO_2-bridged dimer, $[(4,4'\text{-}Me_2\text{-}bpy)(CO)_3Re\text{–}C(O)O\text{–}Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)]$ was identified as an intermediate and both $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)]_2(OCO_2)$ and $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)(OC(O)OH)]$ were detected as oxidation products.

The photochemical properties of $[Ru(CO)_3(dmpe)]$ (dmpe = 1,2-bis(dimethylphosphino)ethane) have been studied by matrix isolation at 12 K and laser flash photolysis with UV-vis and IR detection at ambient temperatures.[30] UV photolysis ($\lambda_{ex} = 234\text{–}376$ nm) in a matrix resulted in the formation of $[Ru(CO)_2(dmpe)\cdot S]$ (S = matrix host). Laser flash photolysis in heptane solution ($\lambda_{ex} = 266$ or 308 nm) revealed that $[Ru(CO)_2(dmpe)\cdot(heptane)]$ was a short-lived intermediate fragment that reacted rapidly with $[Ru(CO)_3(dmpe)]$.

2.1.4 *Polynuclear Systems*

A number of tetranuclear rhenium(I) cyclophane complexes have been isolated by the reaction of $[Re(CO)_5Cl]$ with excess bridging pyridine ligands such as pyrazine, 4,4′-bipyridine, 1,2-bis(4-pyridyl)ethylene, and bridging porphyrin units including 2,8,12,18-tetrabutyl-3,7,13,17-tetramethyl-5,15-bis(4-pyridyl)$(H)_2$porphyrin and its zinc(II)-coordinated counterpart.[31] The cavity lengths of these molecular squares varied from ca. 3 to 20 Å. Heterometallic molecular squares have been constructed by the reaction of the monomer $[Re(CO)_3(4,4'\text{-}bpy)Cl]$ and $M(dppp)(OTf)_2$ (M = Pd(II) or Pt(II)). Most of these rhenium(I) squares displayed ^{3}MLCT emission upon photoexcitation and the emission maxima occurred at ca. 584–661 nm in CH_2Cl_2 at room temperature. It is noteworthy that the emission intensity of the Re_2Pd_2 square increased in the presence of anions such as BF_4^-, OTf^-, and ClO_4^-. The potential applications of these cyclophanes in differentiating molecules of various sizes were investigated.

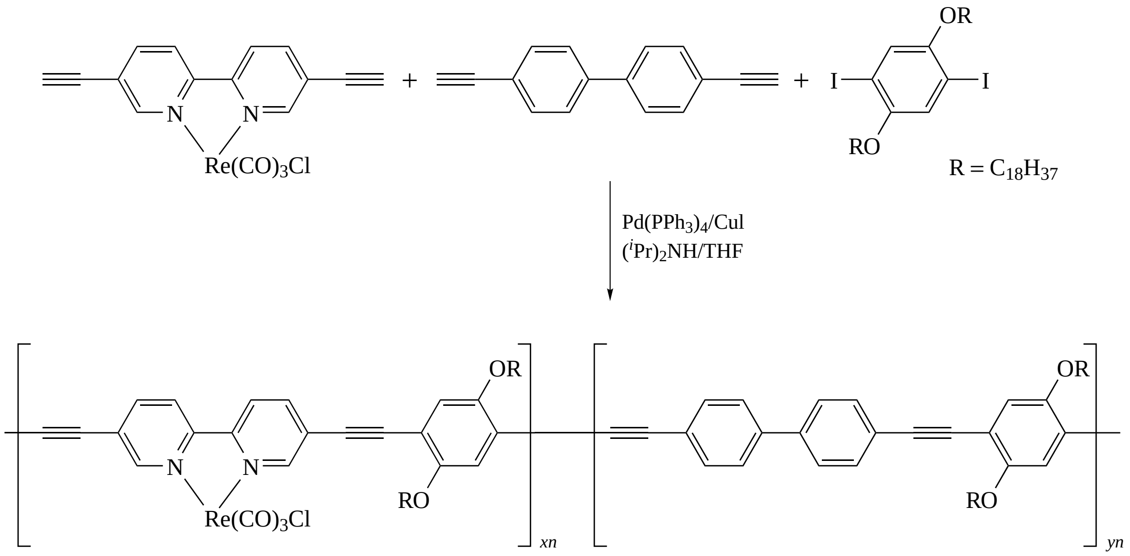
The luminescence of a thin film coated with $[Re(CO)_3(\mu\text{-}4,4'\text{-bipyridine})Cl]_4$ was quenched by nitrobenzene vapor because of electron transfer. Recently, mesoporous thin films of $[Re(CO)_3(\mu\text{-L})Cl]_4$ (L = 4,4′-pyrazine or 4,4′-bipyridine) have been utilized as sensors for volatile organic compounds (VOCs). The host-guest interaction between the rhenium cyclophanes and VOCs was confirmed by quartz crystal microbalance studies.

Luminescent π-conjugated polymers obtained from Pd-mediated cross-coupling of $[Re(CO)_3(bpy\{C{\equiv}CH\}_2)Cl]$, 4,4′-diethynylbiphenyl, and 1,4-$(I)_2$-2,5-$(C_{18}H_{37}O)_2$-C_6H_2 have been isolated and characterized.[32] The synthesis of these polymers is illustrated in Scheme 1. Four polymers with various mole fractions (from 0 to 0.5) of the rhenium(I) carbonyl unit showed intense $^1IL(\pi \rightarrow \pi^*)$ (polymer backbone) emission at 435 nm in THF solutions. The emission quantum yield and lifetime decreased with increasing mole fraction of rhenium(I), suggesting that the diffusing $^1IL(\pi \rightarrow \pi^*)$ exciton was dynamically quenched by the rhenium(I) traps. In low-temperature glass, the polymers showed $^1IL(\pi \rightarrow \pi^*)$ fluorescence. For those polymers that contained the rhenium(I) units, additional emission bands at 643 and 700 nm were also observed. The former was the $^3IL(\pi \rightarrow \pi^*)$ phosphorescence of the polymer, while the latter was the $^3MLCT(d\pi(Re) \rightarrow \pi^*(polymer))$ phosphorescence. Both the $^3IL(\pi \rightarrow \pi^*(polymer))$ states and the $^3MLCT(d\pi(Re) \rightarrow \pi^*(polymer))$ states were observed in the transient absorption difference spectra of those polymers containing the rhenium(I) carbonyl unit. The photophysics of related rhenium(I)-phenylene-ethynylene oligomers have also been studied by UV-vis transient absorption spectroscopy and time-resolved, step-scan Fourier transform infrared spectroscopy, establishing the $^3IL(\pi \rightarrow \pi^*)$ nature of the lowest-lying excited state.[33]

The optoelectronic properties of conjugated polymers containing the rhenium diimine unit $[Re(CO)_3(phen)Cl]$ have been studied.[34] Charge-carrier mobility measurements showed that the presence of metal complexes could facilitate the charge-transport process, and the enhancement in carrier mobility was dependent on the metal content in the polymer. The use of transition metal complexes for both photovoltaic and electroluminescence applications was demonstrated.

Ishitani and coworkers reported the photophysical properties of polynuclear luminescent rhenium(I) diimine complexes with bridging pyridine and phosphine ligands.[35] The tetranuclear complex $[\{Re(bpy)(CO)_3(dppe)Re(bpy)(CO)_2\}_2(4,4'\text{-bpy})]^{4+}$ emitted at 695 nm with a very weak emission shoulder at ca. 540 nm. The low-energy emission was assigned to an ^3MLCT ($d\pi(Re) \rightarrow \pi^*(bpy)$) state involving the central $[\{(dppe)Re(bpy)(CO)_2\}_2(4,4'\text{-bpy})]$ unit, while the high energy one to another ^3MLCT state involving the terminal $[Re(bpy)(CO)_3(dppe)]$ unit. Intramolecular energy transfer from the terminal Re-bpy units to the central Re-bpy units was suggested. For the trinuclear complex $[Re(bpy)(CO)_3(dppe)Re(bpy)(CO)_2(4,4'\text{-bpy})\text{-}Re(bpy)(CO)_3]^{3+}$, dual luminescence at ca. 540 and 670 nm was observed. The 540-nm emission was assigned to an ^3MLCT state of the $Re(bpy)(CO)_3(4,4'\text{-bpy})$ unit, while the 670 nm emission was assigned to another ^3MLCT state of the central $[\text{-dppe-}Re(bpy)(CO)_2(4,4'\text{-bpy})\text{-}]$ unit. Similar energy transfer was proposed to occur from the terminal rhenium(I) units to the central one.

Thin films of poly$[Ru(L)(CO)_2Cl_2]$ complexes (L = bpy-pyr1 (**6**) or bpy-pyr2 (**7**)) have been prepared by



Scheme 1 Synthesis of π-conjugated polymer incorporated with rhenium(I) 2,2′-bipyridine units. The values of x and y varied from 0 to 0.5 and 1 to 0.5, respectively

anodic electropolymerization of the corresponding monomeric complexes on platinum and indium–tin oxide electrodes.[36] Photolysis ($\lambda_{ex} = 366$ nm) of the films immersed in CH_3CN led to successive photosubstitutions of the two CO ligands and one Cl^- ligand by CH_3CN for the bpy-pyr1 polymer while only photosubstitutions of the CO ligands occurred for the bpy-pyr2 analogue. On the basis of the photochemistry, images can be created in the films by using masking techniques.

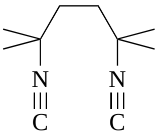
2.2 Isocyanide Systems

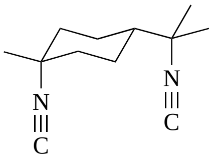
Isocyanides are versatile ligands (*see Isocyanide Ligands*) that have been coordinated to many transition metal centers to give novel organometallic compounds. In particular, the ligands tmb (**8**) and dmb (**9**) have been extensively used to coordinate to metal centers to give dimeric and polymeric materials, and many of which showed attractive spectroscopic and luminescence properties. The dinuclear rhodium(I) isocyanide complex $[Rh_2(dmb)_4]^{2+}$ showed very long Rh–Rh bond distances in the solid states (3.861–4.48 Å).[37] The solution absorption spectrum of the complex displayed an intense $^1(d_{xz}, d_{yz} \rightarrow p\sigma)$ band at 314 nm, where the pσ orbital is the bonding MO formed between the $5p_z$ orbitals of the rhodium(I) centers. The $^1(d\sigma^* \rightarrow p\sigma)$ (where the dσ^* is the antibonding MO formed between the $4d_{z^2}$ orbitals of the rhodium(I) centers) transition appeared as an asymmetric absorption band at ca. 420–440 nm with a long tailing shoulder at ca. 480 nm. The corresponding $^3(d\sigma^* \rightarrow p\sigma)$ transition occurred at ca. 3000 cm^{-1} lower in energy in the polarized single-crystal spectra. Symmetric fluorescence and phosphorescence bands at ca. 546–600 nm and 660–714 nm, respectively, were observed in various media under different conditions. The MM2 calculation results revealed a very shallow ground-state ($^1A_{1g}$) surface with a minimum at 4.75 Å, and an extremely anharmonic excited-state ($^3A_{2u}$) surface with a well-defined minimum at 3.35 Å.

The luminescence properties of the gold(I) isocyanide complex $[Au_2(dmb)(CN)_2]$ have been studied.[38] The crystal structure of the complex showed an intramolecular gold–gold separation of 3.536 Å. The solid sample displayed an emission band at 456 nm ($\tau_o = 0.59$ µs) and a weaker broad emission band at around 600–700 nm. The



tmb

(**8**)



dmb

(**9**)

complex only displayed a high-energy band at 458 nm ($\tau_o = 0.13$ µs) in dichloromethane solution. Other related $[Au_2(diiso)(C{\equiv}CPh)_2]$ and $[Au_2(diiso)(CN)_2]$ (diiso = tmb or dmb) have been shown to display luminescence behavior.[39] Excited states of ^{3}MLCT (d(Au) $\rightarrow \pi^*$(diiso)) and $^3(d\sigma^* \rightarrow p\sigma)$ character were responsible for the emission of the alkynyl and cyano complexes, respectively.

The crystal structure of $[Ir(CN\text{-}CH_3)_2Au(\mu\text{-dppm})_2](PF_6)_2$ consisted of a nearly planar $Ir(CN\text{-}CH_3)_2P_2$ unit that was connected to a very linear AuP_2 unit through two bridging dppm ligands.[40] The fluorescence and phosphorescence of the complex in CH_2Cl_2 occurred at 540 and 668 nm, respectively, which were assigned to singlet and triplet excited states of $(d\sigma^* \rightarrow p\sigma)$ character, respectively.

The M–M bonds of dinuclear d^9–d^9 complexes $[Pd_2(L)_nX_2]$ (X = Cl, Br, py; $n = 1$, L = dmb, tmb; $n = 4$, L = CNR) have been investigated using resonance Raman spectroscopy and UV-vis measurements of the dσ–dσ^* absorption band at various temperatures.[39] There was a clear relationship between the $\lambda_{abs}(d\sigma - d\sigma^*)$ and the internuclear distances between the two palladium(I) centers. The longest $d(Pd_2)$ data gave the smallest dσ–dσ^* gap and hence, the lowest transition energy. Polymeric d^{10} materials $[\{M(dmb)_2Y\}_n]$ (M = Cu, Ag; Y = PF_6^-, BF_4^-, NO_3^-, ClO_4^-, $CH_3CO_2^-$) exhibited a linear structure where the $M(dmb)_2^+$ units were linked together in a double bridging fashion. These polymers displayed emission in the solid state and glass at 77 K upon irradiation. Density functional theory calculations indicated that the HOMO was mainly metal-based in character, while the LUMO was π^*(isocyanide) in nature, and the emission was assigned to an excited state of ^{3}MLCT character. The copper polymer $[\{Cu(dmb)_2TCNQ\}_n]$/TCNQ was photoconducting, and photovoltaic cells were designed using this material.[41]

Mann and coworkers reported the remarkable solvatochromic behavior of luminescent platinum(II) isocyanide/palladium(II) cyanide (*see Cyanides* and ***Cyanide Complexes of the Transition Metals***) complexes $[Pt(p\text{-CN-}C_6H_4\text{-}C_nH_{2n+1})_4][Pd(CN)_4]$ (n = 6, 10, 12, 14).[42] A film of $[Pt(p\text{-CN-}C_6H_4\text{-}C_{10}H_{21})_4][Pd(CN)_4]$ on a microscopy slide changed its color from pink when it was exposed to air saturated with chloroform vapor. The emission band of the solid also displayed a red shift from at 640 to 658 nm. Other volatile organic vapors gave shifts to different extents. As an example, the emission spectra of a related complex $[Pt(p\text{-CN-cyclododecyl})_4][Pt(CN)_4]$ under increasing concentrations of methanol vapor showed a blue shift (Figure 3). The solid

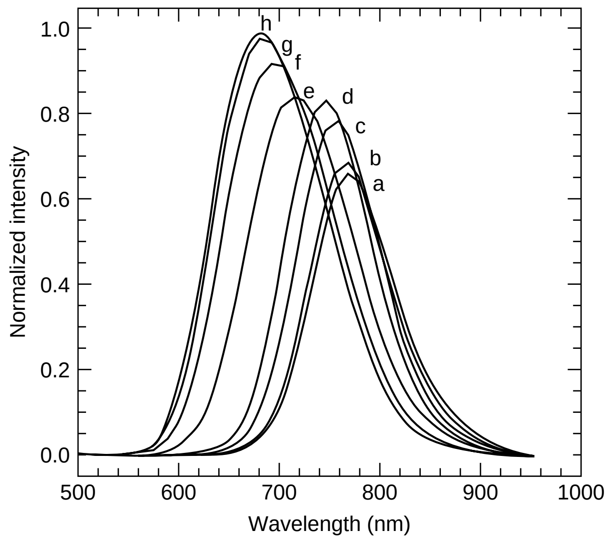


Figure 3 Emission spectra of [Pt(p-CN-cyclododecyl)$_4$] [Pt(CN)$_4$] under varying concentrations of methanol vapor at 25 ± 1 °C. Concentrations (percent saturation): a, 0; b, 1; c, 6; d, 11; e, 22; f, 54; g, 78; h, 100. (Reprinted with permission from Ref. 43. © 2002 American Chemical Society)

of these complexes consisted of infinite stacks of alternating cations and anions with considerable metal–metal interactions along the chains propagated through interionic d_{z^2} and p_z interactions. The large size mismatch between the cation and anion produced a structure with a relatively large free volume, facilitating the rapid and reversible sorption of the volatile organic compounds. The shifts of the absorption and emission bands were attributed to the interactions between the guest molecules and the linear chain chromophore in the ground and/or excited state. As an important step in the development of an 'electronic nose', a three-channel cross-reactive sensor array bead based on related vapoluminescent platinum(II) double-salt materials such as [Pt(CN-cyclododecyl)$_4$][Pt(CN)$_4$], [(phen)Pt(CN-cyclohexyl)$_2$][Pt(CN)$_4$], [Pt(CN-n-tetradecyl)$_4$][Pt(CN)$_4$], and [(phen)Pt(CN-cyclohexyl)Cl]$_2$[(phen)Pt(CN-cyclohexyl)$_2$]$_2$[Pt(CN)$_4$]$_3$ was fabricated.[43]

A series of luminescent mononuclear [(C^N^N)Pt (CNR)]$^+$ (HC^N^N = 6-phenyl-2,2′-bipyridine; R = ^{t}Bu, ^{n}Bu, ^{i}Pr, cyclohexyl, 2,6-Me$_2$C$_6$H$_3$) and dinuclear [{(C^N^N)Pt}$_2$(μ-CN(CH$_2$)$_3$NC)]$^{2+}$ isocyanide complexes has been synthesized, and their spectroscopic and photophysical properties investigated.[44] Close π–π intermolecular contacts (3.4–3.6 Å) and a metal–metal distance 3.3831(9) Å were observed in the mononuclear complexes. At high concentrations, the complex [(C^N^N)Pt(CN^{n}Bu)]$^+$ displayed a weak MMLCT (dσ*(Pt–Pt) → π*(C^N^N)) absorption shoulder at 511 nm (ε = 120 dm^3 mol^{-1} cm^{-1}). The room-temperature emission spectrum of [(C^N^N)Pt(CN-cyclohexyl)]$^+$ for complex concentrations $\geq 7 \times 10^{-3}$ mol dm^{-3} showed a low-energy ^{3}MMLCT band at 710 nm. The mononuclear complexes at high concentration in 77 K glass displayed π–π excimeric emission at 600–625 nm.

2.3 Cyanide Systems (*See Cyanide Complexes of the Transition Metals*)

The pressure-dependent emission properties of M[Au(CN)$_2$] (M = K, Cs) and Cs$_2$Na[Au(CN)$_2$]$_3$ have been investigated.[45] For example, the emission of the single crystals of K[Au(CN)$_2$] showed a large bathochromic shift from 397 to 521 nm when the applied hydrostatic pressure was increased from 1 to 30 kbar. The emission spectra of the single crystals of these complexes at various pressures are shown in Figure 4. The shift was suggested to result from the quasi-one-dimensional metal–metal interactions and the quasi-two dimensional formation of electronic energy bands.

The complexes K[Au(CN)$_2$] and K[Ag(CN)$_2$] in water and methanol displayed intense luminescence that was dependent on the concentration, solvent, temperature, and excitation wavelength.[46] The emission spectra of the gold complex in aqueous solution at ambient conditions showed dual luminescence at ca. 400–410 nm (HE band) and 430–470 nm (LE

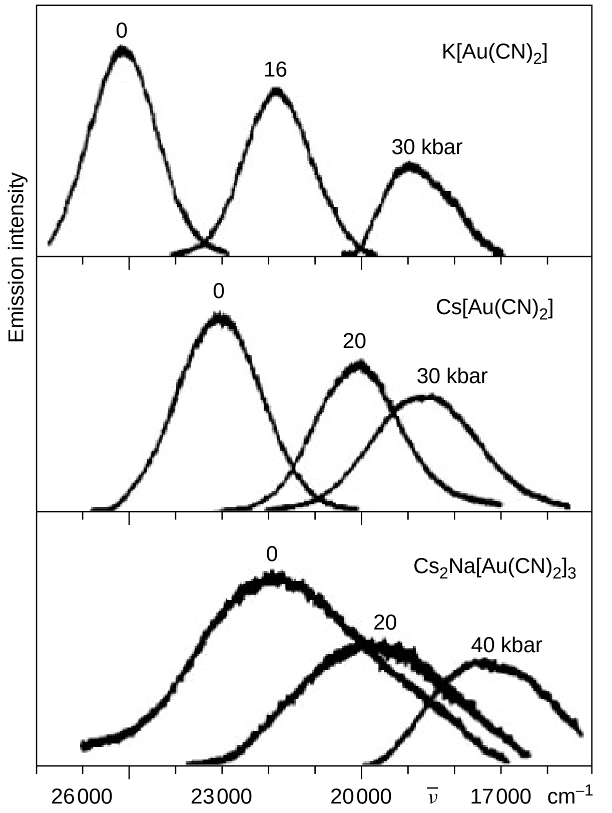

Figure 4 Emission spectra of different M[Au(CN)$_2$] single crystals for various pressures at 295 K (λ_{ex} = 325 nm). (Reprinted with permission from Ref. 45. © 1995 American Chemical Society)

band). As the concentration of the complex was increased, enhancement in the relative intensity of the LE/HE bands and a red shift of the LE band were observed. The luminescence was assigned to $^*[Au(CN)_2^-]_n$ and $^*[Ag(CN)_2^-]_n$ excimers and exciplexes of different n and geometries. MP2 calculations on the lowest-energy triplet excited state of staggered $[Au(CN)_2^-]_2$ showed the formation of a gold–gold σ-bond with an internuclear distance of 2.66 Å. The assignment of exciplex emission was based on the large Stokes' shifts and the structureless feature of the emission bands, which suggested very distorted excited states. EHMO calculations using the models $[M(CN)_2^-]_n$ and $^*[M(CN)_2^-]_n$ (M = Au, Ag; $n = 2, 3$) also suggested the formation of M–M bonds in the first excited electronic states.

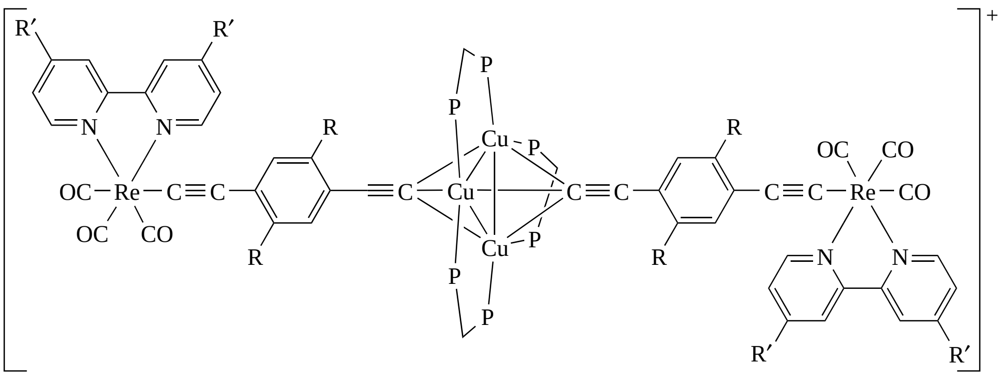
A linear chain with weak gold···gold interactions was observed in the crystal structure of $[(TPA)_2Au][Au(CN)_2]$, while a helical chain was observed in (TPA)AuCl.[47] Intrachain Au···Au separations of 3.457(1) and 3.396(2) Å were observed in these compounds, respectively. Although single crystals of $[(TPA)_2Au][Au(CN)_2]$ were nonemissive even at cryogenic temperature, the finely ground sample displayed excitation wavelength-dependent and intense blue to green emission. The chloro complex (TPA)AuCl emitted at 580 nm at 78 K. Owing to the absence of significant metal–metal interactions in the crystal structures of these complexes, it was suggested that localized surface defects comprising dimeric or oligomeric units were responsible for the emission of the powder.

3 ALKYNYL SYSTEMS

3.1 Rhenium(I) (*See Rhenium: Organometallic Chemistry*) Alkynyls

A series of rhenium(I) complexes $[Re(CO)_3(N\text{–}N)(\{C{\equiv}C\}_n\text{–}R)]$ containing conjugated alkynyl ligands displayed remarkable luminescence properties.[48,49] The origin of the emission was assigned to an ^{3}MLCT ($d\pi(Re) \rightarrow \pi^*(N\text{–}N)$) excited state. It is interesting to note that the emission energy of these complexes increased with an increasing degree of conjugation in the alkynyls (E_{em} ($n = 3$) > E_{em} ($n = 2$) > E_{em} ($n = 1$)). EHMO calculations revealed a LUMO (*see LUMO*) of significant π^*(N–N) character, while the HOMO (*see HOMO*) was mainly the antibonding overlap between $d\pi$(Re) and π(C≡C) orbitals. Lengthening the alkynyl unit would raise the π(C≡C) level and result in a closer energy match between the $d\pi$(Re) and π(C≡C) orbitals. This was expected to increase the energy of the HOMO and led to a decrease in the HOMO–LUMO gap. However, such a decrease in emission energy was not observed upon the lengthening of the alkynyl unit, and a possible reason was that the overlap integral between the $d\pi$(Re) and π(C≡C) orbitals was reduced because of the more delocalized electron density in the alkynyl. Dinuclear rhenium(I) alkynyl complexes $[Re(CO)_3(N\text{–}N)\{C{\equiv}C\}_nRe(CO)_3(N\text{–}N)]$ ($n = 2, 4, 6$) and mixed-metal alkynyl complexes $[\{\eta^2\text{-}Re(CO)_3(N\text{–}N)(C{\equiv}CPh)\}_2M]^+$, $[M_3(P\text{-}P)_3\{\mu_3-\eta^1\text{-}C{\equiv}C\text{–}[C_6H_2R_2\text{-}2,5]_n\text{–}C{\equiv}C\text{-}4\text{-}Re(CO)_3(N\text{–}N)\}_2]^+$ (M = Cu, Ag; $n = 0, 1$), such as (**10**) and $[Ag_6(\mu\text{-dppm})_4\{\mu_3\text{-}C{\equiv}CC{\equiv}C\text{–}Re(N\text{–}N)(CO)_3\}_4]^{2+}$ (**11**) were isolated and shown to display rich emission properties.[50,51] An ^{3}MLCT ($d\pi(Re) \rightarrow \pi^*(N\text{–}N)$) excited state, possibly mixed with some ^{3}LLCT ($\pi(C{\equiv}C) \rightarrow \pi^*(N\text{–}N)$) character, was identified for these systems.

A redox-driven luminescence switch constructed from the linking of the rhenium(I) alkynyl to an iron(II) alkynyl has been synthesized.[52] The complex $[Re(bpy)(CO)_3(C{\equiv}C\text{–}C_6H_4\text{–}C{\equiv}C\text{-}p)Fe(C_5Me_5)(dppe)]$ was nonluminescent because the emissive ^{3}MLCT ($d\pi(Re) \rightarrow \pi^*(bpy)$) state was quenched effectively by the low-lying MLCT and LF excited state of the iron(II) moiety. However, the one-electron oxidized form of the complex, $[Re(bpy)(CO)_3(C{\equiv}C\text{–}C_6H_4\text{–}C{\equiv}C\text{-}p)Fe(C_5Me_5)(dppe)]^+$, displayed typical ^{3}MLCT ($d\pi(Re) \rightarrow \pi^*(bpy)$) emission at 590 nm in CH_2Cl_2 at 298 K due to the absence of the intramolecular quenching pathway.



$[Cu_3(P\text{-}P)_3\{\mu_3\text{-}\eta^1\text{-}C{\equiv}C\text{-}(C_6H_2R_2\text{-}2,5)\text{-}C{\equiv}C\text{-}4\text{-}Re(CO)_3(N\text{-}N)\}_2]^+$

(**10**)

(**11**)

3.2 Platinum(II) (*See Platinum: Organometallic Chemistry*) and Palladium(II) (*See Palladium: Organometallic Chemistry*) Alkynyls

The luminescence properties of *trans*-$Pt(C\equiv CH)_2(PEt_3)_2$ and *trans*-$Pt(C\equiv CPh)_2(PEt_3)_2$ have been investigated.[53,54] The complex *trans*-$Pt(C\equiv CPh)_2(PEt_3)_2$ displayed an intense structured emission in the solid state and in glass at 77 K. The presence of vibrational progressions in $\nu(C\equiv C)$ mode (and additional phenyl-localized modes in the phenylalkynyl complex) in the emission spectra of these complexes, together with the nonemissive nature of *trans*-$[PtCl_2(PEt_3)_2]$ suggested that the emission originated from an ^{3}MLCT ($d\pi(Pt) \rightarrow \pi^*(C\equiv C)$) excited state.[54] A similar ^{3}MLCT excited state, probably with some mixing of ^{3}IL ($\pi \rightarrow \pi^*(PhC\equiv C)$) character, was also proposed to the emission of the related complex *trans*-$[Pt(C\equiv CPh)_2(dppm\text{-}P)_2]$. The assignment was supported by resonance Raman (*see Resonance Raman Spectroscopy*) spectroscopic results[55] and EHMO studies on the model complex *trans*-$[Pt(C\equiv CPh)_2(dmpm\text{-}P)_2]$.[56]

Yam and coworkers extended the photophysical studies from the mononuclear to the dinuclear platinum(II) A-frame $[Pt_2(\mu\text{-dppm})_2(\mu\text{-C}\equiv CR)(C\equiv CR)_2]^+$ (**12**) and face-to-face $[Pt_2(\mu\text{-dppm})_2(C\equiv CPh)_4]$ (**13**) alkynyl complexes.[54] The low-temperature emission spectra revealed rich vibronic-structured bands with progressional spacings typical of the $\nu(C\equiv C)$ mode. The absorption and emission bands of these complexes occurred at lower energy than those of the mononuclear complexes. The solid-state emission energy increased with the increasing $\pi^*(C\equiv CR)$ orbital energy. These observations suggest that the origins of the absorption and phosphorescence were MMLCT ($d\sigma^* \rightarrow p\sigma/\pi^*(C\equiv CPh)$) in nature. The alkynyl moieties can be used to coordinate to other transition metal centers: for example, the mixed-metal alkynyl complex $[Pt_2(\mu\text{-dppm})_2(C\equiv CPh)_4\{Cu(CH_3CN)\}_2]^{2+}$ (**14**) has been isolated.[57] The MMLCT absorption and emission of this complex occurred at lower energy than those of the parent diplatinum complex $[Pt_2(\mu\text{-dppm})_2(C\equiv CPh)_4]$ because of a shortening of the Pt···Pt distance as well as an enhanced π-accepting ability of the $C\equiv CPh$ groups upon the π-coordination to copper(I). The narrowing of the HOMO-LUMO energy gap due to these factors is illustrated in Figure 5.

(**14**)

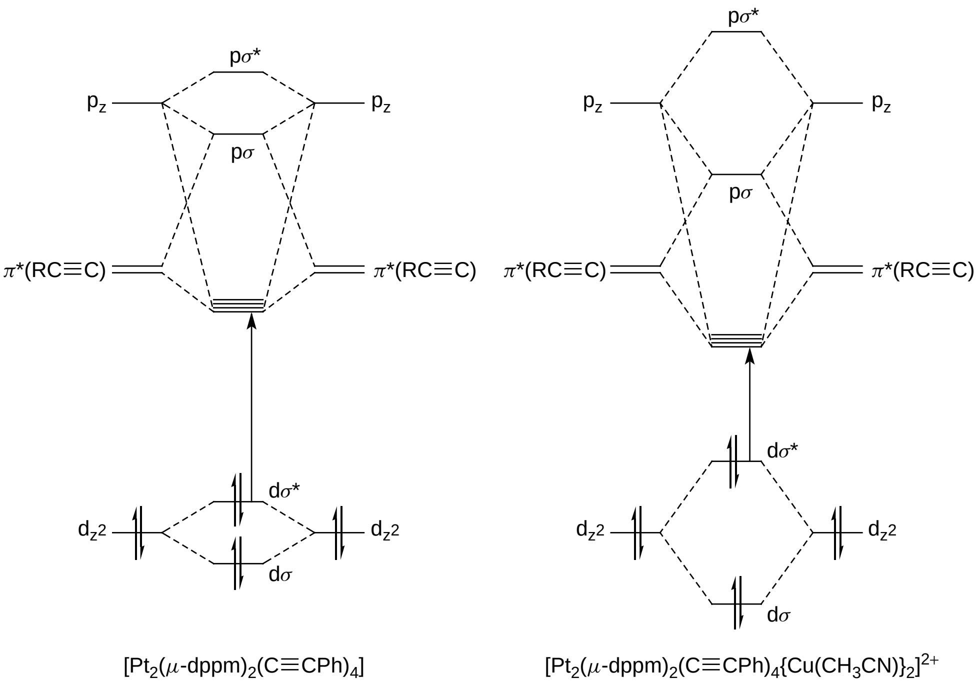

Figure 5 Diagrams showing the narrowing of HOMO-LUMO energy gap of the face-to-face dinuclear platinum(II) complex $[Pt_2(\mu\text{-dppm})_2(C{\equiv}CPh)_4]$ upon copper(I) coordination. (Reprinted with permission from Ref. 54. © 2002 American Chemical Society)

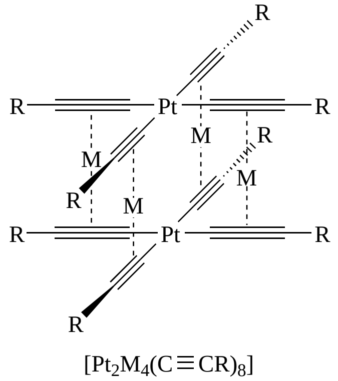
Other mixed-metal platinum(II) alkynyl complexes such as $[Pt_2M_4(C{\equiv}CR)_8]$ (M = Cu, Ag) (**15**) and their dimers, trimers, and higher aggregates such as $[\{Pt_2Ag_4(C{\equiv}C^tBu)_8\cdot(bpy)\}]_n$, have been shown to display photoluminescence in the solid state and in frozen solutions.[58,59] The emission of $[Pt_2M_4(C{\equiv}CR)_8]$ was assigned to an ^{3}LMCT (RC≡C → Pt_2M_4) or ^{3}LMMCT (RC≡C → $M_4Pt{-}PtM_4$) state. The polymer $[\{Pt_2Ag_4(C{\equiv}C^tBu)_8\cdot(bpy)\}]_n$ showed intense and long-lived bluish-green emission. The higher intensity and longer lifetime of this emission with respect to the parent complex $[Pt_2Ag_4(C{\equiv}C^tBu)_8]$ suggested a substantial reduction in the overall deactivation via nonradiative mechanism. The higher aggregates were shown to emit at lower energy than the respective monomers.[59]



$[Pt_2M_4(C{\equiv}CR)_8]$
(15)

A series of branched palladium(II) and platinum(II) complexes containing the rigid conjugated arylalkynyl ligand 1,3,5–$(HC{\equiv}CC_6H_4{-}C{\equiv}C{-}p)_3C_6H_3$ has been synthesized and characterized.[60,61] A red shift in the absorption energy upon going from the palladium(II) complex to its platinum(II) counterpart was observed, suggestive of the presence of ^{1}MLCT (dπ(M) → π*(C≡CR)) (M = Pd, Pt) character in the transitions. The emission of these complexes at low temperature was assigned to an excited state of mixed ^{3}IL (π(C≡CR) → π*(C≡CR))/^{3}MLCT (dπ(M) → π*(C≡CR)) character.

Polymeric species $\{Pt(X^nBu_3)_2{-}C{\equiv}C{-}(C{\equiv}C)_m{-}C{\equiv}C\}_n$ and $\{Pt(X^nBu_3)_2{-}(C{\equiv}C)_m{-}C_6H_4{-}(C{\equiv}C)_m{-}p\}_n$ ($m = 0, 1$) have been synthesized.[62] The absorption and emission spectra of these complexes showed extended π-electron conjugation through the metal sites on the chain, with a lower π–π* energy gap for the triacetylenic than for the diacetylenic polymers. Well-resolved vibronic structure associated with the ν(C≡C) frequency was observed in both the absorption and emission spectra, indicating strong electron-phonon coupling for these polymers.

Apart from phosphine ligands, polypyridine ligands have been incorporated into platinum(II) alkynyl moieties to give luminescent complexes. The use of polypyridine ligands is interesting because their planar structure and the square-planar coordination geometry of the d^8 platinum(II) center could modify the excited state of these luminescent complexes by π–π and/or Pt···Pt interactions. The complex

[Pt(4,4′-Ph_2-bpy)(C≡C–Ph)$_2$] showed intermolecular π-stacking of the alkynyl and phenyl moieties with the bipyridine group.[63] Excitation of these complexes gave ^{3}MLCT (5d(Pt) → π*(N–N)) emission. The complex [Pt(4,4′-^{t}Bu$_2$-bpy)(C≡C–C≡C–Ph)$_2$] showed structured emission spectra in the solid state and rigid glass. The low-energy shoulder at 603 nm in the 77 K solid-state emission was suggested to be excimeric emission. The electroluminescence properties of these platinum(II) diimine alkynyls were investigated. A related series of cyclometalated platinum(II) alkynyl complexes [Pt(bzq)(C≡CR)$_2$]$^-$ (R = ^{t}Bu, SiMe$_3$, Ph, Tol, $C_6H_4CF_3$-4, C_5H_4N-2) has also been synthesized, characterized and shown to be strongly emissive in the solid state and in frozen solutions.[64]

The solvent-induced aggregation of a platinum(II) terpyridine alkynyl complex has been studied.[65] X-ray crystallography revealed that the complex [Pt(terpy)(C≡C–C≡CH)]$^+$ crystallized in two forms: (1) a dark green form in which platinum atoms formed a linear chain and were equally spaced, with partial stacking of the terpy units; and (2) a red form that showed a dimeric structure with alternating short and long Pt···Pt distances arranged in a zig-zag fashion. Both forms dissolved in acetonitrile and acetone to form yellow solutions with high-energy ^{1}IL (π → π*(C≡C–C≡CH)) absorption bands at 313, 329, and 340 nm, and a less intense ^{1}MLCT (d(Pt) → π*(C≡C–C≡CH)) band at ca. 416 nm. Addition of diethyl ether into such solutions changed the color from yellow to green, and then to blue, with the appearance of a new absorption band at ca. 615 nm in the spectra (Figure 6a). These observations were absent for the structural analogue [Pt(^{t}Bu$_3$-terpy)(C≡C–C≡CH)]$^+$, which did not exhibit any π–π or Pt···Pt interactions in its crystal structure. The changes displayed by the platinum(II) terpy complex were likely to result from the aggregation of the complex induced by the addition of diethyl ether, and the low-energy absorption band was assigned to an ^{1}MMLCT (dσ*(Pt)$_n$ → π*(C≡C–C≡CH)) transition. The appearance of the absorption band was accompanied by a new emission band at 785 nm (Figure 6b), which was likewise assigned to an ^{3}MMLCT (dσ*(Pt)$_n$ → π*(C≡C–C≡CH)) excited state. These remarkable changes in the absorption and emission properties of the complex induced by the solvent composition could be utilized as versatile reporters and probes of environmental changes.

Three novel luminescent dinuclear platinum(II) complexes with bridging alkynyls have been studied.[66] The complexes [Pt(^{t}Bu$_3$-terpy)–{C≡C}$_n$–Pt(^{t}Bu$_3$-terpy)] (n = 1, 2, 4) showed intense high-energy ^{1}IL (alkynyl and ^{t}Bu$_3$-terpy) absorption bands at ca. 308–342 nm. Low-energy absorption bands at ca. 428–522 nm were assigned to ^{1}MLCT (dπ(Pt) → π*(^{t}Bu$_3$-terpy)) transitions mixed with ^{1}LLCT (π(alkynyl) → π*(^{t}Bu$_3$-terpy)) character. Remarkably, the low-energy absorption bands shifted to higher energy upon elongation of the alkynyl units. A similar observation has been made and explained for a series of rhenium(I) alkynyl complexes. A blue shift in the 77-K glass-emission energy was also observed for the platinum(II) complexes on going from $n = 1$ to 2. A highly structured emission spectrum was, however, observed for the complex [Pt(^{t}Bu$_3$-terpy){C≡C}$_8$Pt(^{t}Bu$_3$-terpy)], which was likely to be a consequence of the involvement of a high degree of ^{3}IL (alkynyl) character in the emissive state.

Weder and coworkers reported the use of the dinuclear platinum(II) alkene complex [Pt$_2$(μ-Cl)$_2$(PhCH=CH$_2$)$_2$Cl$_2$]

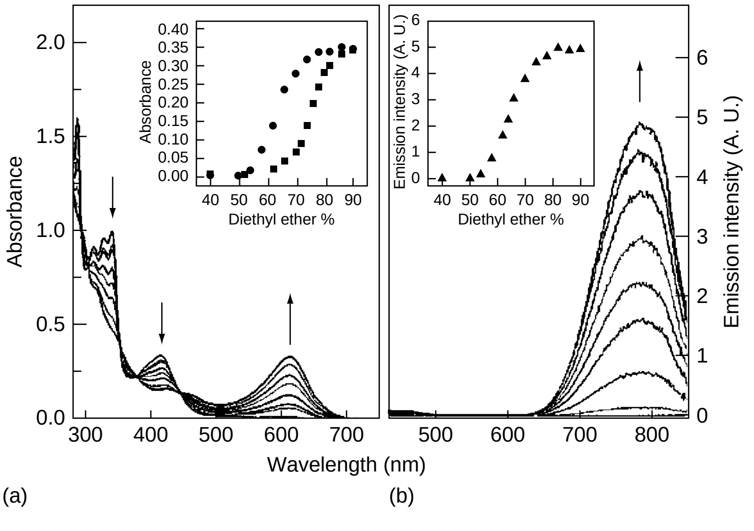


Figure 6 (a) UV-vis absorption changes of [Pt(terpy)(C≡C–C≡CH)]$^+$ (concentration = 1.47×10^{-4} M) in acetonitrile with increasing diethyl ether content. in the formation of a three-dimensionally cross-linked, conjugated poly(*p*-phenylene ethynylene)-platinum(II) network, in which the ethynylene moieties of the polymer are coordinated to the platinum(II) centers.[67] The formation of these polymeric materials is shown in Scheme 2. The photoluminescence of the PPE polymer was significantly quenched after the platinum(II) coordination. The observations were suggested to be a result of exciton migration along the polymer main chains to

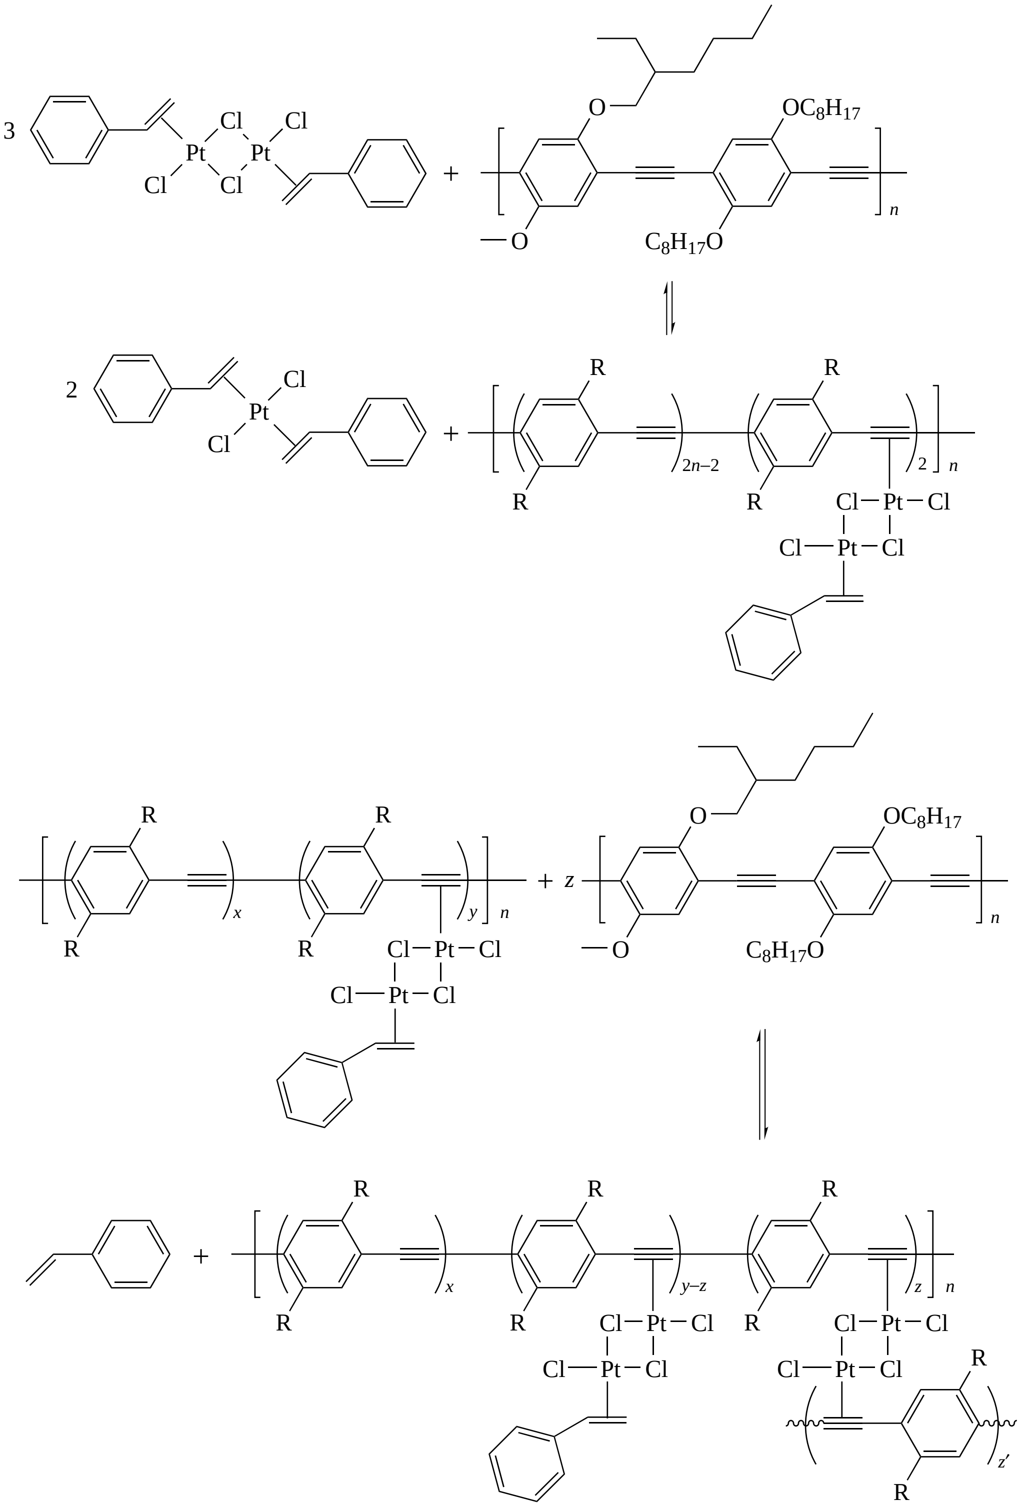


Scheme 2 Suggested equilibria for the reaction of $[Pt_2(\mu\text{-}Cl)_2(PhCH{=}CH_2)_2Cl_2]$ and poly(*p*-phenylene ethynylene)

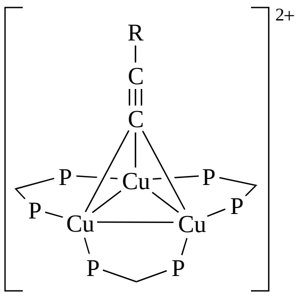
the complexation sites, which seemed to represent low-energy states and provided pathways for nonemissive radiation processes. In a related study, a PPE derivative was reacted with a platinum(0) styrene complex [Pt(styrene)$_3$] to form a polymer network in which the platinum(0) centers were π-bonded to the ethynylene moieties of the polymer chains.[68] A similar decrease in the photoluminescence intensity of the polymer was also observed.

A hexanuclear luminescent platinum(II) complex [Pt$_2$(μ-dppm)$_2$(C≡C-py-4)$_4${Pt(terpy)}$_4$](CF$_3$SO$_3$)$_8$ has been isolated and characterized.[69] The slight red shift of the ^{3}MMLCT emission band relative to that of the parent complex [Pt$_2$(μ-dppm)$_2$(C≡C-py-4)$_4$] was attributed to the increased Pt$\cdots$Pt interaction due to a shrinkage of the Pt$\cdots$Pt bond distance in the Pt$_2$(dppm)$_2$ core in the hexanuclear structure and an increase in the π-accepting ability of the ethynylpyridine units upon coordination of the Pt(terpy) moieties.

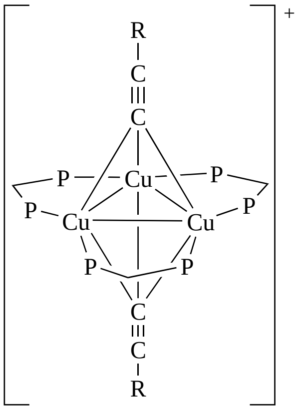
Luminescent platinum(II) alkynyl polymers *trans*-[–Pt(PBu$_3$)$_2$C≡CRC≡C–]$_n$ (R = 9,9-dihexylfluorene-2,7-diyl; 9-butylcarbazole-3,6-diyl) have been prepared.[70] The absorption and luminescence spectra were compared to those of the monomeric model complexes *trans*-[Pt(Ph)(PEt$_3$)$_2$C≡CRC≡CPt(Ph)(PEt$_3$)$_2$] and other fluorene derivatives. The optical gap and intersystem crossing from the singlet excited state to the triplet excited state were found to increase with a decreasing degree of conjugation. The photoconducting properties of these polynuclear platinum alkynyl complexes were also investigated.

3.3 Copper(I) (*See Copper: Organometallic Chemistry*), Silver(I) (*See Silver: Organometallic Chemistry*) and Gold(I) (*See Gold: Organometallic Chemistry*) Alkynyls

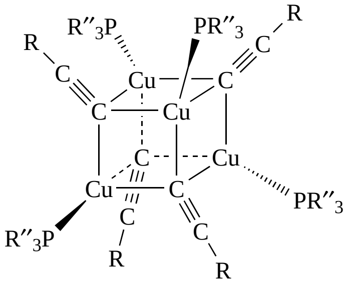
The photophysical properties of a wide range of copper(I) alkynyl complexes have been studied.[49,71] These examples can be classified into the following groups: a dinuclear complex with bridging alkynyls, [Cu$_2$(PPh$_2$CH$_3$)$_2$(μ-η^1-C≡CPh)$_2$], trinuclear complexes with one or two μ_3-bridging alkynyls, [Cu$_3$(P-P)$_3$(μ_3-η^1-C≡CR)]$^{2+}$ (**16**), [Cu$_3$(P-P)$_3$(μ_3-η^1-C≡CR)$_2$]$^+$ (**17**), and [Cu$_3$(P-P)$_3$(μ_3-η^1-C≡CR)(μ_3-η^1-C≡CR′)]$^+$, mixed chloro- and alkynyl-bridged trinuclear complexes, [Cu$_3$(P-P)$_3$(μ_3-η^1-C≡CR)(μ_3-Cl)]$^+$, tetranuclear metallocubane-type complexes with four or three μ_3-bridging alkynyls, [Cu$_4$(PR″$_3$)$_4$(μ_3-η^1-C≡CR)$_4$] (**18**) and [Cu$_4$(PPh$_3$)$_4$(μ_3-η^1,η^1,η^2-C≡C–C$_6$H$_4$O-CH$_3$-4)$_3$]$^+$ (**19**), tetranuclear complexes with a C$_2$ bridging alkynyl, [Cu$_4$(P-P)$_4$(μ_4-η^1,η^2-C≡C)]$^{2+}$ (**20**), and hexanuclear complexes with a bis(μ_3-bridging alkynyl), [Cu$_3$(P-P)$_3$(μ_3-η^1-C≡C–C$_6$H$_4$–C≡C-4)Cu$_3$(P-P)$_3$]$^{4+}$ (**21**). All these copper(I) alkynyls showed intense and long-lived green to orange emission upon irradiation. Systematic variations on the identity of the phosphine ligands, and substituents on the alkynyls revealed that the nature of the emissive state was ^{3}LMCT (alkynyl → Cu$_n$)/^{3}MC(3d → 4s/4p) with predominantly ^{3}LMCT (alkynyl → Cu$_n$) character. The mixing



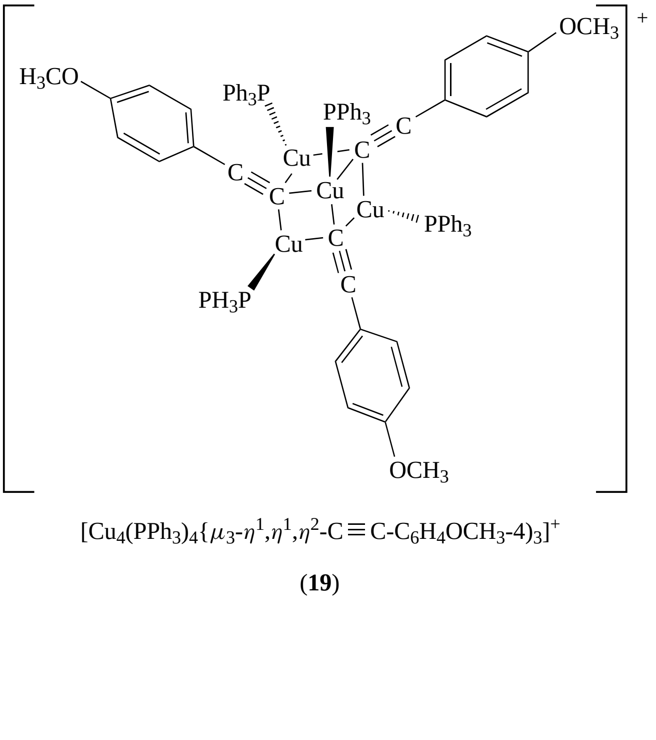
[Cu$_3$(P-P)$_3$(μ_3-η^1-C≡CR)]$^{2+}$
(**16**)



[Cu$_3$(P-P)$_3$(μ_3-η^1-C≡CR)$_2$]$^+$
(**17**)

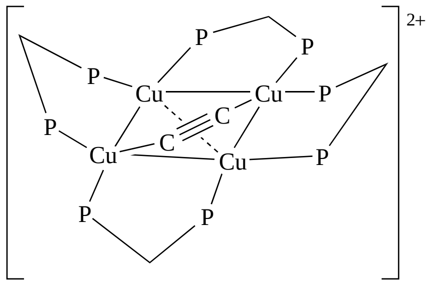


[Cu$_4$(PR″$_3$)$_4$(μ_3-η^1-C≡CR)$_4$]
(**18**)



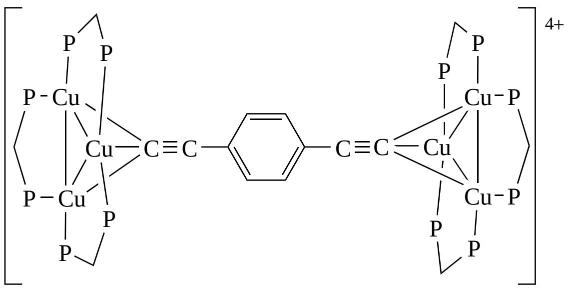
[Cu$_4$(PPh$_3$)$_4${μ_3-η^1,η^1,η^2-C≡C-C$_6$H$_4$OCH$_3$-4)$_3$]$^+$

(**19**)



$[Cu_4(P\text{-}P)_4(\mu_4\text{-}\eta^1,\eta^2\text{-}C{\equiv}C)]^{2+}$

(**20**)



$[Cu_3(P\text{-}P)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}C\text{-}C_6H_4\text{-}C{\equiv}C\text{-}4)Cu_3(P\text{-}P)_3]^{4+}$

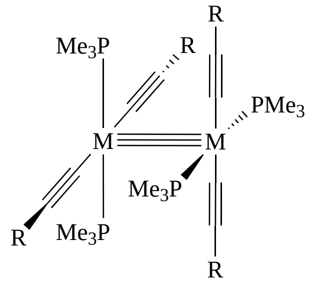
(**21**)

of ^{3}MC (3d → 4s/4p) character, resulted from Cu···Cu interaction, into the excited state was proposed on the basis of the short Cu···Cu distances revealed by crystallographic studies. However, ^{3}IL (alkynyl) character existed in the excited states of some of these examples, especially those with highly conjugated alkynyl ligands such as –C≡C–C_6H_4 –C≡C-4 and –C≡C–C≡C–R and alkynyl ligands with a strong electron-withdrawing substituent such as –C≡C–C_6H_4–NO_2-4. A small blue shift in the emission energy was observed for the silver(I) analogues of some of these complexes such as $[Ag_3(P\text{-}P)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CR)]^{2+}$ and $[Ag_3(P\text{-}P)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}C\text{–}C_6H_4\text{–}C{\equiv}C\text{-}4)Ag_3(P\text{-}P)_3]^{4+}$, which was in agreement with the assignment of an ^{3}LMCT (alkynyl → M_n)/^{3}MC (d → s/p) mixed state.

The copper(I) alkynyls displayed rich photochemistry and particularly strong photoreducing properties. The transient absorption difference spectrum of $[Cu_3(dppm)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CPh)_2]^+$ and the electron acceptor 4-(methoxycarbonyl)-*N*-methylpyridinium ion showed an intense characteristic pyridinyl radical absorption band at ca. 400 nm. An additional broad near-infrared absorption band was also observed and it was assigned as an intervalence-transfer transition of the mixed-valence transient species $[Cu^ICu^ICu^{II}(dppm)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CPh)_2]^{2+}$. The interesting photophysical and photochemical properties of other copper(I) alkynyl complexes such as [Cu(BTA)(hfac)],[72] $[Cu_{16}(hfac)_8(C{\equiv}C^tBu)_8]$,[73] and $[Cu_{20}(hfac)_8(C{\equiv}CCH_2Ph)_{12}]$[73] have also been studied.

Luminescent dinuclear gold(I) alkynyl complexes $[PCy_3\text{–}Au\text{–}\{C{\equiv}C\}_n\text{–}Au\text{–}PCy_3]$ (n = 1, 2, 3, 4) have been isolated and their spectroscopic properties investigated.[74] Bonding of the C_n moieties to gold(I) centers enabled the lowest-energy ^{3}IL ($\pi \rightarrow \pi^*$(C≡C)) excited states to acquire sufficient allowedness via gold spin-orbit coupling to appear prominently in both the absorption and emission spectra. The spectra showed very rich vibronic structures with the appearance of the characteristic ν(C≡C) mode. The origin lines were observed at 331, 413, 502, and 574 nm for n = 1, 2, 3 and 4 respectively. A plot of ν_{0-0} versus $1/n$ gave an estimation of the ν_{0-0} for $[PCy_3\text{–}Au\text{–}\{C{\equiv}C\}_\infty\text{–}Au\text{–}PCy_3]$ to be ca. 11 000 cm^{-1} (λ_{0-0} = 909 nm). The excited state of $[PCy_3\text{–}Au\text{–}\{C{\equiv}C\}_2\text{–}Au\text{–}PCy_3]$ was a powerful reducing agent as revealed by an excited-state reduction potential $E°(Au_2{}^+/Au_2^*)$ of ≤ -1.85 V versus SSCE.

The isolation and photophysical studies of conjugated polymeric gold(I) complexes $[\text{–}Au\text{–}C{\equiv}C\text{–}Ar\text{–}C{\equiv}C\text{–}Au\text{–}LL\text{–}]_n$ (Ar = aryl; LL = diphosphine or bis(isocyanide))[75] and dinuclear gold(I) ring complexes such as $[C_6H_4(OCH_2C{\equiv}CAu)_2\{\mu\text{-}Ph_2P(CH_2)_nPPh_2\}]$ containing bridging diphosphine and dialkynyl ligands[76] have been reported. The alkynyl ligands and Au···Au interactions were found to play an important role in the emission properties of these systems.



$[M_2(C{\equiv}CR)_4(PMe_3)_4]$

(**22**)

3.4 Molybdenum(II) (*See Molybdenum: Organometallic Chemistry*) and Tungsten(II) (*See Tungsten: Organometallic Chemistry*) Alkynyls

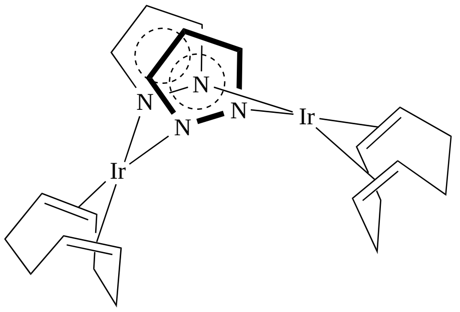
The electronic and resonance Raman spectra of dinuclear metal–metal bonded alkynyl complexes $[M_2(C{\equiv}CR)_4(PMe_3)_4]$ (M = Mo, W; R = CMe_3, $SiMe_3$, $CHMe_2$, Ph, (*see also* ***Dinuclear Organometallic Cluster Complexes***)) (**22**) displayed an unprecedented degree of ligand orbital mixing with the formally metal-metal-localized δ and δ^* frontier orbitals.[77,78] In particular, the $^1(\delta \rightarrow \delta^*)$ transitions of these complexes occurred at substantially lower energy with higher intensity than those of their structural counterparts $[M_2(X)_4(PMe_3)_4]$ (X = halides, Me, NCO, NCS). The 77 K absorption spectrum of $[Mo_2(C{\equiv}CSiMe_3)_4(PMe_3)_4]$ showed progressional spacings that were greater than the ground-state metal–metal stretch. An assignment to the ν(MoC) was

therefore proposed instead of the common $\nu(Mo_2)$ mode. It was suggested that the $^1(\delta \rightarrow \delta^*)$ transitions displayed significant frontier orbital mixing between the $[\delta,\delta^*]$ orbitals of the M_2 core and the $[\pi,\pi^*]$ orbitals of the alkynyl ligands.

4 ALKENYL, ARENE, AND ARYL SYSTEMS

4.1 Alkenyl Systems

Similar to other d^8–d^8 systems, the dinuclear iridium(I) complex $[Ir(\mu\text{-pz})(COD)]_2$ (**23**) showed spin-allowed and spin-forbidden ($d\sigma^* \rightarrow p\sigma$) absorption bands at 498 and 585 nm, respectively.[79,80] Under ambient conditions, the complex displayed fluorescence at 564 nm and phosphorescence at 687 nm, which were assigned to singlet and triplet excited states of ($d\sigma^* \rightarrow p\sigma$) character. The triplet excited state of the complex was a powerful reductant with an excited-state reduction potential $E°$ ($Ir_2^{+/0*}$) of −1.81 V vs. SSCE. Facile electron transfer reactions occurred between the excited complex and methyl viologen and other pyridinium acceptors. The absence of an inverted effect for the forward electron transfer reactions, and the presence of such inverted behavior for the back-electron-transfer reactions were observed and explained.[80]



$[Ir(\mu\text{-pz})(COD)]_2$

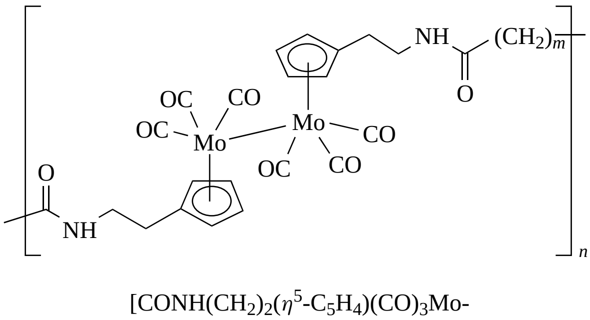
(**23**)

Irradiation of the complexes *trans*-$[W(CO)_4(\eta^2\text{-alkene})_2]$ (alkene = propene, 1-butene, cyclopentene) in an alkane solution led to the loss of alkene and CO.[81] The liberation of alkene was accompanied by the formation of 16-electron coordinatively unsaturated species: *trans*- and *cis*-$[W(CO)_4(\eta^2\text{-alkene})(\text{solvent})]$. In the case of propene and 1-butene, these species transformed into *cis*-$[WH(\eta^3\text{-allyl})(CO)_4]$. In the presence of excess alkenes, the 16-electron species bound alkene to give *cis*-$[W(CO)_4(\eta^2\text{-alkene})_2]$. The CO loss upon irradiation of *trans*-$[W(CO)_4(\eta^2\text{-alkene})_2]$ led to the formation of *mer*- and *fac*-$[W(CO)_3(\eta^2\text{-alkene})_2(\text{solvent})]$, which transformed to *mer*- and *fac*-$[W(CO)_3(\eta^2\text{-alkene})_3]$ in the presence of excess alkenes.

Perutz and coworkers demonstrated that photoreaction of $[Rh(\eta^5\text{-}C_5H_5)(PPh_3)(C_2H_4)]$ with SiR_3H (R = ^{i}Pr, Et) and hexafluorobenzene produced $[Rh(\eta^5\text{-}C_5H_5)(PPh_3)(SiR_3)(H)]$ and $[Rh(\eta^5\text{-}C_5H_5)(PPh_3)(\eta^2\text{-}C_6F_6)]$, respectively.[82] Oxidative addition of the C–H bonds of partially fluorinated arenes C_6F_5H and 1,3-$C_6F_2H_4$ led to the formation of $[Rh(\eta^5\text{-}C_5H_5)(PPh_3)(Ar_F)(H)]$ ($Ar_F = C_6F_5$, 2,6-$C_6H_3F_2$). Oxidative addition of benzene may be detected following photolysis in benzene-THF mixtures at 233 K ($\lambda_{ex} < 400$ nm), but the product decomposed upon warming. Recent work showed that photolysis of the bis-alkene complex $[Rh(\eta^5\text{-}C_5H_5)(C_2H_4)_2]$ with pyridine compounds such as 4-methylpyridine, 4,4′-Me_2-bpy and 2,2′-dipyridylketone gave a variety of products.[83]

4.2 Arene and Aryl Systems

Tyler and coworker reported photochemically active polymers $[CONH(CH_2)_2(\eta^5\text{-}C_5H_4)(CO)_3Mo\text{-}Mo(CO)_3(\eta^5\text{-}C_5H_4(CH_2)_2NHCO)(CH_2)_m]_n$ (m = 4, 8) (**24**).[84] Owing to the presence of metal–metal bonds along the backbone, the polyamides were photochemically reactive. Metal–metal bond photolysis reactions similar to the $Cp_2Mo_2(CO)_6$ dimer were observed, as evidenced by the disappearance of the $^1(d\pi \rightarrow \sigma^*)$ (508 nm) and $^1(\sigma \rightarrow \sigma^*)$ (388 nm) bands in the absorption spectrum. It was proposed that the reaction occurred by photolysis of the Mo–Mo bond followed by trapping of the metal radicals with atmospheric oxygen. This proposal has been confirmed by a related polymer system in which built-in metal-radical traps (chlorine atoms) were incorporated into the polymers.[85] The effect of radical size, chain length, and mass on the cage recombination efficiency of photochemically generated radical cage pairs of related polymers were studied in detail.[86]



$[CONH(CH_2)_2(\eta^5\text{-}C_5H_4)(CO)_3Mo\text{-}Mo(CO)_3(\eta^5\text{-}C_5H_4(CH_2)_2NHCO)(CH_2)_m]_n$

(**24**)

The MLCT states of d^6 complexes with polypyridine ligands are well known. Analogous systems of organometallic d^6 complexes with arenes as 6π-electron ligands are expected

to exhibit interesting luminescence properties. Unfortunately, the MLCT states of such complexes are apparently located above the LF states and therefore these complexes do not exhibit luminescence. However, for d^{10} systems, such LF states are absent and thus, emission properties of d^{10} arene complexes are anticipated. The copper(I) benzene complex $Cu_2(CF_3SO_3)_2(C_6H_6)$ showed an absorption band at 315 nm ($\varepsilon = 1200\,dm^3\,mol^{-1}\,cm^{-1}$) in benzene solution, which was assigned to an ^{1}MLCT (d(Cu) → $\pi^*(C_6H_6)$) transition.[87] While the complex was not emissive in solution, excitation of a solid sample of the complex resulted in intense ^{3}MLCT (d(Cu) → $\pi^*(C_6H_6)$) emission at 518 nm ($\tau_o = 0.5\,\mu s$).

The basic reaction of the tricarbonyl(cyclohexadienyl)iron cation $[(C_6H_7)Fe(CO)_3]^+$ consists of an addition of a nucleophile to the cyclohexadienyl ligand yielding a substituted cyclohexadiene ligand.[88] Assuming the cation contains an iron(0) center and a coordinated cyclohexadienyl cation, the complex was expected to have low-lying MLCT (Fe(0) → $C_6H_7^+$) transitions. Photolysis of the complex in solution resulted in the formation of 1,3-cyclohexadiene and 1,3,5,-hexatriene. The photolysis was also accompanied by the evolution of CO, a rise in pH and the formation of Fe^{2+}. In the MLCT excited state, the Fe(II) and $C_6H_7^-$ were expected to be formed. In contrast to the ground state, this excited state was expected to facilitate an electrophilic attack at the cyclohexadienyl ligand. In aqueous solution, the attack of protons led to the formation of $[(C_6H_8)Fe(CO)_3]^{2+}$ which was unstable and susceptible to the attack by water molecules to give $[Fe(H_2O)_6]^{2+}$. This mechanism also explained the release of CO and a rise in pH of the reaction mixture during irradiation.

Different techniques have been used to study the products of photoreactions of organometallic compounds: for example, irradiation of the arene complexes $[CpFe(\eta^6\text{-arene})]^+$ resulted in the substitution of the arene by solvent or other potential ligands present in solution.[89] In solutions containing an epoxide monomer, this photochemical reaction generated a species that initiated polymerization. Ion cyclotron resonance Fourier transform mass spectrometry and electrospray ionization mass spectrometry were used to elucidate the mechanism of these photoinitiated polymerizations.

The alkane C–H bond activation reaction by arene complexes such as $[(\eta^5\text{-}C_5H_5)Rh(CO)_2]$ has attracted much interest. Subpicosecond infrared spectroscopic measurements revealed that the reactive intermediate in the cyclohexane activation by $[(\eta^5\text{-}C_5H_5)Rh(CO)_2]$ was associated with an absorption band at 1963 cm^{-1}.[90] This transient intermediate was identified to be the cyclohexane solvate $[(\eta^5\text{-}C_5H_5)Rh(CO)(C_6H_{12})]$. The mechanism of the photolysis of $[(\eta^5\text{-}C_5H_5)Ir(CO)_2]$ in cyclohexane has also been studied.[91] About 20% of the excited molecules underwent dissociation to lose a CO ligand, leading to $[(\eta^5\text{-}C_5H_5)Ir(CO)]$ or a solvate of this species, which were responsible for the activation of the alkane.

The crystal structures of the aryl complex $[Au(C_6Cl_5)_2]_2[Tl(OPPh_3)][Tl(OPPh_3)(L)]$ (L = THF, acetone) showed extended unsupported chains with short intermolecular interactions between alternating gold(I) and thallium(I) centers (3.0529(3)–3.3205(3) Å).[92] At room temperature, the THF and acetone complexes emitted at 497 and 501 nm, respectively. At low temperature, the luminescence was dependent on the excitation wavelengths. DFT and time-dependent DFT calculations on simplified model systems revealed that the site-selective excitation behavior was due to the different thallium(I) environments. The vaporchromic behavior of a related polymeric complex $\{Tl[Au(C_6Cl_5)_2]\}_n$ has also been reported recently.[93] This polymer showed a wide range of emission wavelengths in the presence of different volatile organic compounds. These observations were suggested to be due to weak interaction of the Tl(I) centers with the organic compounds.

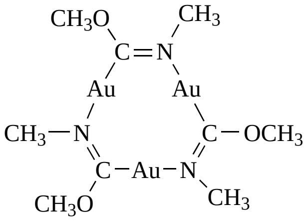
5 ALKYLIDENES (*See Carbene Complexes*) AND ALKYLIDYNE SYSTEMS

5.1 Gold (*See Gold: Organometallic Chemistry*) and Silver (*See Silver: Organometallic Chemistry*) Alkylidenes

Balch and coworkers described the solvent-induced luminescence properties of the organometallic complex $[Au_3(\mu\text{-}CH_3N{=}COCH_3)_3]$ (**25**).[94,95] Intense and long-lived yellow luminescence was observed when a solvent such as $CHCl_3$ was in contact with the solid sample of the complex that had been irradiated with ultra-violet light. Upon photoexcitation, the complex emitted at 446 nm ($\tau_o = 1$ ms) and 552 nm ($\tau_o = 1.4$, 4.4 and 31 s) in the solid state and at 422 nm in $CHCl_3$. Gold···gold contacts of 3.308(2) Å were observed in the trimeric structure of the complex. The triangular units also showed some stacking interactions, leading to intermolecular gold···gold distances of ca. 3.346(1) Å. The solvent-induced luminescence was suggested to result from the supramolecular aggregation of the complex.

Several trinuclear complexes of gold(I) interact with silver and thallium salts to intercalate Ag^+ and Tl^+ cations, thereby forming chains in the crystal structures.[96] The complexes $[\{(\mu\text{-C,N-L})_3Au_3\}_2M]X$ (μ-C,N-L = 1-benzylimidazolate, 1-methylimidzaolate, $C(OEt){=}NC_6H_4\text{-}CH_3\text{-}p$; M = Ag^+, Tl^+; X = BF_4^-, PF_6^-, ClO_4^-) have been isolated. The sandwich (*see Sandwich Compound*) clusters center the cations between the planar trinuclear moieties producing structures of $(B_3AB_3B_3AB_3)_n$ units. Short Au···Au contacts (ca. 3.0 Å) were observed between BAB molecular centers. Crystalline sample of the complexes showed intense luminescence:

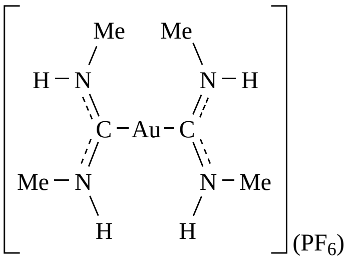
for example, [{(μ-1-benzylimidazolate)$_3$Au$_3$}$_2$Ag](BF_4) displayed green emission at 535 nm ($\tau_o = 550$ and 115 ns) at 298 K. Upon cooling to 77 K, the solid showed orange emission at 570 nm ($\tau_o = 1100$ and 220 ns). The emission was assigned to excited states of Au···Au character delocalized along the crystallographic axis of the chain. Thermal contraction led to a reduction in the intermolecular metal–metal distances along the chain and thus a decrease in the band gap and emission energy.



[Au$_3$(μ-CH$_3$N=COCH$_3$)$_3$]

(**25**)

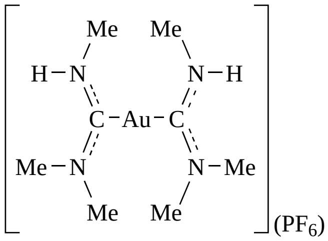
The crystal structures and luminescence properties of three gold(I) alkylidene complexes [Au{C(NHMe)$_2$}$_2$](PF_6) (**26**), [Au{C(NHMe)$_2$}$_2$](BF_4), and [Au{C(NMe$_2$)(NHMe)}$_2$](PF_6) (**27**) have been reported.[97] Solid samples of [Au{C(NHMe)$_2$}$_2$](PF_6) and [Au{C(NHMe)$_2$}$_2$](BF_4) emitted at 484 and 482 nm at room temperature. Their close structural analogue [Au{C(NMe$_2$)(NHMe)}$_2$](PF_6) did not show emission in the solid state at room temperature or 77 K. The solid-state emission of [Au{C(NHMe)$_2$}$_2$](PF_6) and [Au{C(NHMe)$_2$}$_2$](BF_4) was attributed to the formation of extended chains of gold(I) centers that were connected through aurophilic attractions and an excited state of metal-centered ^{3}(d$\sigma^* \rightarrow$ pσ) character was assigned. This assignment was supported by the short Au···Au distances for [Au{C(NHMe)$_2$}$_2$](PF_6) (3.1882(1) Å) and [Au{C(NHMe)$_2$}$_2$](BF_4) (3.4615(2) Å).



[Au{C(NHMe)$_2$}$_2$](PF_6)

(**26**)

Although shorter Au···Au distances were observed for the halide salts [Au{C(NHMe)$_2$}$_2$](X) (3.1231(3) and 3.1297(4) Å for X = Cl and Br, respectively), solid samples of these complexes emitted at apparently higher energy, at 391 and 412 nm for X = Cl and Br, respectively, than their PF_6^- and

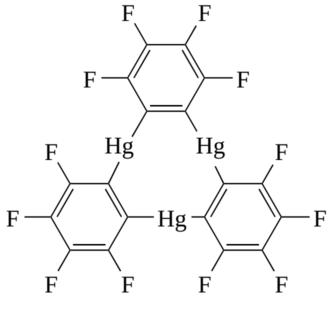


[Au{C(NMe$_2$)(NHMe)}$_2$](PF_6)

(**27**)

BF_4^- counterparts.[98] This observation was attributed to the fact that [Au{C(NHMe)$_2$}$_2$](X) existed as dimeric units in the crystals. In contrast, infinite gold chains were observed for both the PF_6^- and BF_4^- complexes.

The trinuclear complex [(μ-1-benzylimidazolate)$_3$Au$_3$] has a strong tendency to form stacked compounds. Reaction with TCNQ and C_6F_6 gave dark green [{(μ-1-benzylimidazolate)$_3$Au$_3$}$_2$(TCNQ)]$_n$ and colorless [{(μ-C(OEt)=NC$_6$H$_4$-CH$_3$-*p*)$_3$Au$_3$}$_2$(C_6F_6)]$_n$ polymers, respectively.[99] While the gold(I) trimer displayed blue photoluminescence, the adduct [{(μ-C(OEt)=NC$_6$H$_4$-CH$_3$-*p*)$_3$Au$_3$}$_2$(C_6F_6)]$_n$ was nonemissive. X-ray crystallographic studies revealed that the presence of C_6F_6 disrupted the intermolecular aurophilic bonding in the [μ-C(OEt)=NC$_6$H$_4$-CH$_3$-*p*$_3$Au$_3$] units. When the adduct was immersed in a solvent that does not dissolve the gold(I) trimer, such as diethyl ether, the adduct lost its crystallinity and the resulting power exhibited the blue emission of the gold(I) trimer, indicating that C_6F_6 was liberated. Other stacked assemblies formed by gold(I) trimers such as [(μ,-1-benzylimidazolate)$_3$Au$_3$] and [(μ-C(OEt)=NC$_6$H$_4$-CH$_3$-*p*)$_3$Au$_3$] with the trinuclear mercury(II) complex [Hg$_3$(μ-C,C-C$_6$F$_4$)$_3$] (**28**) have been isolated and shown to exhibit remarkable luminescence properties.[100]



[Hg$_3$(μ-C, C-C$_6$F$_4$)$_3$]

(**28**)

Recently, the adducts formed between [Hg$_3$(μ-C, C-C$_6$F$_4$)$_3$] and polyaromatics including pyrene, naphthalene, and biphenyl, respectively, have been isolated.[101] The crystalline samples of the adducts showed red, green, and blue phosphorescence, respectively, at 77 K and room temperature (Figure 7). Owing to the heavy atom effects, these adducts

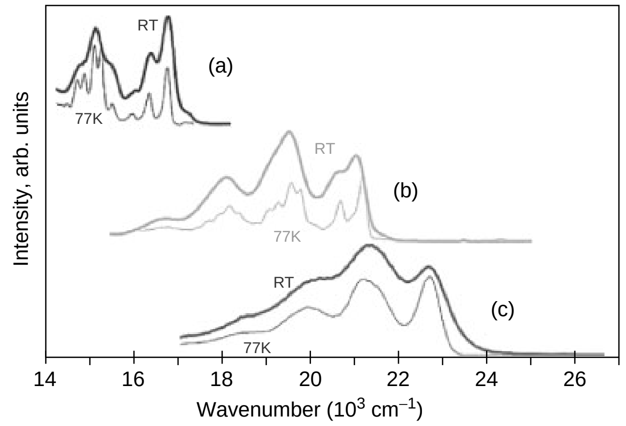


Figure 7 Emission spectra of crystalline solids formed between $[Hg_3(\mu\text{-}C,C\text{-}C_6F_4)_3]$ and polyaromatics including (a) pyrene, (b) naphthalene, and (c) biphenyl. Intensities of different spectra were adjusted arbitrarily for clarity. (Reprinted with permission from Ref. 101. © 2003 American Chemical Society)

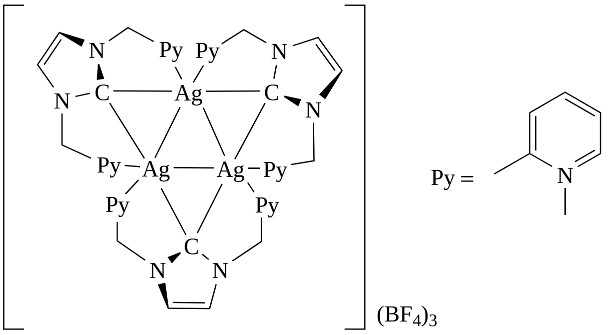
exhibited very long $^3(\pi \rightarrow \pi^*)$ phosphorescence lifetimes (454–712 μs) at room temperature.

Luminescent silver(I) alkylidene complexes $[((pyCH_2)_2im)_2Ag](X)$ ($X = BF_4^-$, Cl^-), $[((pyCH_2)_2im)_3Ag_3](BF_4)_3$ (**29**)[102] and related silver(I) *N*-heterocyclic alkylidene complexes,[103] and gold(I) alkylidene complexes $[Au(R_2\text{-}bimy)L]$ (R = Et, Me; L = Cl, Br, I, bimy, SC_6H_5, C≡CPh)[104] have been synthesized and found to display intense luminescence.

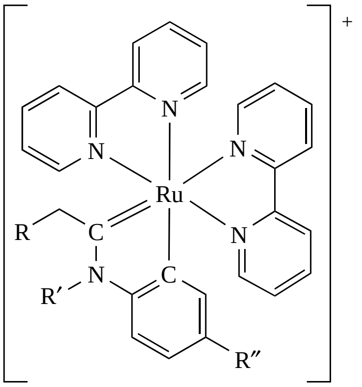


$[((pyCH_2)_2im)_3Ag_3](BF_4)_3$

(**29**)

5.2 Ruthenium (*See Ruthenium: Organometallic Chemistry*) and Rhenium (*See Rhenium: Organometallic Chemistry*) Alkylidenes

A series of luminescent ruthenium(II) cyclometalated aminoalkylidene complexes (*see Alkylidene*) $[Ru(N\text{–}N)_2\{=C(CH_2R)NR'C_6H_3R''\}](OTf)$ (N–N = bpy, phen; R = C_6H_5, C_6H_3S, C_6H_4-Cl-*p*; R′ = H, CH_3; R″ = H, OCH_3-*p*, Br-*p*, CF_3-*p*) such as (**30**) has been shown to exhibit ^{3}MLCT ($d\pi(Ru) \rightarrow \pi^*(N\text{–}N)$) luminescence at ca. 782–813 nm.[105] The assignment was supported by EHMO calculations, which showed that the HOMO was mainly ruthenium-based, while the LUMO had substantial diimine character. A related luminescent ruthenium(II) alkylidene complex containing a benzo-15-crown-5 ring (*see Crown Ethers*) has also been isolated recently.[106] The uptake of sodium and lithium ions by this crown-ether complex was investigated by spectroscopic titrations and mass spectrometry.



$[Ru(bpy)_2\{=C(CH_2R)NR'C_6H_3R''\}]^+$

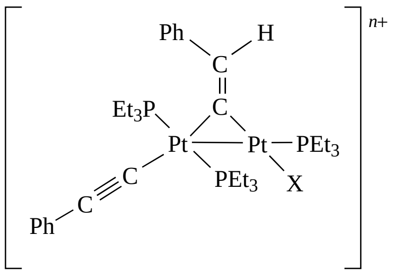
(**30**)

A series of rhenium alkylidene complexes $[HNCH_2CH_2NHCRe(CO)_3(N\text{–}N)]^+$ has been successfully isolated.[107] HF-SCH and MP2 MO calculations on $[HNCH_2CH_2NHCRe(CO)_3(NHCHCHNH)]^+$ and its fragments $[Re(CO)_3(NHCHCHNH)]^+$ and $[HNCH_2CH_2NHC]$ showed that the HOMO was essentially the nonbonding d_{xz}(Re) orbital (*z*-axis taken as the Re–C(alkylidene) axis), which was close in energy to the nonbonding d_{yz}(Re) and $d_{x^2-y^2}$(Re) orbitals. The LUMO comprised p_z(N–N) and p_z(alkylidene). Thus, the lowest-energy transition could be formulated as $d(Re) \rightarrow \pi^*(N\text{–}N)$ mixed with a small amount of $d(Re) \rightarrow \sigma^*$(alkylidene) character. A single configuration interaction (CIS) calculation suggested that the absorption band of $[HNCH_2CH_2NHCRe(CO)_3(phen)]^+$ at ca. 363 nm and the less intense shoulder at ca. 450 nm were ^{1}MLCT and ^{3}MLCT ($d(Re) \rightarrow \pi^*(phen)$) transitions, respectively. The complexes displayed photoluminescence and the emission was assigned to an $^3(d_{xz}(Re) \rightarrow \pi^*(N\text{–}N))$ excited state with partial $^3(d_{xz}(Re) \rightarrow p_z$(alkylidene C)) character.

5.3 Platinum (*See Platinum: Organometallic Chemistry*) Alkylidenes

The luminescence properties of a series of dinuclear platinum alkenylidene complexes $[Pt_2(\mu\text{-}C{=}CHPh)(C{\equiv}CPh)$

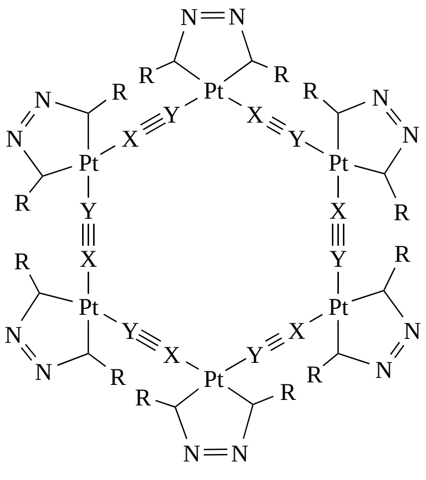
$(PEt_3)_3(X)]^{n+}$ (X = PEt_3 (n = 1), halide, SPh (n = 0)) (**31**) and their structural analogues have been studied.[108] The complexes displayed $^1(Pt_2 \rightarrow C{=}C)$ absorption bands at ca. 370–494 nm. Most of the complexes were emissive at low-temperature alcohol glass. The emission occurred at 546–710 nm (τ_o = 10–330 μs) and was assigned to an excited state of $^3(Pt_2 \rightarrow C{=}C)$ CT character.



$[Pt_2(\mu\text{-}C = CHPh)(C{\equiv}CPh)(PEt_3)_3(X)]^{n+}$

(**31**)

The hexanuclear Pt(II) alkylidene complex $[\{Pt(CN)(C_{10}H_{21}N_4)\}_6]$ (**32**) was synthesized.[109] The absorption spectrum of this complex displayed an intense band at 356 nm (ε = 18 000 $dm^3\,mol^{-1}\,cm^{-1}$), attributed to an ^{1}MLCT (Pt $\rightarrow$ π^*(alkylidene)) transition. The emission of the complex at 507–519 nm was assigned to an excited state of ^{3}MLCT (Pt $\rightarrow$ π^*(alkylidene)) parentage.

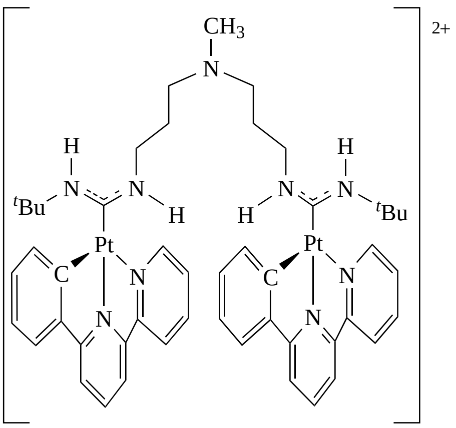


X≡Y = C≡N or N≡C; R = $NHCH_3$

$[\{Pt(CN)(C_{10}H_{21}N_4)\}_6]$

(**32**)

Mononuclear platinum(II) alkylidene complexes $[(CNN)Pt\{C(NHR^1)(NHR^2)\}]^+$ and its dinuclear counterpart, $[\{(CNN)Pt\}_2\mu\text{-}\{C(NH^tBu)(NH(CH_2)_3)\}_2NMe]^{2+}$ (**33**) have been synthesized and characterized.[110] The ^{3}MLCT (d(Pt) $\rightarrow$ π^*(CNN)) emission of the mononuclear complexes occurred at 542–558 nm in CH_3CN at 298 K. The emission maximum of the dinuclear complex occurred at 545 nm, and fell within the range observed for its mononuclear counterparts. This suggested the absence of interactions between the platinum(II) centers because Pt–Pt and/or ligand–ligand interactions would yield MMLCT emission at λ_{em} > 600 nm. The photochemistry of these platinum(II) alkylidene complexes was investigated. Two related platinum(II) alkylidene complexes $[(C_{10}H_{21}N_4)Pt(CN)(CN^tBu)]$ and $[(C_{10}H_{21}N_4)Pt(CN^tBu)_2]^+$ have also been synthesized and characterized.[111] The solvent- and pH-dependent photophysical properties of these complexes have also been studied.



$[\{(CNN)Pt\}_2\mu\text{-}\{C(NH^tBu)(NH(CH_2)_3)\}_2NMe]^{2+}$

(**33**)

5.4 Tungsten (*See Tungsten: Organometallic Chemistry*) and Molybdenum (*See Molybdenum: Organometallic Chemistry*) Alkylidynes

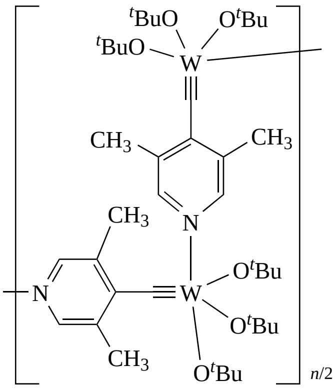
Bocarsly and Mayr first reported the luminescence properties of transition metal alkylidyne (*see Alkylidyne*) complexes $[XW(CO)_2(L_2)(CPh)]$ (X = halides, L_2 = TMEDA, $(py)_2$ or dppe).[112] The complexes exhibited broad and structureless emission bands at ca. 625–640 nm, which was attributable to an excited state of ^{3}MLCT (d_{xy}(W) $\rightarrow$ π^*(W≡C)) character. With an extension of the alkylidyne unit, the complexes $[XW(CO)_2(L_2)(C\text{-}C_6H_4\text{-}p\text{-}(C{\equiv}C\text{-}C_6H_4\text{-}p\text{-})_n\text{-}N{\equiv}C)]$ (L_2 = TMEDA, dppe; n = 0, 1) containing an isocyanide moiety have been shown to possess rich luminescence properties.[113] Perturbation of the absorption and emission properties of the complexes by coordination of the isocyanide moiety to metal-containing fragments such as *fac*-$ReCl(CO)_3$, *cis*-$PdCl_2$, *trans*-PdI_2, and *trans*-PtI_2 was also studied.

Irradiation of the alkylidyne-carbonyl tungsten complexes *cis*-$[ClW(CO)_2(PMe_2R)_2(CPh)]$ (R = Me or Ph) with visible light in the presence of electrophiles ECl (E = H, $C(O)CMe_3$, $C(O)C_6H_4\text{-}OCH_3\text{-}p$, $Si(CMe_3)_2Ph$) afforded the complexes *trans*-$[(Cl)_2W(CO)(PMe_2R)_2(EOC{\equiv}CPh)]$ that contained a four-electron-donor alkyne ligand.[114] The reactions were accompanied by the photoinduced cis–trans isomerization

of the starting complex. Therefore, the same products were produced when the trans-isomers were used. This photoinduced alkylidyne-carbonyl coupling reaction was an efficient method for the synthesis of metal-coordinated ynols and alkyne derivatives.

The lowest-energy absorption bands of the metallobutadiyne complexes [HC≡W(dmpe)$_2$(C≡CR)] (R = H, SiMe$_3$, Ph, C$_6$H$_4$-(C≡CPr^n-*p*)) occurred at ca. 449–494 nm and were assigned to a ^{1}(d$_{xy}$ → π^*(W≡C)) transition.[115] The energy decreased with increasing π-conjugation of the alkynyl ligand. Concerning the HOMO of [HC≡W(dmpe)$_2$(C≡CR)], the energy and orbital interactions of the tungsten d$_{xy}$ orbital were independent of the nature of the axial ligands, since this orbital was nonbonding with respect to the HC≡W–C≡CR axis. However, for the LUMO, mixing of the π^*(W≡C) and π^*(C≡CR) orbitals was symmetry-allowed and the former was stabilized while the later was destabilized. This mixing resulted in a red shift of the ^{1}(d$_{xy}$ → π^*(W≡C)) transition energy of these complexes relative to [HC≡W(dmpe)$_2$(X)] (X = Cl, I, ^{n}Bu).

Two tungsten alkylidyne polymers [W(≡C–(4-NC$_5$H$_2$-3,5-Me$_2$))(O^{t}Bu)$_3$]$_n$ (**34**) and [W(≡C–(3-NC$_5$H$_4$))(O^{t}Bu)$_3$]$_n$ (**35**) displayed emission at 635 and 640 nm, respectively, in the solid state at 77 K.[116] Under similar conditions, the monomeric [W(≡CR)(O^{t}Bu)$_3$] (R = aryl, alkyl) complexes were nonemissive. It was proposed that the [W≡C–pyridine] π-system contributed significantly to the frontier orbitals of these luminescent polymeric materials.

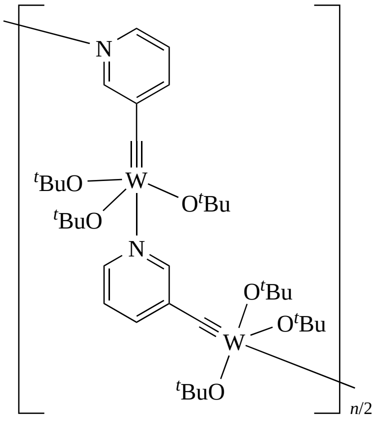


[W(≡C-(4-NC$_5$H$_2$-3,5-Me$_2$))(O^{t}Bu)$_3$]$_n$

(**34**)

Che and coworkers reported a series of luminescent molybdenum and tungsten alkylidyne complexes [(η^3-L)Cl(CO)$_2$M≡CPh]$^+$ (M = Mo, W; L = HCpy$_3$, Ppy$_3$, MeP$_3$, TACN, Me$_3$TACN) containing a tridentate ligand L.[117] The complexes displayed orange–red emission at ca. 614–669 nm (τ_o = 9–250 ns), which was assigned to an excited state of ^{3}(d$_{xy}$ → d$_{\pi^*}$(d$_{xz}$, d$_{yz}$)) character.

McElwee–White and coworkers investigated the luminescence and photochemical properties of the molybdenum and



[W(≡C-(3-NC$_5$H$_4$))(O^{t}Bu)$_3$]$_n$

(**35**)

tungsten alkylidyne complexes [(η^5-C$_5$H$_5$)(L)$_2$M≡CR] (M = Mo, W; L = P(OMe)$_3$, CO; R = Ph, Me, cyclo-C$_3$H$_5$).[118] Upon excitation, [(η^5-C$_5$H$_5$)(CO){P(OMe)$_3$}M≡CPh] in THF solutions at room temperature emitted at ca. 696 and 705 nm, for M = Mo and W, respectively. The origin of the emission was assigned to an ^{3}MLCT (d(M) → π^*(M≡C)) excited state. The emission of [(η^5-C$_5$H$_5$)(CO){P(OMe)$_3$}W≡CPh] was quenched in the presence of anthracene and the mechanism was triplet-state energy transfer in nature. In the presence of halocarbons such as CHCl$_3$, the complexes [(η^5-C$_5$H$_5$)(L)$_2$M≡CR] (M = Mo, W; L = P(OMe)$_3$, CO; R = aryl, alkyl) underwent photo-oxidation to give a 17-electron cation radical, which exhibited both metal-centered and ligand-centered reactivity.[119] Transient absorption spectroscopic studies revealed that the triplet excited states of [(η^5-C$_5$H$_5$)(CO){P(OMe)$_3$}M≡CPh] showed absorption bands at ca. 440–445 nm, with distinct shoulders at ca. 395 and 420 nm.[120] However, the transient absorption difference spectrum of [(η^5-C$_5$H$_5$)(CO){P(OMe)$_3$}W≡C-Np-2] showed a featureless band at lower energy (ca. 460 nm), suggesting that the excited state of this complex involved some π or π^* levels of the aryl unit. The ^{3}MLCT (d(W) → π^*(W≡CPh)) emission of the complex [(η^5-C$_5$H$_5$)(CO){P(OPh)$_3$}W≡CPh] at ca. 710 nm (τ_o = 192 ns) was quenched by pyridinium ions and nitroaromatics via an electron transfer mechanism.[121] The total reorganization energy and the excited-state reduction potential $E°([W]^{+/0*})$ were determined to be 0.40 eV and −1.85 V versus SCE. The highly negative potential indicated the strongly reducing nature of the excited alkylidyne complex.

5.5 Osmium (*See Osmium: Organometallic Chemistry*) and Rhenium (*See Rhenium: Organometallic Chemistry*) Alkylidynes

Sullivan reported the photophysical properties of the luminescent osmium alkylidyne complex

$[(NH_3)_5Os{\equiv}CPh](CF_3SO_3)_3$.[122] The high-energy band of this complex at ca. 292 nm ($\varepsilon = 14\,300\,dm^3\,mol^{-1}\,cm^{-1}$) was assigned to an $^1IL(\pi \rightarrow \pi^*)$ transition associated with the alkylidyne moiety in conjugation with the phenyl ring, and the low-energy absorption band at 462 nm ($\varepsilon = 200\,dm^3\,mol^{-1}\,cm^{-1}$) was assigned to a $^1(d_{xy} \rightarrow d\pi^*(d_{xz}, d_{yz}))$ transition. For the C_{2v} symmetry of $[(NH_3)_5Os{\equiv}CPh]^{3+}$, the d_{xz} and d_{yz} orbitals were split into orbitals of different energy by interaction with the phenyl π-system. The emission of the complex at 632 nm ($\tau_o = 55$ ns) was quenched by pyridine and its derivatives. It was suggested that the proton-transfer mechanism from the excited complex to the pyridines was most probable on the basis of (1) isotope studies using $[(ND_3)_5Os{\equiv}CPh]^{3+}$, and (2) the very high quenching rate for pyridine ($k_q = 5 \times 10^9\,mol\,dm^{-3}\,s^{-1}$). The proposal was in agreement with the more electropositive character of the metal center in the excited state due to the promotion of metal-based electron to an orbital of significant carbon character.

Che and coworkers reported a series of luminescent rhenium(V) benzylidyne complexes $[Re(CC_6H_2Me_3\text{-}2,4,6)(dppb)_2Cl]^+$, $[Re(CC_6H_2Me_3\text{-}2,4,6)(L)_2(CO)(H_2O)Cl]^+$ (L = monodentate phosphines), $[Re(CC_6H_2Me_3\text{-}2,4,6)(dppe)(CO)_2Cl]^+$, and $[Re(CC_6H_2Me_3\text{-}2,4,6)(N\text{–}N)(CO)_2Cl]^+$.[123] Different substituents (R) including H, OMe, Me, Cl, Br, and CN were introduced to the benzylidyne moiety to give $[Re(CC_6H_4\text{-R-}p)(dppe)(CO)_2(OTf)]^+$. Excitation of the complexes in CH_2Cl_2 at room temperature resulted in emission at ca. 520–610 ($\tau_o = 0.02$–$4.84\,\mu s$). The emission of the phosphine complexes was assigned to a $^3(\pi(Re{\equiv}C\text{–}Ph) \rightarrow \pi^*(Re{\equiv}C\text{–}Ph))$ state. This assignment was supported by the observations that electron-donating substituents R increased the emission energy of the complexes $[Re(CC_6H_4\text{-R-}p)(dppe)(CO)_2(OTf)]^+$ while electron-withdrawing ones decreased the energy. The excited state of the diimine complexes $[Re(CC_6H_2Me_3\text{-}2,4,6)(N\text{–}N)(CO)_2Cl]^+$ was suggested to be ^3MLCT $(d\pi(Re) \rightarrow \pi^*(N\text{–}N))$ because a red shift in the emission energy was observed for the diimine ligands that contain electron-withdrawing substituents.

6 CYCLOMETALATED SYSTEMS

6.1 Rhodium(III) (*See Rhodium: Organometallic Chemistry*) and Iridium(III) (*See Iridium: Organometallic Chemistry*) Cyclometalates

Watts and coworkers reported the luminescence properties of cyclometalated iridium(III) and rhodium(III) complexes (*see Cyclometalation*).[124] The dichloro-bridged dimers $[M_2(N^{\wedge}C)_4Cl_2]$ (M = Ir, Rh; $HN^{\wedge}C$ = Hppy, Hbzq) displayed intense emission with structural features in $EtOH/MeOH/CH_2Cl_2$ (4:1:1: v:v) glass at 77 K. The emission of the rhodium(III) dimers was assigned to an ^3IL excited state in view of the extraordinarily long lifetimes ($\tau_o = 93\,\mu s$ and 2.7 ms for $N^{\wedge}C$ = ppy and bzq, respectively). However, the excited state of the iridium(III) complexes involved significant ^3MLCT $(d\pi(Ir) \rightarrow \pi^*(N^{\wedge}C))$ character. Relatively intense and structureless emission at ca. 520–550 nm was observed for the iridium(III) dimers in fluid solutions at room temperature, and the emission was assigned to an ^3MLCT excited state. However, the rhodium(III) dimers did not display any emission in fluid solutions at room temperature.

Reactions of the dichloro-bridged rhodium(III) and iridium(III) dimers with diimine ligands resulted in the formation of the luminescent mononuclear complexes $[M(N^{\wedge}C)_2(N\text{–}N)]^+$ (M = Ir, Rh; $N^{\wedge}C$ = ppy, bzq; N–N = bpy, phen).[125] The electronic absorption and emission spectra of these complexes are shown in Figure 8. The rhodium(III) complexes displayed very long-lived emission in

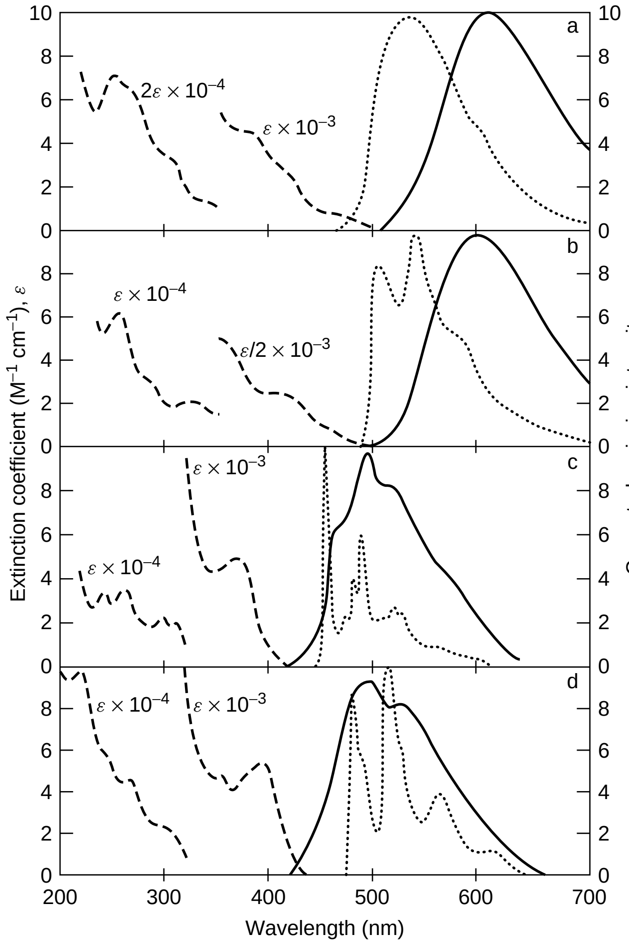


Figure 8 Absorption and emission spectra of mixed-ligand complexes: (- - - -) absorption in methanol at room temperature; (· · · ·) emission in ethanol-methanol (4:1) at 77 K; (———) emission at room temperature in ethanol-methanol (4:1) for iridium(III) complexes and in acetonitrile for rhodium(III) complexes. (a) $[Ir(ppy)_2(bpy)]^+$; (b) $[Ir(bzq)_2(phen)]^+$; (c) $[Rh(ppy)_2(bpy)]^+$; (d) $[Rh(bzq)_2(phen)]^+$. (Reprinted with permission from Ref. 125. © 1987 American Chemical Society)

77 K glass ($\lambda_{em} = 457-538$ nm, $\tau_o = 177-4250$ μs), which was assigned to an excited state of ^{3}IL ($\pi \rightarrow \pi^*$(N^C)) character. Dual emission was observed for the cyclometalated iridium(III) diimine complexes under similar conditions, and charge-transfer excited states involving the cyclometalating and diimine ligands were identified.

The photophysics and excited-state properties of cyclometalated rhodium(III) and iridium(III) complexes [M(N^C)$_2$(N–N)]$^+$ (M = Rh(III), Ir(III); N^C = ppy, thpy; N–N = bpy, en) have been investigated.[126] The lowest excited states for the rhodium(III) complexes were ^{3}IL ($\pi \rightarrow \pi^*$) (N^C), while those for the iridium(III) counterparts can be ^{3}IL or ^{3}MLCT in character, depending on the environment.

The absorption and emission properties of the cyclometalated rhodium(III) complexes [Rh(N^C)$_2$(N–N)]$^+$ (N^C = ppy, thpy, N–N = bpy, phen, biq) have been studied.[127,128] The complexes showed intense ^{1}MLCT (dπ(Rh) $\rightarrow \pi^*$(N^C)) bands at ca. 360–380 nm. At 77 K, these complexes emitted strongly at 454–546 nm ($\tau_o = 0.04-5$ ms). The luminescence was assigned to predominantly ^{3}IL involving (1) the cyclometalating ligand for the bpy and phen complexes, and (2) the diimine ligands for the biq complexes.

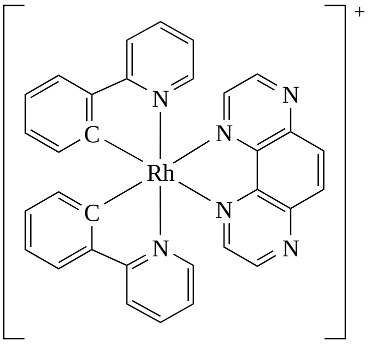
Vogler and coworker reported the interesting photoluminescence properties of the cyclometalated rhodium(III) complexes with cyanide ligands [Rh(ppy)$_2$(CN)$_2$]$^-$.[129] The yellow complex showed intense absorption bands at 264, 302, and 363 nm. It is noteworthy that the complex displayed bluish-green luminescence in CH_3CN at room temperature, which was uncommon for rhodium(III) ppy complexes because the low-lying LF states of rhodium(III) prevented these complexes from emitting at room temperature. In contrast, the strong LF strength of the CN$^-$ ligand shifted the d-d states to higher energy and thus allowed the complex to emit at room temperature. The emission spectrum displayed vibronic features at 460, 490, 520 (sh), 565 (sh), and 610 (sh) nm and the emission was assigned to an ^{3}IL excited state involving the ppy ligands.

A series of *facial* homoleptic cyclometalated iridium(III) complexes has been synthesized and their photophysical properties investigated.[130] The ^{3}MLCT emission of the complexes in toluene 298 K occurred at 558–652 nm ($\tau_o = 0.74-4.7$ μs). An OLED device that used [Ir(1-phenylisoquinolinato)$_3$] as a phosphorescent dopant produced pure-red emission with very high efficiency.

The intense and long-lived luminescence of these complexes has been utilized in the development of the oxygen sensor.[131] Four mononuclear and dinuclear cyclometalated iridium(III) diimine complexes were immobilized in polymerized poly(ethylene glycol) ethyl ether methacrylate matrices, and the oxygen quenching on the luminescence of the films was studied. Linear Stern–Volmer plots were obtained. Despite the difference in the luminescence energy and lifetimes of the complexes, similar Stern–Volmer slopes were observed. The size and charge of the complexes played an important role in the sensitivity of the systems.

In another example, the cyclometalated iridium complex [Ir(ppy)$_2$(4-vinylpyridine)Cl] has been attached via hydrosilation (*see Hydrosilation*) to hydride-terminated poly(dimethylsiloxane) to produce a luminescent material.[132] Evaluation of this material as a luminescent oxygen sensor revealed significantly improved sensitivity over dispersions of the original vinyl pyridine complex in poly(dimethylsiloxane). The luminescent material was blended with polystyrene to give a new sensor that exhibited increased sensitivity and maintained short response times to rapid changes in air pressure.

In contrast to common luminescent rhodium(III) systems, the complexes [Rh(ppy)$_2$(TAP)]$^+$ (**36**) and [Rh(ppy)$_2$(HAT)]$^+$ (**37**) showed structureless emission spectra in fluid solutions at room temperature and in rigid glass at 77 K.[133] In addition to the observation of the irreversible oxidation wave, the emission was assigned to an ^{3}SBLCT (σ(Rh–C) $\rightarrow \pi^*$(TAP or HAT)) excited state. The iridium(III) complex [Ir(ppy)$_2$(HAT)]$^+$ displayed dual emissions in 77 K glass, which was assigned to excited states of ^{3}MLCT (dπ(Ir) $\rightarrow$ π^*(HAT)) and ^{3}SBLCT (σ(Ir–C) $\rightarrow \pi^*$(HAT)) character. Recently, optically active cyclometalated rhodium(III) complexes Δ-[Rh(thpy4,5p(*R*,*R*)py)$_2$(TAP)]Cl (**38**), Λ-[Rh (thpy4,5p(*S*,*S*)py)$_2$(TAP)]Cl (**39**), and Δ-[Rh(phpy4, 5p(*R*,*R*)py)$_2$(TAP)]Cl (**40**) have been prepared, characterized, and their photophysical properties studied.[134] The nature of the excited states was investigated by time-dependent DFT calculations.



[Rh(ppy)$_2$(TAP)]$^+$
(**36**)

Campagna and coworkers reported the synthesis and photophysical studies of a number of luminescent cyclometalated mononuclear and dinuclear rhodium(III) and iridium(III) complexes such as [M^1{(2,3-dpp)M^2(ppy)$_2$}$_3$]$^{5+}$ (M^1 = Ru, Os, M^2 = Rh, Ir).[135] For the rhodium(III) complexes, the emission was assigned to ^{3}MLCT states involving the ruthenium(II) or osmium(II) center and the bridging 2,3-dpp ligand. However, for the heterometallic iridium(III) complexes [Ru{(2,3-dpp)Ir(ppy)$_2$}$_3$]$^{5+}$ and [Os{(2,3-dpp)Ir(ppy)$_2$}$_3$]$^{5+}$, the emission originated from ^{3}MLCT excited states of (dπ(Ir) $\rightarrow \pi^*$(2,3-dpp)) and (dπ(Os) $\rightarrow$

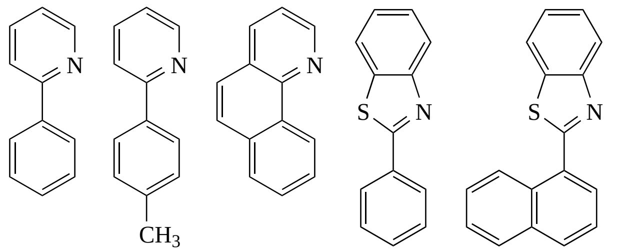
π^*(2,3-dpp)) character, respectively. Other luminescent dinuclear cyclometalated iridium(III) complexes have been synthesized using bridging diimine ligands with an ester-linked chelating site.[136]

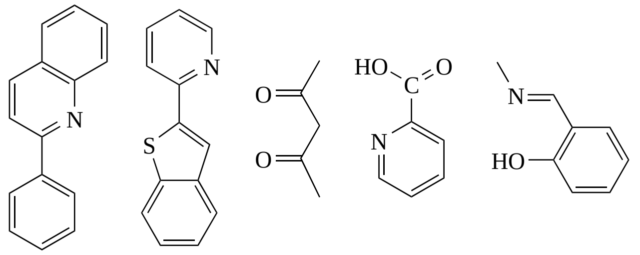
Barton and coworker reported the preparation of two cyclometalated rhodium(III) complexes $[Rh(ppy)_2(chrysi)]^+$ and $[Rh(ppy)_2(phi)]^+$ and their spectral properties.[137] Both complexes bound to DNA and caused cleavage upon photoactivation. While $[Rh(ppy)_2(chrysi)]^+$ caused photocleavage of DNA selectively at the single CC mismatch, the phi analogue cleaved B-DNA nonspecifically. However, compared to the bpy analogue $[Rh(bpy)_2(chrysi)]^{3+}$, the binding of $[Rh(ppy)_2(chrysi)]^+$ to DNA was decreased by a factor of 14 because of the lower charge of the complex. The overall DNA-photocleavage efficiencies of the ppy complexes were significantly lower than those of their bpy counterparts because of the reduced photoefficiencies.

Thompson and coworkers reported a class of neutral cyclometalated iridium(III) complexes $[Ir_2(N^\wedge C)_4Cl_2]$ and $[Ir(N^\wedge C)_2(LX)]$ (HN^C = Hppy (**41**), Hmppy (**42**), Hbzq (**43**), Hbt (**44**), Hbsn (**45**), Hpq (**46**), Hbtp (**47**); HLX = Hacac (**48**), Hpic (**49**), Hsal (**50**)).[138,139] Upon photoexcitation, the mononuclear complexes displayed long-lived and intense emission in CH_2Cl_2 at 77 K and under ambient conditions. The emission wavelengths varied from 512 to 612 nm and the lifetimes from 1.4 to 5.8 µs at room temperature. The emission energy was sensitive to the identity of the cyclometalating ligand N^C and, to a less extent, the anionic ancillary ligand LX. The emission was assigned to an excited state of predominantly ^{3}IL ($\pi \rightarrow \pi^*$(N^C)) character. Since heavy metal complexes, particularly those containing platinum and iridium, can serve as efficient phosphors in organic light-emitting devices,[140] three of the acac complexes were used as

dopants for OLEDs.[139] The OLEDs fabricated using the complexes $[Ir(ppy)_2(acac)]$, $[Ir(bt)_2(acac)]$, and $[Ir(btp)_2(acac)]$ displayed green, yellow, and red electroluminescence respectively, with very similar current-voltage characteristics and high external quantum efficiencies (from 6 to 12.3%). The high efficiencies resulted from efficient trapping and radiative relaxation of the singlet and triplet excitons formed in the electroluminescent process.



Hppy (**41**) Hmppy (**42**) Hbzq (**43**) Hbt (**44**) Hbsn (**45**)



Hpq (**46**) Hbtp (**47**) Hacac (**48**) Hpic (**49**) Hsal (**50**)

The luminescent iridium(III) complexes $[Ir(pba)_2(N–N)](PF_6)$ displayed indistinguishable and structured emission spectra with very long emission lifetimes (4.3–5.7 µs) in fluid solutions at 298 K.[141] These observations suggested that the emissive state of these complexes was ^{3}IL ($\pi \rightarrow \pi^*$(pba)) in nature. Since the aldehyde moieties of these complexes can react with the primary amine groups of biomolecules to form stable secondary amines after reductive amination, the protein avidin was labeled with these complexes to give luminescent conjugates. The intense and long-lived ^{3}MLCT ($d\pi$(Ir) $\rightarrow \pi^*$(N–N)) emission of the bioconjugates was exploited in the design of a competitive bioassay for biotin.

6.2 Platinum(II) (*See Platinum: Organometallic Chemistry*) and Gold(III) (*See Gold: Organometallic Chemistry*) Cyclometalates

A series of mono and multinuclear dicyclometalated platinum(II) complexes $[Pt(C\text{^}N\text{^}C)L^1]$, $[Pt_2(C\text{^}N\text{^}C)_2(\mu\text{-}L^2)]$, and $[Pt_3(C\text{^}N\text{^}C)_3(\mu_3\text{-dpmp})]$ (HC^N^CH = 2,6-diphenylpyridine; L^1 = monodentate pyridine, isocyanide, and phosphine derivatives, L^2 = bidentate pyridine and phosphine derivative) has been synthesized and characterized.[142] X-ray crystallographic studies revealed π–π interactions between the planar Pt(C^N^C) units and, in some cases, between the phenyl rings of ligands. Some of the complexes displayed vibronically structured emission bands at 508–526 nm in 77 K alcohol glass, which was assigned to ^{3}IL excited states. Both π–π^* excimeric and ^{3}MLCT emissions were observed in these examples.

A sol-gel oxygen sensor based on such luminescent complexes has been reported.[143] The complex [Pt(MeOPh-C^N^N)X] (MeOPh-HC^N^N = 3-phenyl-5-*p*-methoxylphenyl-2,2′-bipyridine, $X = NH_2(CH_2)_3Si(OCH_2CH_3)_3$) was homogeneously incorporated into sol-gel glass by condensation with $Si(OCH_2CH_3)_4$. The emission spectrum of the film displayed a peak at ca. 520 nm and a shoulder at 650 nm, and was assigned to an excited state of ^{3}MLCT (d(Pt) $\rightarrow \pi^*$(MeOPh-C^N^N)) character. Owing to its triplet nature, the emission was quenched by oxygen. This oxygen sensor had the advantage of a large quenching response because of the very long excited-state lifetime ($\tau_o = 7.3$ µs) of the immobilized luminescent complex in the absence of oxygen.

A dinuclear cyclometalated platinum(II) complex $[Pt_2L_2(dppm)]^{2+}$ (L = 4-(*p*-diethylphosphonophenyl)-6-phenyl-2,2′-bipyridine) has been employed as a luminescent probe for SDS micelles.[144] Addition of SDS micelles to an aqueous solution of the complex led to an emission band at 530 nm, which was similar to the ^{3}MLCT emission of mononuclear species. The observations were attributed to the absence of intramolecular and/or intermolecular Pt(II)–Pt(II) interactions when the complex was incorporated in the SDS micelles. Addition of NaCl solution into a micellar solution of the complex resulted in an additional ^{3}MMLCT (($d\sigma^*$)$\rightarrow$ (π^*)) emission band at 650 nm. It was suggested that addition of sodium cations would force two cyclometalated platinum(II) units sufficiently close for intramolecular metal–metal and/or ligand–ligand interactions to occur, and thus the observation of ^{3}MMLCT luminescence.

The cyclometalated platinum(II) complex attached with a PEG substituent [Pt(NNC-PEG)Cl] displayed a weak and broad emission band at ca. 543 nm in water at low concentrations of the complex.[145] At [Pt] $\geq 10^{-4}$ M, a new emission band at 710 nm due to Pt–Pt and/or ligand-ligand interaction was observed. In the presence of BSA, the emission intensity of the complex was significantly enhanced, which was attributed to the binding of the complex to the hydrophobic regions of the protein. A binding constant of $2.7 \times 10^4\ mol^{-1}\ dm^3$ was estimated. Upon addition of urea, the emission intensity was first enhanced and eventually reduced. These observations were interpreted in terms of (1) tighter binding of the complex by the BSA molecule at low urea concentrations, and (2) denaturing of the protein that occurred at high urea concentrations.

Luminescent cyclometalated platinum(II) and gold(III) complexes $[Pt(dpp\text{-}CNN)(MeCN)]^+$,[146] $[Pt_2(pby\text{-}CNN)_2(dppm)]^{2+}$,[146] and [Au(4-MeOPh-Phbpy)Cl][147] have been prepared and their interactions with calf thymus DNA and synthetic oligonucleotide duplexes poly(dG-dC)$_2$ and poly(dA-dT)$_2$ have been investigated. An intercalative binding mode was proposed for these complexes.

A series of luminescent cyclometalated platinum(II) complexes containing crown-ether (*see Crown Ethers*) pendants [Pt(C^N^C)(L)] (HC^N^CH = 2,6-diphenylpyridine, L = monodentate phosphine-crown ether and pyridine-crown ether ligands) and their crown ether-free and terpyridine derivatives have been isolated and characterized.[148] The complexes showed high-energy structured ^{3}IL emission bands in alcohol glass at 77 K. In CH_2Cl_2 at room temperature, an additional broad emission band at 620–625 nm was also observed when the concentration of the complexes was increased. The emission was suggested to be derived from a ground-state oligomerization or aggregation process due to Pt–Pt and/or ligand-ligand interactions. The binding of sodium, barium, and potassium ions by the crown-ether complexes was investigated. The neutral cyclometalated crown-ether complexes bound the cations with a higher binding constant than their positively charged terpyridine analogues.

The intense absorption band of the cyclometalated platinum(II) complex $[Pt(thpy)_2]$ at 420 nm was assigned to an ^{1}MLCT (d(Pt) $\rightarrow \pi^*$(thpy)) transition.[149] In degassed CH_3CN, the complex displayed ^{3}MLCT luminescence at ca. 580 nm ($\tau_o = 2.4\,\mu s$). In contrast, in CH_2Cl_2, $CHCl_3$, or a mixture of CH_3CN and CH_2Cl_2, the complex underwent photooxidative addition reactions with the formation of [Pt(thpy)(Cl)(R)] (R = CH_2Cl, $CHCl_2$). The results were interpreted on the basis of a mechanism involving generation of $Pt(thpy)_2Cl\bullet$ and $CH_2Cl\bullet$ radicals via (1) a charge-transfer-to-solvent CTTS excited sate, populated from the IL and LMCT states obtained by light absorption and (2) the thermally relaxed ^{3}MLCT emissive state through the conversion to CTTS or bimolecular reaction with CH_2Cl_2.

The pressure- and temperature-dependent emission properties of $[Pt(thpy)_2]$ doped into an n-decane Shpol'skii matrix have been studied.[150] The emitting state was of ^{3}IL ($\pi \rightarrow \pi^*$(thpy)) character with a significant MLCT admixture. The luminescence properties of a related mixed-ligand cyclometalated platinum(II) complex [Pt(thpy)(ppz)] have also been studied and a mechanism involving excimer formation has been suggested for the observed quenching and annihilation reactions.[151] High-resolution optical spectroscopy and optically detected magnetic resonance spectroscopy have been used to study the emitting state of cyclometalated complex [Pt(thpy)(CO)Cl] at 1.2 K and compared to that of other related cyclometalated complexes.[152]

A series of cyclometalated platinum(II) phosphine complexes $[Pt(bzq)(P\text{-}P)](PF_6)$ (P-P = dppm, dppe, dppp) has been synthesized and structurally characterized.[153] The absorption bands at ca. 300 nm ($\varepsilon \approx 2 \times 10^4\,dm^3\,mol^{-1}\,cm^{-1}$) were assigned to ^{1}IL ($\pi \rightarrow \pi^*$) transitions, while the weaker absorption features at lower energy (ca. 340–402 nm) were assigned to ^{1}MLCT (dπ(Pt) $\rightarrow \pi^*$(bzq)) transitions. In 77-K alcohol glass, the complex $[Pt(bzq)(dppm)](PF_6)$ displayed structural ^{3}IL (bzq) emission bands at ca. 466, 500, and 538 nm ($\tau_o = 204\,\mu s$).

The structures and emission properties of a series of related complexes $[Pt(N^\wedge C)(dppm)]^+$ (HN^C = Hppy, Hmppy, Hpq) and [Pt(bph)(dppm)] have been investigated.[154] The electronic absorption spectra of the complexes showed high-energy ^{1}IL ($\pi \rightarrow \pi^*$(N^C)) and low-energy ^{1}MLCT (dπ(Pt) $\rightarrow \pi^*$(N^C)) bands. All the complexes displayed long-lived structured intraligand/charge-transfer emission in low-temperature glass.

Thompson and coworkers reported the synthesis, electrochemistry, and photophysics of a series of cyclometalated platinum(II) complexes [Pt(N^C)(L)] containing a monoanionic cyclometalating ligand N^C and a β-diketonato ligand L. DFT calculations were carried out on both the ground (singlet) and excited (triplet) states of these complexes.[155] The HOMO levels were a mixture of Pt and ligand orbitals, while the LUMO was predominantly N^C-based. The structured emission of the complexes ranged from 438 to 612 nm in 2-Me-THF. High emission quantum efficiencies (0.02–0.25) and lifetimes in the microsecond timescale were observed.

7 ALKYL SYSTEMS

Kaim and coworkers attached the ligand 1,4-diaza-1,3-butadiene and its derivatives (R-DAB, where R = alkyl, aryl) to a series of organoplatinum fragments such as $PtMe_2$, $PtMe_4$, and $PtMes_2$.[156] All the complexes displayed low-energy ^{1}MLCT (d(Pt^{II}) $\rightarrow \pi^*$(R-DAB)) and ^{1}SBLCT (σ(Pt^{IV}-C) $\rightarrow \pi^*$(R-DAB)) absorption bands at ca. 304–634 nm. The assignments were supported by DFT calculations on model complexes involving the ligand HN=CHCH=NH. The platinum(II) complexes showed weak ^{3}MLCT emission at ca. 460–630 nm. In contrast, the organoplatinum(IV) complexes show chemical reactivity upon irradiation. For example, in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$, the complexes $[PtMe_4(R\text{-}DAB)]$ (R = ^{t}Bu, p-Tol) reacted with the solvents to form $[PtMe_3Cl(R\text{-}DAB)]$.

Alkyl ligands are strong σ-donors, and coordination of such ligands to metal centers such as rhenium(I) and ruthenium(II) would perturb the electronic structures of the metal centers and give complexes with remarkable photochemical properties.[15] Irradiation of the complexes $[Re(CO)_3(R)(4,4'\text{-}Me_2\text{-}bpy)]$ (R = Et, ^{i}Pr, Bz) into their visible ^{1}MLCT absorption bands (ca. 400–500 nm) resulted in extremely efficient homolytic cleavage of the Re–R bonds with the formation of the radicals $[Re(CO)_3(4,4'\text{-}Me_2\text{-}bpy)]\bullet$ and R•.[157,158] The methyl analogue underwent a similar photochemical reaction, but with a quantum yield of only 0.4. It was proposed that

the ^{1}MLCT (dπ(Re) → π^*(4,4′-Me$_2$-bpy)) excited state of this complex may either pass a barrier of 1560 cm^{-1} to the dissociative ^{1}SBLCT (σ(Re–C) → π^*(4,4′-Me$_2$-bpy)) state and decompose into radicals or simply undergo radiative decay to the ground state, giving typical ^{3}MLCT emission.

The photophysical properties of related ruthenium(II) alkyl complexes [Ru(CO)$_2$(L$_1$)(L$_2$)(N–N)] have been studied.[159] The complex [Ru(CO)$_2$(Cl)(Me)(^{i}Pr-DAB)] showed an ^{1}MLCT (dπ(Ru) → π^*(^{i}Pr-DAB)) absorption band at 450 nm and an ^{3}MLCT (dπ(Ru) → π^*(^{i}Pr-DAB)) emission band at 650 nm ($\tau_o = 0.3$ µs) in 2-Me-THF glass at 90 K. Interestingly, the lowest-energy excited state of the iodo complex [Ru(CO)$_2$(I)(Me)(^{i}Pr-DAB)] was ^{3}XLCT (p(I) → π^*(N–N)) in nature. Meanwhile, the lowest-lying excited states for the complexes [Ru(CO)$_2$(L$_1$)(L$_2$)(N–N)] (L$_1$ = X; L$_2$ = ^{i}Pr, Bz) were ^{3}SBLCT (σ(Ru–C) → π^*(N–N)) in character. In these cases, the σ-orbital was delocalized with contributions from 5p(Ru) and the antisymmetric combination of the σ-orbitals of L$_1$ and L$_2$. Upon irradiation under ambient conditions, the weaker σ-bond (Ru–L$_1$ or Ru–L$_2$) was broken to form radicals.

The synthesis and photochemistry of related rhodium(III) bis(alkyl) complexes *cis,cis*-[Rh(R)$_2$(I)(CO)(dmb)] (R = Me, ^{i}Pr) have been studied.[160] The complexes showed an ^{1}IL (π → π^*(dmb)) absorption band at ca. 295 nm. There was another band at ca. 370 nm for both complexes, which was assigned to an ^{1}XLCT (p(I) → π^*(dmb)) transition. Irradiation of both complexes in solution resulted in Rh–R bond homolysis, as evidenced by IR, UV-vis, and spin-trap EPR investigations. The photoreaction was proposed to occur after crossing from the XLCT state to the reactive SBLCT state.

1 INTRODUCTION

The study of metals in medicine forms an important subdiscipline of inorganic biochemistry.[1–4] The use of metal-based drugs predates the emergence of inorganic biochemistry in the 1970s and 1980s and even the development of modern medicinal chemistry in the period between World War I and World War II. In prehistoric times and through the age of the alchemists, metal-based therapies were at best empirical and more often pseudoscientific preparations used to treat of a wide variety of diseases. For example, gold salts were used in the late nineteenth century to treat alcoholism, opium addiction, and neurasthemia (Figure 1(b)), although modern medicine finds no value for such treatments. The third edition of the *National Formulary*, published in 1906, lists 454 preparations, of which 149, or roughly one-third, are metal-based.[5] They were formulated as elixirs, ointments, powders, pills, and tinctures that contain either a single metal species or mixtures of several metal species. In some cases, metal ions were combined with other substances, including herbal extracts such as gentian or cinchona, organic medicinals such as quinine, strychnine, and opium, cod liver oil, and even sherry wine.[5] The inorganic elements found in the 1906 *National Formulary* are shown in the periodic table of Figure 2. It is quite different from the periodic table featured on the cover of a recent student textbook on metals in medicine[3] that prominently featured Li, V, Mn, Fe, Pt, and Au.

The German physicians Paul Ehrlichmann and Robert Koch made pioneering contributions to modern medicine, including scientific approaches to the development of arsenicals and gold compounds, respectively, for treatment of various diseases. The contribution of Paul Ehrlichmann, who is considered the father of modern immunology, included investigation of the medicinal properties of arsenicals, and the final version of the German 200 DM note, Figure 1(a), celebrating his career, depicts the modern crystal structure of the phenylarsine hexamer, $[PhAs]_6$. Robert Koch's research on the antibacterial activity of $K[Au(CN)_2]$ in the search for a treatment for tuberculosis led eventually to the successful use of gold thiolates for treating rheumatoid arthritis. Despite these and other successes, the increasing ability of medicinal chemists to synthesize and screen large numbers of organic compounds for optimal medicinal activity and the concurrent recognition that the chronic and, sometimes, acute toxicity of traditionally used inorganic agents based on arsenic, mercury, and lead inter alia became evident, leading to curtailed use of inorganic medicinals after World War II.

Until the 1960s, research on metal ions in biochemistry and medicine was typically pursued in the realms of clinical medicine, nutritional science and toxicology. Starting in that decade, increasingly powerful physicochemical methods became available to study the roles of metal ions in biological systems. Atomic absorption and emission spectroscopy, later coupled to inductively coupled plasma methods of sample introduction, and the availability of useful isotopes for tracer experiments allowed precise measurement of metal accumulation and fluxes. Powerful techniques including extended X-ray absorption fine structure (EXAFS) and Raman and Mössbauer spectroscopies became available to directly probe the chemical environment of metal ions in biological macromolecules and even tissue preparations ex vivo, providing information about structure, electronic states, ligation and reactivity. Electron spin resonance (ESR) and nuclear magnetic resonance (NMR) methods complemented one another: ESR probes paramagnetic metal ions such as high-spin Fe^{2+} and Fe^{3+}, and low-spin Fe^{3+}, while NMR has been applied to a host of inorganic nuclei including Li, V, Ag, Pt, and Hg among medicinally used species. A renaissance of research on metals in medicine, which benefited from and helped to drive these improvements in physicochemical methods, was stimulated by Professor Barnett Rosenberg's discovery that diamminedichloroplatinum(II), $(H_3N)_2PtCl_2$, has potent antitumor activity (*see* ***Platinum-based Anticancer Drugs***).[6] This chapter concentrates on the roles of gold, silver, platinum, vanadium, and lithium in modern medicine, and briefly reviews current and potential uses of other inorganic medicinal agents.

2 GOLD-BASED ANTIARTHRITICS

2.1 Introduction and History

Gold is arguably the first pure element known to early man, since it could be found in stream beds and other geological formations and was visually attractive and easily workable. Medical treatises from ancient civilizations in Egypt, China,

Greece, and elsewhere included numerous uses of gold for treating a wide variety of ailments.[4] These ancient civilizations attributed magical and healing powers to items fashioned from gold and preparations containing powdered gold.[7,8] As Chinese, Arabic, and European alchemists learned to prepare compounds of gold, these agents were also used to treat a wide variety of ailments.[7,8] Gold found many medical uses derived from these traditions late into the 19^{th} century, as exemplified by the gold treatments shown in Figure 1(b). The modern use of gold treatments, now known as chrysotherapy, after Chryses, a golden-haired maiden of Greek mythology, trace their scientific origins to the pioneering work of Dr. Robert Koch, a German physician, who studied the antibacterial properties of potassium aurocyanide, $K[Au(CN)_2]$, while screening potential chemotherapeutic agents against *tubercle bacilli*. This led to the experimental, but ultimately unsuccessful, use of other gold compounds to treat tuberculosis for a period of time in the late nineteenth and early twentieth centuries.[9,10] The Parisian physician Jacque Forestier, who noted beneficial effects of gold treatments on the rheumatoid arthritis of some patients, initiated its use for that disease. A double-blind trial by British Rheumatism Council after World War II demonstrated that it was efficacious for many patients and generated long

lasting remissions of the disease state for some patients. Starting in the early 1970s, Dr. Blaine Sutton at Smith, Kline & French Laboratories developed an oral gold preparation, auranofin, which was finally licensed in the late 1980s.[11] In modern medicine, gold compounds have found use in treating rheumatoid arthritis and related disease states, and are being actively synthesized and screened for antitumor, antiparasitic, and antiviral activity.

2.2 The Element and Oxidation States

Gold (Z = 79), which is found in the sixth row of the periodic table, between platinum and mercury, belongs to group Ib (or group 11) and lies below copper and silver, with which it shares common properties (*see* ***Periodic Table: Trends in the Properties of the Elements***). This triad is referred to as the coinage metals. Elemental gold is a shiny, yellow substance, which is malleable and ductile and a good conductor of heat and electricity. The reduction potential for gold(I) is strongly positive, resulting in a natural inertness, which befits its description as a noble metal:

$$Au^+ + e^- = Au^\circ \qquad E^0{}_{1/2} = +1.68 \text{ volts} \tag{1}$$

It is inert to common acids and can be dissolved by using aqua regia (~3:1 HCl:HNO_3) or liquid bromine for laboratory purposes. The inertness of gold, its yellow color, and the unusual preference of gold(I) for two-coordination can all be traced to the uniquely strong influence of relativistic effects on the 6s orbital. This effect is maximal at gold, compared to platinum, mercury and more distant neighbors along the sixth period of elements.[12]

Compounds in oxidation states −I through V are known.[13,14] The common and stable oxidation states that dominate the aqueous chemistry of gold are Au(I) and Au(III). The aquated ions are unstable to reduction, but many complexes are stabilized by a variety of soft ligands. The remaining oxidation states (−I, II, IV, V) exhibit interesting chemical and physicochemical properties, but have not yet found medicinal applications.

Gold in the +1 oxidation state, which has a d^{10} electron configuration, can form complexes with two, three, or four bound ligands. Relativistic effects operating on the 6s orbital generate a large s-p energy gap that favors linear, two-coordination over three- and four-coordination.[12] As a result gold(I) reacts with the heavier halides and cyanide to form AuX_2^- ions, but not the corresponding AuX_3^{2-} or AuX_4^{3-} complexes, in contrast to silver(I) and copper(I), which have smaller s-p gaps and form numerous three- and four-coordinate species in addition to two-coordinate linear complexes with these anions. Gold in the +3 oxidation state forms principally square-planar, four-coordinate complexes typical of d^8 transition metal ions (Figure 3). A limited number of complexes with five-coordination have been characterized, and typically contain a chelating ligand such as *o*-phenanthroline or biphenyl with one donor atom coordinated in the square plane and the second at an elongated distance along the perpendicular axis.

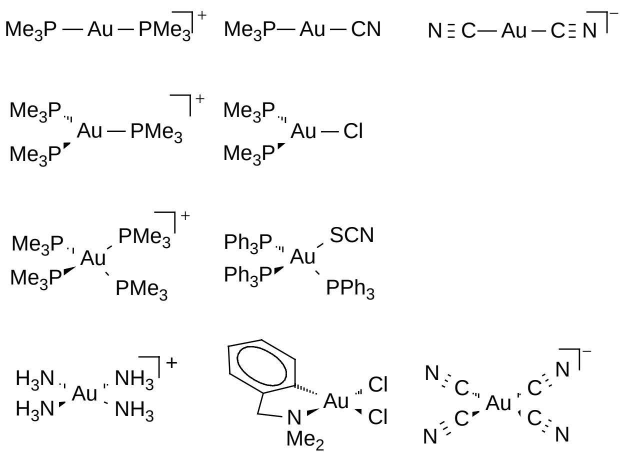

Figure 3 Coordination geometries for gold(I) and gold(III) complexes: examples of (a) negative, neutral and positively charged linear gold(I) complexes; (b) trigonal and tetrahedral gold(I) complexes and (c) square-planar gold(III) complexes (Et = ethyl; Me = methyl; Ph = phenyl; SG = glutathionate-(S))

2.3 Antiarthritic (Chrysotherapy) Agents

The compounds currently in clinical use for treating rheumatoid arthritis, shown in Figure 4, are all gold(I) thiolates.[15] The first-generation drugs include, sodium bis(thiosulfato)gold(I) (sanochrysin), which has a well-defined stoichiometry and structure, and three oligomeric gold(I) thiolates with thiomalate (myochrysine), thioglucose (solgonal) or thiopropanolsulfonate (allochrysin) ligands in approximately 1:1 ratio to the gold. None of the oligomeric preparations have been amenable to crystallization, although a close analog of myochrysine, $CsHNa_2(AuSTm)_2$, was crystallized by a vapor deposition method.[16] This elegant structure consists of double-helical strands of polymer with 1:1 ratio of gold and thiomalate stabilized by gold–gold interactions between the intertwined strands (Figure 5). Viewed along the helical axes, alternating helices spiral clockwise and counterclockwise and contain exclusively R- or exclusively S-thiomalate to facilitate helical packing. Other model compounds form discrete structures: $[Au(S\text{-}C_6H_2\text{-}i Pr_3)]_6$ crystallizes in hexameric rings formed by alternate linear gold(I) ions and bridging thiolate ligands. Recently reported catenated ring structures found for the *p*-*t*-butylphenylthiolato and *o*-*t*-butylphenylthiolato complexes of gold(I) have the stoichiometries, $[RSAu]_{10}$ and $[RSAu]_{12}$, respectively (Figure 6).[17] The first consists of two linked pentamers and the second of two linked hexamers. The ability to form both catenane structures, stabilized by gold–gold interactions, and simpler oligomers suggest why

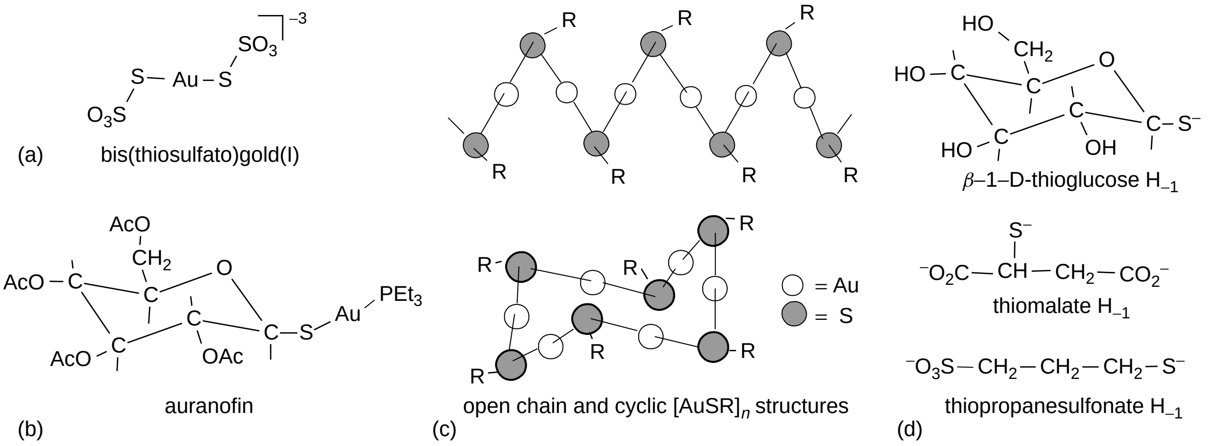

Figure 4 Structures of clinically used antiarthritic gold complexes

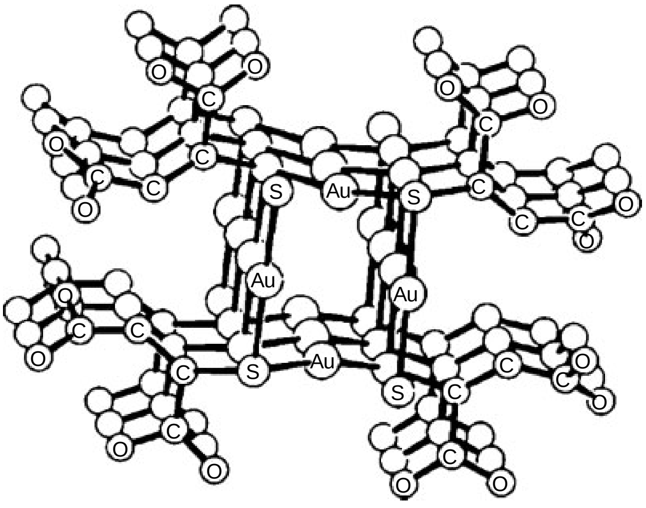

Figure 5 The structure of a single helix in [$CsHNa_2(AuSTm)_2$], viewed along the helical axis. Alternating helices contain exclusively R- or S-thiomalate and coil clockwise and counterclockwise in the structure. Aurophilic interactions, arising from relativistic effects on the gold 6s orbital, stabilize the helices and are evident in the figure

the oligomeric gold(I) thiolates have been so difficult to crystallize.

Only one second-generation drug, auranofin (2,3,4,6-tetraacetyl-*β*-1-D-thioglucopyranosato-*S*-(triethylphosphine) gold(I)), has been clinically tested and approved for use against arthritis. It is a discrete, well-characterized monometallic species (Figure 4(b)) having essentially linear coordination ($\angle$S-Au-P = 174°) to the tetraacetylthioglucose and phosphine ligands. The simpler analogues Et_3PAuCl and $Et_3PAuSTg$, Tg = *β*-1-D-thioglucopyranosato-*S*, exhibit similar antiarthritic activity, but the chloride compound induced severe intestinal distress when administered to patients, and the thioglucose analogue is hygroscopic, which severely limited shelf life of the medicinal preparation. Both untoward side effects are absent with the acetylated sugar moiety of auranofin. In vivo, the tetraacetylthioglucose ligand is rapidly displaced in ligand exchange reactions and the phosphine is more slowly displaced over about 24 hours. The phosphine ligand renders the compound lipophilic, thereby allowing oral administration, and allows it to enter cells more rapidly.

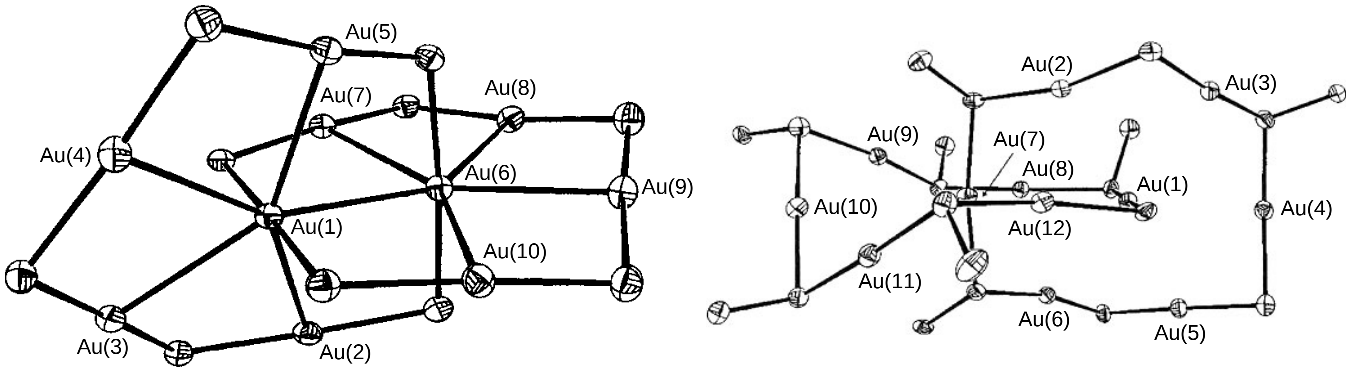

Figure 6 Structures of the gold(I) monothiolate catanes, $[AuSR]_{10}$ and $[AuSR^1]_{12}$, R = *p*-*t*Bu-$C_6H_4S^-$ and R^1 = *o*-*t*Bu-$C_6H_4S^-$. The ability to form stable catenated ring systems may explain the difficulties encountered in preparing crystalline forms of the gold(I) thiolates used clinically.[17]

2.4 Chrysotherapy for Rheumatiod Arthritis

Rheumatoid Arthritis (RA) is an autoimmune disease, in which the synovial tissues that line and lubricate the joints are under attack by the immune system. To date, neither a triggering agent (viral, microbial, etc.) nor a self-antigen has been identified. Gold drugs are considered to be disease modifying anti-rheumatic drugs (DMARDS) that retard and sometimes cause remission of the disease state.[18] The response of patients to gold therapy is typically manifest only after 3 to 6 months. Since RA is a cyclic disease with flare-ups and quiescent periods, it is frequently difficult to evaluate the effectiveness of various treatments. One accepted effect of chrysotherapy is its anti-inflammatory activity.[18,19] Additional mechanisms of action that may contribute to chrysotherapy are inhibition of various enzymes, antimicrobial activity, reduction of humoral immunity, inhibition of the complement pathway, effects on lymphocytes, monocytes, or neutrophils – especially inhibition of T-cell proliferation and of polymorphonuclear monocyte activation. Multiple mechanisms of action may be acting in concert, and there is not wide acceptance of any one or combination as the primary biological action underlying chrysotherapy.[18,19] Auranofin, which is orally administered, exhibits fewer toxic side effects than the conventional parenteral agents, but a metaanalysis of 66 clinical trials establishes that it is somewhat less effective than the latter.[20] Both oral and parenteral drugs are still used clinically although improved, competing therapies have decreased the use of chrysotherapy worldwide.

2.5 Pharmacology – Prodrugs

The parenterally administered gold drugs are absorbed into the blood stream and the resulting gold concentration reaches a maximum within several hours and then decreases to a basal level. Auranofin is administered orally and several weeks are required to achieve substantial blood concentrations of gold. Although there is no direct correlation of blood gold levels with therapeutic benefit, concentrations in excess of 300 mg dL^{-1} are typically considered to carry increased probability of side effects. Because auranofin carries a phosphine ligand and is lipophilic, unlike the parenteral drugs, its metabolism differs in the blood and especially at the cellular level. Absorption of gold from auranofin in the intestines is accompanied by hydrolysis of the acetyl groups from the tetraacetylthioglucose by enzymes in the intestinal wall lining,[21] but gold from the parenteral drugs is not absorbed by the gut or intestines. Gold accumulated from the parenteral drugs is excreted primarily via the kidneys and urine, but when auranofin is administered a large fraction is excreted via the bile, which establishes a reabsorption cycle with the intestines.[22]

In vivo studies indicate that gold-based chrysotherapy agents are prodrugs, species that undergo transformation after administration to form the active species.[15] The metabolism occurs rapidly by ligand exchange reactions. Radiotracer studies of $[Au^{35}STm]_n$, $[Au^{35}Stg]_n$, and $Et_3{}^{32}PAu^{35}SATg$ administered to laboratory animals demonstrate that within hours, substantial displacement of the thiolate ligands from gold has taken place. In the case of auranofin, the tetraacetylthioglucose ligand is essentially displaced within less than an hour and the triethylphosphine within a day. Gold present in the serum is bound primarily to serum albumin; only relatively small concentrations of low-molecular weight (so-called ‘free’) gold species are present. Extensive studies of albumin-gold adducts have identified cysteine-34 as the primary binding site at which reactions of the gold drugs take place. Table 1 lists complexes that have been characterized by a variety of physical methods including crystallography, EXAFS, Mössbauer, NMR, and other spectroscopic techniques.[15]

Table 1 Protein complexes of gold drugs & metabolites[15]

Complex	Au ligation	d(Au-X)/pm
Alb–S–$(AuSTm)_{0.4}$	S–Au–S	228 (S)
Alb–S–(AuSAtg)	S–Au–S	228 (S)
Alb–S–$AuPEt_3$	S–Au–P	227 (S), 230 (P)
Alb–N_{his}–$AuPEt_3$	N–Au–S	–
Alb–SH·$[Au(CN)_2]$	C–Au–C	
Alb–SH·$[Au(CN)_2]_3$	C–Au–C	
Hb–S($AuPEt_3$)	S–Au–P	
Au,Cd,Zn-MT	S–Au–S	229 (S)
$(TmSAu)_{20}$MT	S–Au–S	230 (S)
Cyclophilin – N_{his}–Au[26]	N–Au–P	206 (N), 227 (P)

The crystal structure of human albumin located Cysteine-34 at the turn between helices h2 and h3 with the side chain sulfhydryl group oriented toward the protein interior,[23] consistent with EPR studies suggesting that it is 950 pm below the surface.[24] Sadler has demonstrated by ^{1}H NMR studies that the cys-34 residue must move outward from the crevice created by the helices before it can react to form disulfide bonds or bind to Et_3PAu^+ derived from auranofin.[25] These structural observations are consistent with the kinetic mechanism for the reactions of albumin with auranofin and its triisopropylphosphine analogue, which revealed a slow crevice opening reaction in equilibrium between open and closed forms of albumin. The kinetic model accounts for a process that is first order in protein when the auranofin is present in excess,

$$\text{rate} = k_1[\text{AlbSH}], \tag{2}$$

which is controlled by the rate of the crevice opening, and the second order kinetics observed when equilibrium mixtures of reactants and products are examined by ^{31}P NMR methods:

$$\begin{aligned} \text{rate}_f &= k_2[\text{AlbSH}][\text{R}_3\text{PAuSAtg}] \\ \text{rate}_r &= k_{-2}[\text{AlbSAuPR}_3][\text{AtgSH}]. \end{aligned} \tag{3}$$

Extrapolation to the physiological situation, in which albumin (ca. 440 μM) is in excess of auranofin (10–25 μM), predicts a rapid reaction of auranofin with the open-crevice form,

$$\text{rate} = k_4[\text{AlbSH}][\text{R}_3\text{PAuSAtg}],\ k_4 = (8 \pm 2) \times 10^2\text{M}^{-1}\text{s}^{-1}, \quad (4)$$

that is consistent with the rapid loss of ATgSH from auranofin in animal model studies.

Metallothionein (MT), a metal-binding protein rich in cysteine residues, which binds Cu^{+} and Zn^{2+} under normal physiological conditions and Cd^{2+} after accumulation of the metallotoxin (*see* ***Metallothioneins***), also binds gold(I) after exposure of organisms to gold drugs and complexes. AuSTm and Et_3PAuCl react with Cd,Zn-MT to displace Zn^{2+} preferentially and on exposure to excess gold Cd^{2+}. The gold may bind with loss or retention of the carrier ligands depending on conditions. Et_3PAu^{+} from Et_3PAuCl is transferred to Cys-β92 of hemoglobin (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***), but auranofin does not react. This establishes a relative affinity of thiols for gold as Albumin Cys-35 > AtgSH > Hemoglobin Cys-β92 > Chloride.

In contrast to albumin, hemoglobin and metallothionein, in which gold(I) coordination to cysteine thiol residues has been clearly established by physicochemical methods, the binding of gold to cyclophilin is unusual in that the Et_3PAu^{+} moiety binds to a histidine residue in preference to the two free thiols present in the protein structure.[26] When cysteine-34 of albumin is blocked by chemical modification, Et_3PAuCl, but not auranofin, will bind to the numerous histidine residues present.

Because the triethylphosphine ligand used in auranofin is pyrophoric (i.e. it spontaneously catches fire on exposure to air), its separation from auranofin and subsequent fate in vivo is a consequential matter. In vivo, it is readily, although less spectacularly, oxidized to triethylphosphine oxide ($Et_3P{=}O$), which is quite water soluble and harmlessly excreted in the urine.[15,22,27] Triethylphosphine, when directly added to a solution of albumin, is oxidized at the expense of the protein disulfide bonds.[28] Either by allowing AlbS-$AuPEt_3$ formed in vitro to remain in the presence of the displaced AtgSH or by adding a thiol such as glutathione after purifying it, the formation of $Et_3P{=}O$ is stimulated, which suggests a likely mechanism for the displacement and subsequent oxidation of Et_3P in biological systems. Red blood cells (RBCs) also contribute to phosphine oxidation. After taking up Et_3PAu^{+} from auranofin, they release the gold concomitantly with glutathione to form an extracellular albumin adduct, AlbS-Au-SG, where GS^{-} is the anion of glutathione, and release the phosphine as $Et_3P{=}O$.

Although they are significant intermediates in the in vivo ligand exchange reactions that metabolize the gold drugs and transport gold in vivo, the albumin complexes formed by direct reaction with the clinically used chrysotherapy agents, Table Au-1, are unlikely to be the active therapeutic agents. Additional metabolic reactions, recognized in the late

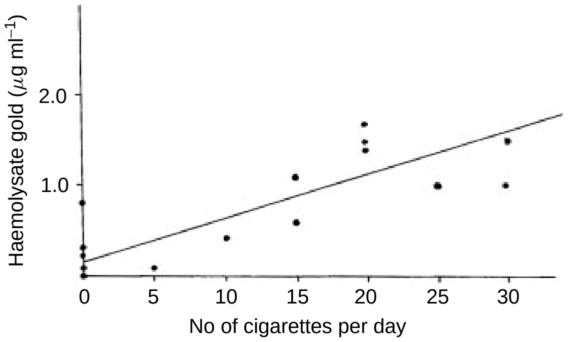

Figure 7 A plot of the gold concentrations in red blood cell lysates as a function of the patient's smoking habits. (Reprinted from Ref. 33. © 1991, with permission from Elsevier)

1980s, further alter the nature of gold in vivo. Graham and colleagues investigated the role of immunogenerated cyanide,[29,30] and Gleichmann and his colleagues in Germany observed evidence for the oxidation of gold drugs to gold(III) species,[31,32] a possibility long noted, especially by Smith and coworkers.[33] Interestingly, both processes involve a common enzyme, myleoperoxidase (MPO; *see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***), a participant in the oxidative burst of immune cells.

Tobacco-smoking patients exhibit higher levels of gold in their red blood cells (Figure 7), even when taking the parenteral drugs that don't lead to RBC uptake of gold in vitro.[34,35] Graham *et al.* showed that cyanide, present in tobacco smoke at ca. 1700 ppm,[36] alters the blood distribution of gold by forming $[Au(CN)_2]^{-}$, which is accumulated by RBCs.[33,34,37] Macrophage cells can generate cyanide from thiocyanate, and in the presence of thiocyanate and polymorphonuclear monocytes stimulated to undergo the oxidative burst, aurothiomalate is converted to aurocyanide.[29,30] The aurocyanide, in turn, inhibits the macrophages from further release of reactive oxygen species, which may be involved in joint damage.[29] Aurocyanide, $[Au(CN)_2]^{-}$, has been observed in the urine and blood of patients treated with any of the three gold drugs used clinically in the US.[38] The low levels of free aurocyanide found in their serum may be in equilibrium with albumin to which aurocyanide binds at multiple sites and remains intact, based on the characteristic Mössbauer spectrum for the linear ion.

The oxidation of gold(I) to gold(III) metabolites was detected in mice by use of the popliteal lymph node assay,[31,32] which is a classical test to distinguish the immunoreactivity of metabolites from their progenitor substances. The significance for chrysotherapy was confirmed by showing an amanestic response of T-cells from chrysotherapy patients to gold(III) but not to the gold(I) thiolates that were administered to them.[39] In vitro studies with hypochlorite generated by the action of myleoperoxidase demonstrated that AuStm, AuStg, auranofin and $[Au(CN)]_2^{-}$ are all oxidized to gold(III) under biomimetic conditions[40,41] Further, MPO and its substrates H_2O_2 and

Cl^-, from which hypochlorite is generated, are sufficient to oxidize AuSTm to gold(III).[40] The gold(III) species are not immunogenic but likely react with proteins to generate antigenic species and may carry oxidizing equivalents from the site of the oxidative burst to other cells or macromolecules.

The uptake and release of gold by a variety of cell types, especially the red blood cell and various immune cells, has been investigated. The rate, extent, and mechanism of uptake vary according to the cell type and the gold complex. Based on studies of the transfer of Et_3PAu^+ into macrophage cells, Mirabelli *et al.* developed the sulfhydryl shuttle model (Figure 8).[27] The Et_3PAu^+ moiety is transferred from auranofin and other ligands in the extracellular environment to membrane proteins containing sulfhydryl groups, which then transport it through the membrane to the intracellular environment, where it may react with a variety of thiol or selenocysteine containing ligands (e.g. glutathione, hemoglobin, Se-dependent glutathione peroxidase, and thiol-proteases) in RBCs and other cells. Gold may efflux from RBCs either as the original Et_3PAu^+ moiety[27] or as a thiolate complex, such as glutathionatogold(I). The latter forms an AlbS-Au-SG complex in the extracellular environment, which in effect results in a phosphine for glutathione ligand exchange reaction.[42] The parenteral drugs do not typically deliver gold into cells, except in the case of phagocytic cells, which can incorporate the oligomeric complexes,[43] or in the presence of cyanide.[30,33–35] Consequently, metallothionein (*see* ***Metallothioneins***), the inducible heavy-metal-binding protein, is synthesized in CHO cells that are exposed to auranofin[43,44] but not when the cells are exposed to AuSTm.[45] Even CHO cells that are stimulated to overproduce MT are not resistant to the growth inhibitory effects of AuSTm. Smith, Reglinski, *et al.* have observed that the effects of AuSTm on cells can be effected via interactions with cell membranes without its incorporation into the cytosol or organelles.[33,46]

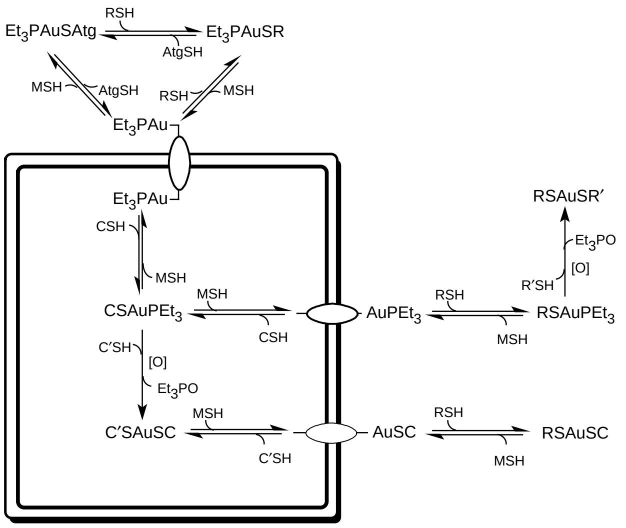

Figure 8 The sulfhydryl shuttle model for Et_3PAu^+ accumulation and efflux through cellular membranes. CSH and RSH = cellular and extracellular thiols, protein, or small molecule; MSH = membrane sulfhydryl-dependent transport systems

Enzyme inhibition has been extensively explored as a source of the antiarthritic activity of gold compounds and may play a role in the anti-inflammatory effects by inhibiting enzymes in the prostaglandin biosynthesis pathway. An early tabulation of data[47] has not been updated although many additional enzymes and gold complexes have been studied. Many thiol-dependent enzymes are inhibited by gold complexes, which are presumed to undergo reactions with active site thiols in a manner analogous to their reactions with Cys-34 of albumin. The measured inhibition constants, as tabulated previously, range from millimolar to the micromolar level. Since only 10–25 μM gold concentrations are achieved in vivo during therapy, only those enzymes with smaller K_i values are likely to be inhibited.[47] Selenols (RSeH) have a much higher affinity for gold(I) than do the corresponding thiols (RSH), and as a result, selenium-dependent enzymes are readily inhibited at gold concentrations comparable to and sometimes significantly lower than the therapeutically relevant gold concentrations. Examples include Se-dependent glutathione peroxidase and Se-dependent thioredoxins.[48–50]

2.6 Cancer Chemotherapy

Gold compounds have been tested extensively for antitumor activity and many active compounds have been examined in cell culture and sometimes in animal models in vivo.[15,51,52] Three rationales are frequently cited: (1) analogies of gold(III) square-planar complexes to their platinum(II) analogues; (2) immunomodulatory properties related to use against RA, and (3) complexation of gold(I) and gold(III) compounds with active organic chemotherapy agents to modulate the properties of metal and ligand. The screening of numerous auranofin analogues with variations in the phosphine and thiolate ligands, led to the development of a promising antitumor agent, $[Au(DPPE)_2]Cl$ (DPPE = bis(diphenylphosphino)ethylene), which was identified as a stable metabolite of a dinuclear gold compound by Berners-Price *et al.*:[53]

$$(\mu\text{-DPPE})(AuCl)_2 \longrightarrow [Au(DPPE)_2]^+ \quad (5)$$

Unfortunately, development of this compound was thwarted by the discovery of significant cardiovascular toxicity caused by the inhibition of mitochondrial function. This represents a demonstrable targeting of gold to a particular organelle and suggests that better delivery of gold to inflamed joints in chrysotherapy may be achievable with ligands that are less labile than the currently used monodentate thiolates. Early screening of gold(III) complexes for antitumor activity was not fruitful. In contrast, (dimethylaminomethylphenyl)dichlorogold(III) and its acetate analogue, are stabilized by the chelating C,N donor ligand that generates a neutral complex and stabilizes the

gold(III) against reduction in vivo. They show promising activity, with a different mechanism of action than cisplatin, but clinical trials have not been undertaken.[54]

2.7 Anti-HIV and Antiparasitic Activities

Gold complexes have been tested and shown to have anti-HIV activity, as reviewed elsewhere.[15] Gold thioglucose (AuStG) showed promising activity against the KL4-3 strain of HIV. It reacts with Cys-532 on the viral coat protein gp 160, but the activity is specific to this strain and it is not effective against more virulent strains. AuStG is also effective against reverse transcriptase (RTase) in cell-free extracts, but is not an effective inhibitor of HIV in cell cultures since it does not enter the cell. Aurocyanide, $[Au(CN)_2^-]$, inhibits the proliferation of the T-9 strain of CD4+ T-cells in vitro, and is effective at doses as low as 20 nm. These promising leads have not led to more extensive investigations of gold-based anti-HIV drugs, even though a clinical report suggests that auranofin treatment stimulated CD4+ T-cell counts in an AIDS patient undergoing gold treatment for psoriatic arthritis but not anti-HIV therapy.

Gold compounds are being actively explored for the treatment of a variety of parasites. Antimalarial activity of gold has been investigated, based in part on the observation that antimalarial drugs, for example, chloroquine, are also effective against rheumatoid arthritis. The chloroquine complex of triphenylphosphinegold(I) is more active against *Plasmodium falciparum* (see $IC_{50} = 5.1 \times 10^{-9}$ M) and *Plasmodium berghei* (2.3×10^{-8} M) than chloroquinediphosphate or other metal complexes.[48] *Schistosoma mansoni*, another tropical parasite, is dependent on a novel thioredoxin glutathione reductase enzyme (*Sm*-TGR) to protect it from oxidative stress in the host organism. *Sm*-TGR combines thioredoxin reductase and glutathione reductase activities in a single selenium-dependent enzyme. The IC_{50} values for inhibition of the glutathione reductase and thioredoxin reductase by auranofin are 10 and 7 nM, respectively, suggesting that gold complexes have potential use against this disease.[49]

3 SILVER ANTIBACTERIAL AGENTS

3.1 Introduction and History

Silver has long been known to exhibit antibacterial properties, which may have been an unwitting advantage to those who could afford silver vessels and tableware. Silver sulfadiazine is a widely used and very effective burn ointment, and silver-treated catheters greatly reduces the rate of infection associated with their use. The element is not known to be essential, although trace amounts (<1 mg total body burden) are accumulated, with blood levels typically below $10\,\mu g\,L^{-1}$.[55]

An early record that the ancients recognized and exploited silver's microcidal properties is the report by Herodotus that the King of Persia stored boiled water in silver urns for his military campaigns.[56] Raulin showed as early as 1869 that silver vessels prevented the growth of *Aspergillus niger* in their contents.[57] Uses of silver in modern medicine are based on its effective antibacterial and antifungal actions, including topical application of silver sulfadiazine for burns, and antimicrobial coatings for catheters that reduce the frequency of infections.[58,59] The once prevalent use of silver nitrate to treat opthalmia neonatorum has been discontinued owing to rare but serious complications and the availability of safer alternatives. C. L. Fox, Jr, introduced silver sulfadiazine in the late 1960s as a treatment of surgical wounds and burns.[60–62] Various forms of silver are also used in some water purification devices to eliminate microbial contamination.[58]

3.2 The Element and Ion

Silver (Z = 47) falls in group IB (group 11), between copper and gold, and has intermediate chemical and physical properties (*see* ***Periodic Table: Trends in the Properties of the Elements***). The elemental form is a shiny white color and tarnishes by forming a black residue, particularly in polluted urban environments. It is more reactive than gold and less reactive than copper. There are two stable isotopes, ^{107}Ag (51.82% abundance) and ^{109}Ag (48.18% abundant). Both are NMR active with nuclear spins, I = 1/2, and have reasonable receptivity.[63] The $5s^1\,4d^{10}$ electron configuration of atomic silver favors formation of a stable Ag^+ ion, having a d^{10} electron configuration, which forms salts with halides, nitrate, sulfate and a wide variety of other common anions. Ag(I) readily forms linear two-coordinate, trigonal-planar three-coordinate and tetrahedral four-coordinate complexes. Silver–silver interactions have been noted in many cases. It also forms Ag(II) and Ag(III) complexes under a variety of conditions, but these oxidation states are less common and more reactive than the simple monovalent ion. The standard electrode potential for formation of silver metal from silver ion is positive,

$$Ag^+ + e^- = Ag^\circ \qquad E^0{}_{1/2} = +0.7996 \text{ volts} \qquad (6)$$

as generations of introductory students learned after splashes of silver nitrate on their skin generated black splotches of colloidal silver stain. Ligands such as cyanide, thiolates and phosphines stabilize silver against reduction and reverse the sign of the reduction potential.

3.3 Medical Applications

Silver sulfadiazine (AgSD; Figure 9) is a preferred antimicrobial agent for severe burn cases, and is applied after debridement of the wounds as an ointment containing

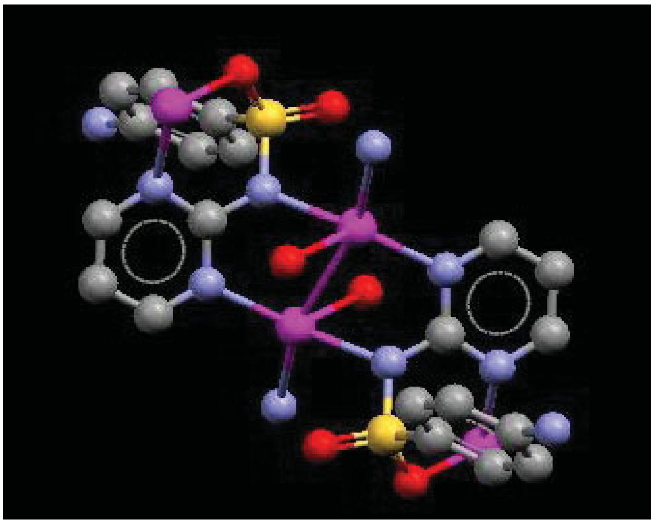

Figure 9 The coordination of silver in silver sulfadiazine, the topical agent for burns and wound treatment: the Ag–Ag dimeric unit stabilized by two head-to-tail bridging sulfadiazine ligands bound via pyrimidinyl and sulfamido nitrogen donor atoms; only the nitrogen and sulfur donor atoms of the third sulfadiazine ligands are shown. SULPMS from the Cambridge Crystallography Database

1% micronized AgSD. Only a very few orally active antibiotics are also suitable as topical applications, whereas AgSD, which is stable to light and over time and relatively insoluble, is very effective in topical applications. It is active against a wide variety of bacterial species and yeasts (fungi). The sulfadiazine ligand is a classical sulfa drug, generated by a sulfonamide linkage between *para*-amino sulfonic acid and 2-aminopyrimidine. The crystal structure of the silver complex consists of bridging silver cations coordinated to four donor atoms provided by three different sulfadiazine molecules to generate a complex, double-stranded polymer.[64,65] Interestingly, silver ions are paired in an arrangement with short silver–silver distances, 2.916 Å, linked by two bridging sulfadiazine molecules arranged in a head-to-tail fashion so that each silver binds to the sulfonamide nitrogen of one ligand and a pyrimidine ring nitrogen of the opposing ligand. Each silver is also coordinated by a pyrimidine ring nitrogen and a sulfonamide oxygen from a chelating sulfadiazine as shown in Figure 9.[64,65] The associated silver atom and four donor atoms are arranged in a distorted trigonal-bipyramidal array (Figure 9). Although the AgSD structure is often simplified and presented either as (i) a cationic silver associated with a deprotonated sulfadiazine or (ii) silver coordinated to a monodentate sulfadiazine via the deprotonated sulfonamide nitrogen or (iii) silver chelated by the pyrimidine nitrogen and sulfonamide oxygen, it is, in fact, the complex ligation into a double-stranded polymer that explains the low solubility and great stability of AgSD.

An important advantage of AgSD for chemoprophylaxis of burn wounds is that most bacterial species are unable to develop resistance against it.[60] After the infectious bacterium

Table 2 Susceptibility of *P. aeruginosa* to antimicrobial drugs after ten passages through subinhibitory concentrations[60]

Antimicrobial agent(s)	MIC (nmol mL^{-1}) Before passage	After passage	Decrease in susceptibility
AgSD	50	80	1.6-fold
Norfloxacin	5	200	40-fold
Ofloxacin	5	200	40-fold
Pefloxacin	5	500	100-fold
Fortaz	1.5	200	130-fold
AgSD + Norflaxacin	7.7	75	10-fold
AgSD + Ofloxacin	3	50	17-fold
AgSD + Fortaz	12	100	8-Fold

Pseudomonas aeruginosa was successively recultured 10 times through subinhibitory doses of various antibiotics, the MIC (mimimum inhibitory concentration) was determined and compared to the values measured before the passages (Table 2). The susceptibility of AgSD decreased only marginally, 1.6-fold, while the organic antibiotics showed 40- to 130-fold decreases.

Silver sulfadiazine is quite insoluble and releases the silver slowly, thereby maintaining a constant concentration of the free silver ion, which is the therapeutic agent. Although sulfadiazine itself has antimicrobial activity, the evidence that silver ion itself is the principle agent of AgSD arises from the following key observations: (1) *para*-aminobenzoic acid, a sulfadiazine antagonist, does not inhibit the action of AgSD, (2) using both ^{35}S- and ^{110}Ag-labelled AgSD preparations, it was shown that the silver was associated with the bacteria, but ^{35}S was not incorporated into it.[66] Norflaxacin, pefloxacin and oflaxacin are quinolone drugs that are also effective antibiotics, but subject to the development of bacterial resistance. They exhibit synergistic activity when used in combination with Ag–SD,[60,65–68] and the development of resistance to the organic agents is significantly reduced (Table 2).

3.4 Bacterial Silver Resistance

Long-term concerns about the potential for development of silver-resistant bacteria and fungi, especially in hospital and clinical settings, have led to extensive investigations of bacterial silver resistance.[69] Early studies were directed at studying the phenomenon as a function of the microorganism and exposure conditions. More recently, cellular and molecular biology approaches have allowed the mechanisms of silver resistance to be unraveled and compared to bacterial resistance to other metal ions. A gene family, silA, silB, silC, silE, silP, silR, silS, was identified as a silver resistance determinant on the plasmid of a hospital burn-ward *Salmonella* isolate.[70,71] The corresponding proteins coded by these genes have homologues in bacterial resistance genes to other metals. SilS and SilR, which resemble the CzcS and CzcR proteins of the cadmium, zinc, cobalt resistance mechanism, are a membrane-bound silver ion sensor and an aspartyl phosphate

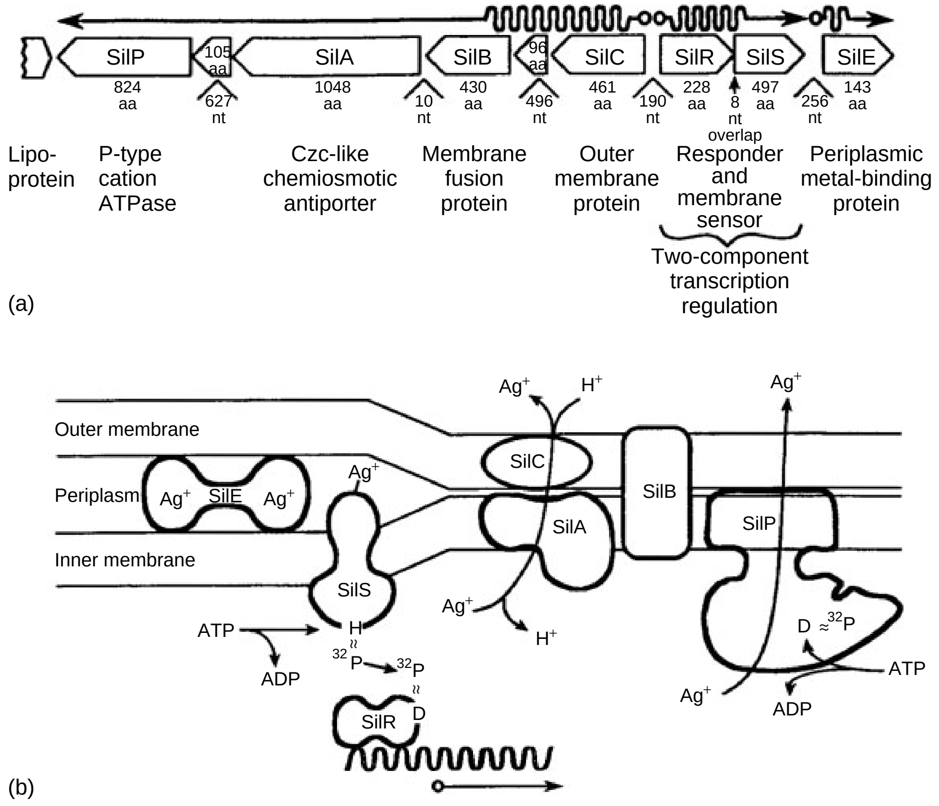

Figure 10 The silver resistance genes, transcripts and the organization of the protein products in the membrane of *Salmonella*.[70,71] (a). Top line shows the mRNAs. The open boxes indicate different genes or open reading frames (ORFs) and their orientations. The nucleotides between the genes (nt) and the amino acids of the proteins (AA) are indicated. (b). The proposed functions and organization of the protein products relative to the bacterial structure are indicated. (Ref. 71. Reproduced by permission of Nature Publishing Group (www.nature.com))

transcriptional responder (Figure 10). The silA, silB, silC, and silP genes are cotranscribed to generate a SilABC complex that functions as a cation–proton antitransporter and SilP, an ATP-dependent active transporter that also generates a silver efflux.[71,72] A detailed understanding of the structure-function relationships of this protein family may suggest treatment protocols, such as combination therapy with two active antibacterial agents, that will retard the development and widespread transference of resistance.

3.5 Screening of New Complexes for Antimicrobial Activity

Exploration of new complexes with useful antimicrobial activities has stimulated extensive development of synthetic chemistry of silver(I) complexes. The incorporation of novel ligands can moderate the physical and chemical properties of complexes. For example, the bis(diphosphine)silver(I) complexes (which are analogues of the bis(diphosphine)gold(I) complexes with promising antitumor activity compromised by their antimitochondrial activity) were examined for antitumor and antimicrobial activity by Berners-Price *et al.*[73] 2-Substituted benzimidazole derivatives of silver(I) are more effective than the copper analogues against *Staphylococcus aureus* (MIC = 9.8 vs 78 and 9.8 vs 156 $\mu g\,mL^{-1}$) when the substituents are 2-pyridyl and 5-methyl-2-pyridyl.[74] These and two related complexes showed similar MIC values (9.8 to 39 $\mu g\,mL^{-1}$) against a panel of 7 additional infectious agents including *P. aeruginosa* and *Candida albicans*. Five sulfacetamide silver derivatives, which introduce two sulfonamide linkages, were tested against two *Aspergillus* species (*niger* and *flavus*) and *C. albicans*.[75] The silver complexes were more effective (MIC range 3–12 $\mu g\,mL^{-1}$) than the zinc analogues (13–22 $\mu g\,mL^{-1}$) or the ligands (>88 $\mu g\,mL^{-1}$).

4 Pt-BASED ANTITUMOR AGENTS (*See also Platinum-based Anticancer Drugs*)

4.1 Introduction and History

The serendipitous discovery of antitumor activity for platinum compounds by Professor Barnett Rosenberg occurred

during research based on the novel premise that the organization of the chromosomes of dividing cells resemble the patterns of magnetic field lines and, therefore, bacterial growth might be altered in electric fields. Cells grown in electric fields generated with gold or silver electrodes reproduced indistinguishably from the controls, whereas cell growth in cultures where the field was generated by platinum electrodes was inhibited.[6,76] Further investigation revealed that *cis*-diamminedichloroplatinum(II) and *cis*-diamminetetrachloroplatinum(IV) formed in the latter culture were responsible for the growth inhibition. In vitro and in vivo testing demonstrated the effectiveness of the Pt(II) complex against leukemia and other tumor cells. Subsequent clinical trials established the utility of cisplatin for treating ovarian and testicular cancer, in particular, and for other tumors in combination therapy with organic antitumor agents. Since then thousands of platinum(II) and platinum(IV) agents have been tested as potential antitumor agents, and nearly 30 have proceeded through at least phase I clinical testing.

4.2 The Metal and Its Oxidation States

Platinum (Z = 78) is a whitish, noble metal found in group 10 (or VIIIB) of the periodic table, in the triad with and lying below nickel and palladium (*see* ***Periodic Table: Trends in the Properties of the Elements***). It can be found in elemental form in the mountains of Columbia, where the pre-Columbian natives used it. European chemists discovered and reported it in the mid-1700s. Like gold and silver, it has a positive reduction potential:

$$Pt^{2+} + 2e^- = Pt^0 \qquad E^0{}_{1/2} =\sim +1.2 \text{ volts} \tag{7}$$

The metal does not react with oxygen, even when heated, and is resistant to the actions of either nitric or hydrochloric acid.

The principal oxidation states are Pt(II) and Pt(IV). Pt(II) is the prototypical d^8 ion and forms square-planar, four-coordinate complexes, which are somewhat sluggish in their ligand exchange reactions. Pt(IV) is a d^6 metal ion and forms octahedral 6-coordinate complexes, which exhibit the typical kinetic inertness associated with the d^6 configuration. Pt(IV) is an oxidizing agent and is reduced to Pt(II) under biological conditions by agents such as thiols. The oxidation states Pt(I) and Pt(III) are also known, primarily in complexes with Pt–Pt bonds. The Pt(0) oxidation state has a d^{10} configuration and forms linear 2-coordinate, trigonal 3-coordinate and tetrahedral 4-coordinate complexes. It is principally Pt(II) and Pt(IV) that are relevant to the medicinal chemistry of antitumor agents.

4.3 Clinically Used Platinum Antitumor Agents

The five platinum-based antitumor agents that are presently licensed[77,78] are shown in Figure 11 and listed in Table 3. Cisplatin (Figure 11(a)), as described above, was the first to be licensed, and remains an important and widely used clinical treatment. Used in combination therapy with a variety of organic drugs, it has found exceptional application against ovarian and testicular cancers and is also used to treat a wide variety of tumors including melanoma, bladder carcinoma, neuroblastomas, cervical carcinoma, oropharyngeal carcinoma, osteosarcoma, and lymphoma. It is one of the three leading antitumor drugs in worldwide clinical use, but nonetheless suffers from undesirable side effects including nephrotoxicity and frequent instances of drug resistance that limit its usefulness.

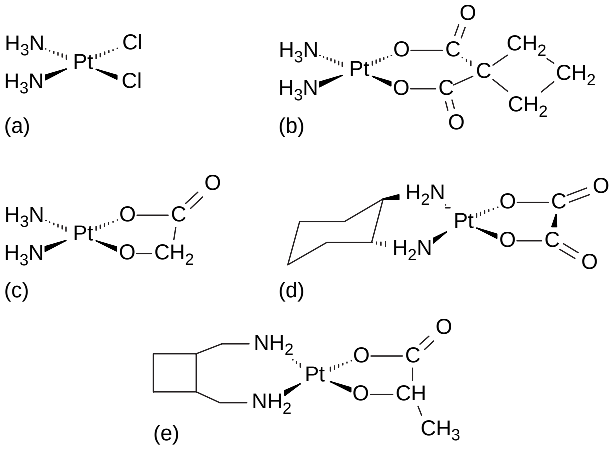

Figure 11 Clinically used platinum antitumor agents: (a) cisplatin; (b) carboplatin; (c) nedaplatin; (d) oxaliplatin; (e) lobaplatin

Table 3 Platinum antitumor agents approved for clinical use[80–83]

Structure[a]	Name	Effective against	Mode	Limiting toxicity	Approval
a	cisplatin	testicular, ovarian[b]	IV	nephrotoxicity	worldwide
b	carboplatin	testicular, ovarian[b]	IV	thrombocytopenia	worldwide
c	nedaplatin	head and neck, lung	IV	myleosuppression	Japan
d	oxaliplatin	colorectal cancer	IV	sensory neuropathy	France
e	lobaplatin	myelogenous leukemia		thrombocytopenia	China

[a]Figure 11. [b]Also used in combination therapy for a range of additional tumors.

The success of cisplatin in the clinic has stimulated the synthesis and preclinical testing of over 3000 related and unrelated platinum compounds since Rosenberg's initial report in 1965. It also spawned extensive searches for antitumor activity by complexes of other metals including gold, rhenium, ruthenium, tin, titanium and rhodium.[79] Four additional platinum-based drugs are presently licensed. Carboplatin (Figure 11(b)) retains the *cis*-diammine structure of cisplatin, but substitutes a chelating dicarboxylato ligand for the chloride ligands. It exhibits similar therapeutic profiles and is a safer drug with fewer side effects.[77,80] Like cisplatin it is licensed for use worldwide.

Three complexes, nedaplatin, oxaliplatin and lobaplatin (Table 3), have been licensed in particular countries for specific uses and are undergoing active clinical trials elsewhere. All three retain the *cis*-nitrogen donor atom arrangement found in cisplatin and have a bidentate oxygen-donor ligand. Nedaplatin (Figure 11(c)) contains the *cis*-diammineplatinum core with a chelating glyoxylate ligand, coordinated through the alkoxide oxygen and a carboxylate group oxygen atom. It has been approved in Japan for use against head and neck, testicular, nonsmall cell lung, oesophageal, ovarian, and cervical cancers.[81] In oxaliplatin (Figure 11(d)), the nitrogen donor atoms are provided by the chelating ligand *trans*-L-DACH (*trans*-L-1,2-diaminocyclohexane) and the labile ligand is a chelated oxalate ion.[80] It is licensed in France for colorectal cancer and is being tested in phase I trials in combination therapy with irinotecan (CPT-11), an agent able to block a resistance-developing repair mechanism, and in phase II trials with raltitrexed (taxol). Clinical trials against other tumor types are also under way: phase II trials in combination with 5-fluoruracil against metastatic prostate cancer and phase I trials in combination with irinotecan and 5-fluorouracil against advanced gastrointestinal malignancies. The presence of the bulky DACH ligand may contribute to its lack of cross-resistance to cisplatin.[77] Lobaplatin contains a chelating butylenediamine ligand, in which the internal carbons form one side of a cyclobutane ring (Figure 11(e)). The remaining coordination positions are occupied by a chelating lactate ligand bound through a carboxylate oxygen and the hydroxyl oxygen.[77,80,82] It has been licensed in China for treatment of myelogenous leukemia. A variety of tumor types respond to lobaplatin and some tumors that readily develop cisplatin resistance are not cross-resistant to it, which is an important therapeutic advantage.[82]

In addition to the compounds approved for use worldwide or in specific countries, at least eight other experimental Pt-based drugs are in phase I or II clinical testing (Table 4). Given the effectiveness of cisplatin and carboplatin against a variety of targets, there is strong interest in developing additional compounds, in which unique ligands may enhance activity against various types of tumors that are refractory to cisplatin or that develop resistance to it.

Three slow-release formulations of platinum compounds are in clinical trials. L-NDDP is a complex of *trans*-R,R-1,2-DACH with two bound neodecanoate ligands (Figure 12(a)) that is formulated in a multilamellar liposome preparation and administered intraperitoneally.[84] The Pt concentrations observed in the peritoneal cavity are approximately 20- to 50-fold greater than that in the plasma and are maintained for prolonged periods.[84] SPI-77 is a liposomal formulation of cisplatin and has been shown to reduce toxicity. It releases the platinum slowly, leading to half-lives for the platinum in vivo in the range of 60–80 hours, compared to ca. 1 hour for traditional IV administration of cisplatin. Lipoplatin, presently in Phase I and II trials, uses an alternative liposomal formulation to deliver cisplatin, which also leads to reduced side effects. Their effectiveness is comparable to cisplatin, and the reduced side effects are a significant clinical benefit.

Five additional complexes that have entered phase I or II trials (Table 4 and Figure 12(b–f)) reflect novel approaches to designing new Pt-based agents. Cycloplatam is a mixed amine-ammine complex, ammine(cyclopentylamine)-S(-)malatoplatinum(II) (Figure 12(b)), which is being developed in Russia and has entered phase II trials there.[85] Reported to be more effective and less toxic than cisplatin, it can be given by oral or intracavitary administration and is being tested against lung, ovarian and prostate cancers. ZD 0473 is also a mixed amine-ammine species, with a 2-methylpyridine ligand replacing one ammine of cisplatin. The methyl group is positioned over the coordination plane of the platinum, which results in steric hindrance to ligand exchange of the chlorides and slower transformation

Table 4 Platinum antitumor agents in Phase I or II clinical trials

Structure[a]	Name	Code	Mode	Limiting toxicity	Phase
a		L-NDDP	ip	neutropenia, thrombocytopenia	I
	Stealth cisplatin	SPI-77		Tbd	II
	Lipoplatin™			Tbd	II
b	cycloplatam		oral, ic	Myleosuppresion	II

into metabolites.[77,80,84] It is active against cisplatin- and carboplatin-resistant tumor lines and is being tested against a variety of tumor types including breast cancer. Heptaplatin (SKI 2053R), which contains a bidentate malonato ligand opposite a substituted butylenediamine ligand (Figure 12(d)), is in phase I clinical trials. It is a less toxic substance than cisplatin, and is also administered intravenously. It is being applied to advanced malignancies. Satraplatin (JM 216, [*cis,cis,trans*-$(CyH_2N)(H_3N)Cl_2(OAc)_2Pt(II)$], Figure 12(c)) the only Pt(IV) complex presently undergoing extensive clinical trials, is an octahedral complex with mutually trans acetate ligands, mutually cis chlorides and mutually cis ammine and cyclohexylamine ligand pairs arranged so that the chlorides are each trans to a nitrogen donor as in cisplatin. The complex can be taken orally and is not cross-resistant to cisplatin in certain tumor lines. Satraplatin's antitumor action is apparently preceded by reduction to a Pt(II) species. BBR 3463 is a trinuclear complex belonging to a large family of potential di- and polynuclear Pt antitumor agents developed by Farrell and coworkers.[86] It is the first multinuclear complex to enter clinical trials and appears to generate a new array of DNA adducts, which may explain the widespread lack of cross-resistance to cisplatin when tested against tumor cell lines.

Approximately 18 additional compounds that had entered clinical trials have been withdrawn from further development, because they lack broader activity than cisplatin or exhibit greater toxicity, or for economic and marketing reasons. Iproplatin (*cis,trans,cis*-bis(isopropylamine)dihydroxodichloroplatinum(IV); [*cis,trans,cis*-$(i\text{PrH}_2N)_2(OH)_2Cl_2Pt(II)$]), for example, showed promise in preclinical testing against tumors and in animal studies, but during clinical testing proved to be more toxic than cisplatin and less effective because the toxicity limited the dosage that could be used.

4.4 Metabolism and Mechanism of Action of Pt-based Antitumor Drugs

Cisplatin and the mononuclear analogues that either have been approved or are presently in clinical trials share a number of traits. Most important are the presence of two mutually cis amine ligands, which are critical to the in vivo activity, and two leaving groups such as chloride or carboxylate ligands. Early structure-function studies established that optimal activity resulted when the ligands trans to the nitrogen donor ligands have intermediate affinities for the Pt(II) center. Weakly bound ligands such as acetate ions decrease the activity compared to cisplatin, as do very strongly bound ligands, for example, the additional ammines in $[Pt(NH_3)_4{}^{2+}]$.[77]

The ligation of platinum in cell culture and in vivo is modified by a series of crucial equilibrium reactions. Using cisplatin as the example, the chloride ions are displaced by water to form sequentially the mono aquo and then diaquo complexes. The resulting aquated ions are involved in acid-base equilibria, which generate the corresponding hydroxo complexes. Under physiological conditions, the hydrolysis is repressed in the serum where the chloride concentration is relatively high ($\sim$150 mM), thereby maintaining the parent drug, whereas after entering the low chloride environment of the cell cytosol ($[Cl^-] \sim 4$ mM), the diaquo metabolite is formed. The diaquo cation is more reactive to ligand exchange reactions, which facilitate a further reaction of the platinum with DNA, leading to the adducts responsible for the antitumor activity.

These reactions can be used to understand many of the structure-function relationships among the approved drugs and those that have undergone clinical testing. For example, carboplatin retains the *cis*-diammineplatinum(II) center, but the chlorides have been replaced by the cyclobutanedicarboxylate ligand. The similar array of

Table 5 Hydroylsis and plasma clearance half-lives for cisplatin and carboplatin[87,88]

Drug	Hydrolysis[a] $t_{1/2,\text{hydrolysis}}$ (hrs)	Total platinum clearance[b] $t_{1/2,\text{fast}}$ (min)	$t_{1/2,\text{slow}}$ (hrs)	Free platinum clearance[b] $t_{1/2,\text{fast}}$ (min)	$t_{1/2,\text{slow}}$ (hrs)
cisplatin	2.4	18–37	44–190	22–78	unobserved
carboplatin	268	98	7– > 24	87	354

[a]pH 7 in chloride-free phosphate buffer. [b]Plasma platinum levels measured by flameless atomic absorption spectrometry; 'free Pt' is that passing through a 50 000 Dalton ultrafiltration membrane.

antitumor activities of cisplatin and carboplatin are in part a consequence of the common hydrolysis products that form when the chloride ions and dicarboxylate ligand, respectively, are displaced to form the *cis*-diamminediaquoplatinum(II) as a common metabolite. Yet, the kinetics of the hydrolysis to the diaquo species are dramatically slowed by the chelating dicarboxylate ligand of carboplatin (Table 5). The slow hydrolysis, in turn, exerts a profound effect on the pharmacokinetics of drug clearance from the body. In particular, the long lasting availability of low-molecular weight (''free'') platinum may contribute to the therapeutic profile of carboplatin. The presence of a chelating amine ligand will also affect the metabolism of platinum-based drugs. Since the ammine ligands of cisplatin are retained in complexes formed with DNA, the DACH-containing drug, oxaliplatin (Figure 11(d)), will retain the chelating 1,2-diaminocychohexane ligand when it binds to DNA. The greater bulk and affinity for platinum are likely to confer additional resistance to DNA repair mechanisms, consistent with the in vitro activity of oxaliplatin against certain Pt-resistant cell lines.

The movement of Pt drugs into the cell is modeled in Figure 13, again using cisplatin as the example. When the drug crosses the cell plasma membrane, it encounters a low chloride concentration and is hydrolyzed to the diaquo complex. The target of the drug is DNA, which is encapsulated behind the double membrane of the nucleus. Platinum reacts via ligand exchange principally at the N-7 position of guanine residues to form intra- and interstrand crosslinks with duplex (*see* ***Nucleic Acid–Metal Ion Interactions***).[89] Guanine-Pt-guanine linkages account for 60–65% of the bound Pt. To lesser extent it also reacts to form adenine-Pt-guanine instrastrand crosslinks that account for about 20–25% of the DNA-bound Pt.[86–88] The effect of the crosslinks is to introduce lesions that disrupt the normal base pairing and cause kinks in the double-helical structure of the DNA (Figure 14). In some cell types these lesions are not readily removed or repaired, and the resulting inhibition of replication and transcription adversely affects the cells, leading to apoptosis. Other cells, unfortunately, are able to repair the lesions or develop other means of resistance such as enhanced biosynthesis of metallothionein, a metal-binding protein (*see* ***Metallothioneins***),[89,91] or glutathione, a cellular

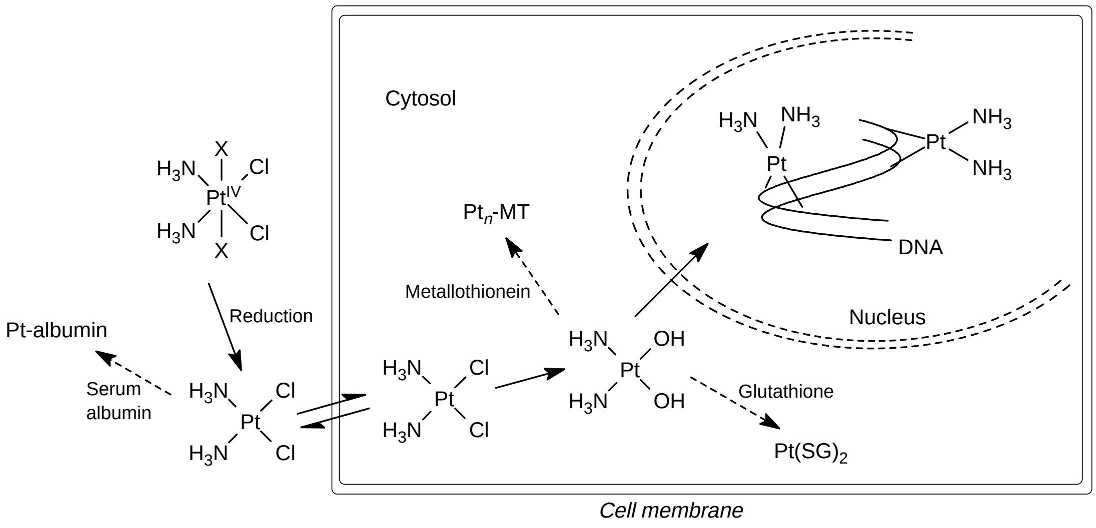

Figure 13 Mechanism of action and competing cellular targets of cisplatin. Solid arrows delineate the normal progression to formation of DNA lesions and dashed arrows represent nonproductive, dead-end reactions with other substances

reductant with an affinity for heavy metal ions, which both bind Pt(II) very tightly.

While binding of cisplatin and its analogues favors the N-7 position of guanine among many possible donor sites in the DNA structure, the reaction is not highly favored over the many alternative non-DNA sites that compete for the platinum.[92] Thioethers can react with cisplatin and in some cases can even displace the amine ligands, but they can in turn be displaced slowly by nucleotides such as guanidine. Sadler carried out interesting competition experiments between methionine, an amino acid with a thioether side chain, and the nucleotide 5′-GMP for $[Pt(dien)Cl^+]$. The sulfur of methionine initially displaces the chloride ion, but is then slowly displaced by the guanine, which reacts at N-7. The biological reductant, glutathione, found at millimolar concentrations in many cells also reacts effectively with cisplatin and analogues.[92,93] In contrast to the reversibility of thioether binding, glutathione is not readily displaced from Pt(II) by nucleotides. MT is another target with a high affinity for Pt(II); it has the ability to react directly with cisplatin without preliminary hydrolysis to the aqueous species.[89,91] MT is a small cysteine-rich metal-binding protein that occurs naturally in cells with Zn^{2+}, and sometimes Cu^+, ions bound to it; exogenous toxic and medicinal metal ions, including Cd(II), Hg(II), Au(I), Ag(I), Pt(II), and Bi(III), react with it after entering cells. Pt(II) complexes react with MT in vivo and in vitro to displace bound Zn^{2+} and the more tightly bound Cd^{2+}.[89,91] The ^{14}C-radiolabelled ethylenediamine ligand in the cisplatin analogue, $[(en)PtCl_2]$, is effectively displaced in reaction with MT, suggesting that both the chloride and ammonia ligands of cisplatin are displaced and that the Pt is fully ligated by cysteine thiolato groups.[89,92]

5 VANADIUM INSULIN MIMICS AND ENHANCERS

5.1 Introduction

Vanadium complexes are under intensive investigation as insulin-enhancing drugs for the treatment of diabetes.[94–97] Because they are orally absorbed, they are potentially very useful for the treatment of diabetes, an increasingly prominent disease in the United States and other nations. Vanadium is found in most plant and animal tissues at low levels and at significantly higher concentrations in tunicates (*see* ***Vanadium in Biology***). It is suggested to be a nutritional trace element, but a specific biological function, which is the sine qua non for essentiality, has not been identified in higher organisms, whereas in many marine organisms and microbes, biological roles for vanadium are now well defined.[98,99] A vanadium-containing nitrogenase enzyme can be biosynthesized by certain bacteria in the absence of molybdenum. Like the molybdenum-containing analogues, the vanadium enzymes have multiple protein subunits and the vanadium is associated with an FeV Cofactor (FeVCo) that has a V:Fe:S ratio of 1:19:19 for the $\alpha\beta_2$ form and 2:30:34 ratio in the $\alpha_2\beta_2$ form in *A. vinelandii*.[98] Lichen and algae also utilize vanadium-dependent enzymes. The brown algae *Ascophyllum nodosum* generates a haloperoxidase that contains two V(V) ions at the active site.[100,101] A vanadium-dependent nitrate reductase, which also has a porphyrin (heme c) cofactor and an N-terminal sequence that is not homologous to the molybdenum-dependent nitrate reductases, has recently been identified in an anaerobic chemolithoautotrophic bacterium. Some species of marine tunicates (in the chordate phylum) accumulate vanadium into their blood cells, imparting a greenish color and, hence, the

name vanadocytes, but no function has been assigned to the accumulated vanadium.[102,103]

5.2 The Element and Ions

Vanadium (Z = 23), was named for the Scandinavian goddess, Vanadis, because of the many brightly colored compounds that it forms (*see* ***Periodic Table: Trends in the Properties of the Elements***). It falls in group 5 (or Vb) of the periodic table and is the lightest element of its triad. The elemental form is bright white in appearance, ductile and soft. Naturally occurring vanadium is almost entirely ^{51}V (99.76% abundance) with a trace of ^{50}V (0.24%). ^{51}V is a useful NMR-active isotope, even though it is a quadrupolar nucleus (I = 7/2). The ^{48}V isotope is a beta emitter having a half-life of 16.0 days, which makes it useful as a tracer in metabolic studies. Complexes in oxidation states from −I to +V have been characterized. The aqueous ions of the lower oxidation states, $[V^{II}(OH_2)_6]^{2+}$ and $[V^{III}(OH_2)_6]^{3+}$, are readily oxidized by air. The principle aqueous ions of the higher oxidation states are the oxo ions, $V^{IV}O^{2+}{}_{(aq)}$ (vanadyl ion) and $V^{v}O_4{}^{3-}$ (vanadate), which at neutral pH exists as an equilibrium mixture of $H_2V^{V}O_4{}^{-}$ and $HV^{V}O_4{}^{2-}$ with a pK_a value of 7.8. The anions are analogous to phosphate ions, but $H_3V^{V}O_4$, a phosphoric acid analogue, is not stable, and at low pH (≤1) the $V^{V}O_2{}^{+}{}_{(aq)}$ is the dominant species. The oxidation states III, IV, and V are most relevant to the aqueous chemistry under biomimetic conditions, and most compounds under consideration for diabetes therapy contain either V(IV) or V(V), although an active V(III) complex of maltol has been identified.

5.3 Insulin-enhancing Vanadium Compounds for Diabetes Mellitus

Diabetes mellitus (DM) is an increasingly common disease of sugar metabolism. Juvenile-onset diabetes, also known as Type I or insulin-dependent diabetes (IDDM), is an autoimmune disease that results in decreased release of insulin by the pancreas. Late-onset diabetes, also known as Type II or non-insulin-dependent diabetes (NIDDM), results from reduced sensitivity of cells to the insulin signal. A convenient animal model for studying diabetes and testing alternative therapies is the streptozotocin-treated diabetic rat. Streptozotocin (STZ) attacks the pancreas and decreases insulin production and release, thus, mimicking many aspects of the human disease.[104] Since insulin is not orally absorbed, the oral administration of vanadium compounds that are insulin-mimetic or insulin-enhancing would be a very attractive therapy[94–97]

The inorganic, bioinorganic and medicinal chemistry of vanadium compounds in the oxidation states III, IV, and V has been studied extensively in this regard. Active compounds of all three oxidation states have been reported to act favorably to improve glucose metabolism. The inorganic salts, particularly sodium vanadate ($NaVO_3$) and vanadyl sulfate ($VOSO_4$) have been carried through phase II clinical testing. They lower gluconeogenesis in the liver, enhance the uptake and oxidation of glucose by adipocytes and stimulate its conversion into glycogen.[94] Although vanadium compounds are sometimes described as insulin mimics, current mechanistic studies suggest that the in vivo actions can better be described as enhancing insulin activity.[105]

The most promising compounds to date are those of V(IV). Figure 15 shows the structures of a variety of vanadyl complexes with chelating ligands that have been prepared and tested in various model systems. The ligands typically function as monoanionic chelating agents, which render the complexes neutral and, therefore, lipophilic, thereby allowing them to pass more easily through cellular membranes by passive diffusion.[94] Table 6 provides further information about their properties. BMOV (bis(maltolato)oxovanadium(IV), Figure 15(a)) has become a benchmark compound for comparison to newer complexes. It is a square pyramidal structure with an axial oxo group, in which vanadium is chelated in a bidentate fashion by two maltol ligands that coordinate via their alkoxy and ketone oxygen atoms. Daily, oral administration of BMOV (0.4 mmol kg^{-1} day^{-1}, which was then lowered to 0.2 mmol kg^{-1} day^{-1}) either in drinking water or by oral gavage (direct introduction to the stomach) produced normalization of blood glucose levels in the STZ-treated diabetic rat. VPA, VO-MPA, VCME, and Naglivan (Figure 15(d–g)) also contain bidentate organic chelates and are also effective when orally administered within the range of 0.1 to 0.7 mmol kg^{-1} day^{-1}.[94] VO-Salen contains a tetradentate Schiff's base ligand (Figure 15(b)). VO-metf (Figure 15(c)), which uses biguanidine ligands, is an example of a metallodrug that incorporates a medicinal ligand effective for the same disorder (metformin or Glucophage™) in the expectation that the metal and ligand will work synergistically.

Bisperoxovanadates with the formulas $[(VO(O_2)_2(L\text{–}L')]^{n-}$ and $[VO(O_2)_2L)]^{n-}$ and monoperoxovanadates with the formulas $[VO(O_2)(OH_2)_2(L\text{–}L')]^{n-}$ and $[VO(O_2)(L\text{–}L')_2]^{n-}$, in which the peroxo ligands bind in an η^2 configuration to form a three-membered ring with the central V(V) center, have also shown good activity in laboratory animals. Their structures are distorted pentagonal bipyramids when a bidentate ligand (L–L′) is used, and a distorted pentagonal pyramid when the ligand are monodentate. The bisperoxo complexes with L–L′ = phenanthroline ($n = 1-$), dimethylphenanthroline ($n = 1-$) and picolinate ($n = 2-$), are effective at much lower doses (~1–6 µmol kg^{-1}) than the vanadyl complexes when administered IV, i.p., or subcutaneously, but only the phenanthroline complex was active (20–200 µmol kg^{-1}) when administered by oral gavage. The neutral oxoperoxodiaquopicolinatovanadium(V) complex with L–L′ = picolinate ($n = 0$) was effective at 0.4 µmol kg^{-1}, whereas the trianionic oxoperoxobis(oxalato)vanadium(V) complex ($n = 3-$) exhibited only marginal activity.

The synthesis, properties, and biological activities of tris(maltolato)vanadium(III) and three analogues have been reported (Table 7). The structures of the [V(ma)$_3$] complex and the ligands are shown in Figure 16. Blood glucose levels in STZ-diabetic rats were determined after 24 hours in comparison to BMOV. The only compound showing significant activity is the tris(maltato)complex, which has activity comparable to that of BMOV, that is, reducing the 24-hr blood glucose level to <9 mM in diabetic rats.

Table 7 Response of STZ-treated diabetic rats to vanadium(III) compounds[106]

	Intraperitoneal administration		Oral gavage
Non-platinum	[glucose]$_{24h}$/mM	Positive responses[a]	[glucose]$_{24h}$/mM

5.4 Metabolism of Vanadium Compounds

Vanadium accumulates in the liver, kidney, and bones of mammals including humans. ^{48}V tracer studies of radiolabeled BMOV, VPA and vanadyl sulfate showed that the liver:kidney:bone ratios of tissue vanadium accumulation were 8:3:2 for ^{48}V-BMOVand 6:4:1 for ^{48}V-$VOSO_4$, with an almost threefold greater overall accumulation of BMOV, clearly demonstrating that the distribution among tissues and the total accumulation are both dependent on the ligation of the complex administered.[91] No toxic or harmful effects of bone accumulation have been reported. The major side effects observed in animal testing and human clinical trials of the vanadium insulin-enhancing agents are episodes of gastrointestinal intolerance and limited weight gain.[96] Green tongue, a phenomenon reminiscent of the greenish vanadocytes in tunicates, has been reported after occupational exposure to airborne compounds in vanadium refineries or to vanadium residues encountered in fuel-fired boiler maintenance operations. The effect is reversible after cessation of exposure and without long-term consequences.

Vanadate enters cells by an active transport process that depends on the structural and electronic similarity to phosphate ion transport, since the isoelectronic species, HZO_4^{2-} and $H_2ZO_4^{-}$, are dominant species for $Z = P$ or V at physiological pH. Neutral vanadyl complexes such as BMOV and $[VO(acac)_2]$, in contrast, enter cells by passive diffusion, which is advantageous for medicinal applications. Accumulating evidence suggests that oxidation-reduction reactions and ligand exchange by hydrolysis and by reaction with endogenous ligands alters the ligation of vanadium and its oxidation states. The binding of vanadium compounds to proteins in the blood alters their bioavailability and transport. A number of studies summarized in recent reviews establish that the order of binding preference tends to be[94,99] transferrin > albumin > immunoglobins.

While the affinity of transferrin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***) for vanadyl is ~10-fold greater than that of albumin, the latter can bind up to 20 vanadyl ions including a specific interaction with cys-34, the only reduced cysteine residue in the protein.

5.5 Possible Mechanisms of Action

As for other several other inorganic medicinal agents, there is not a well-established and generally accepted mechanism of action for vanadium insulin enhancers. After its secretion from the pancreas, insulin concentrations are greatest and its activity is most essential in the liver, muscle and adipose tissue of the body. Crans *et al.* have documented three possible mechanisms that may explain their actions.[99] The most widely studied mechanism is the inhibition of phosphatase enzymes that catalyze the phosphorylation of regulatory proteins. The first enzyme of the insulin regulatory cascade, protein phosphatase 1B (pp1B) is sensitive to vanadium inhibition. Elimination or inhibition of this enzyme leads to increased insulin activity and reduced obesity in mice by preventing phosphorylation of the insulin receptor. Peroxovanadates act as irreversible inhibitors of cysteine-dependent phosphatases by oxidizing the active site cysteines. Vanadyl complexes are competitive inhibitors of phosphatase activity. The overall activity of the drugs in vivo does not, however, correlate with their in vitro inhibitory activity, which may reflect their metabolism in vivo and likely the existence of additional biological actions of the vanadium compounds and metabolites. Reactions of vanadium compounds with transferrin are another mechanism by which metabolic changes can be induced. Binding of vanadyl cation or fragments of vanadium complexes formed by partial ligand displacement may alter metal transport and also the transport of vanadium metabolites in an organism. A third mechanism is the interaction of vanadium complexes with the cellular mechanisms for redox homeostasis. Glutathione, a cellular reductant, is known to reduce vanadium compounds. Since oxidative stress apparently plays a role in the development of the diabetic condition and in the proliferation of complications that can lead to the loss of limbs and other side effects, the interaction of vanadium with the redox state of cells may be an important aspect of its mechanism of action.

Given that the V(III), V(IV), and V(V) oxidation states are all active and that reasonable routes exist for in

vivo oxidation-reduction reactions to interconvert the three states, a redox equilibrium seems quite likely. Since cellular and subcellular environments vary in pH, redox potential, availability of ligands and enzyme activities, a very variable array of metabolites may be present in different tissues and organelles. Indeed, different insulin-enhancing activities may be affected by different oxidation states generated in vivo. For example, peroxovanadates function as irreversible inhibitors of phosphatase enzymes, while vanadyl complexes are reversible inhibitors and much less effective. There is emerging awareness that the vanadium drugs under study may, in fact, be prodrugs that are activated in vivo by redox and ligand exchange processes.

It is interesting that maltol complexes of both V(III) and V(IV) are more active than other analogues with vanadium in the same oxidation state – an observation that suggests some maltol metabolite may have unique or superior activity at one or more sites of action. The finding that $[MoO_2]^{2+}$ and Co(II) complexes of maltol show insulin-mimetic activity – albeit weaker than that of BMOV – is not inconsistent with this suggestion. As a better understanding of vanadium metabolism and the role of the medicinal ligands are delineated, the design of more effective drug molecules can be anticipated.

6 LITHIUM

6.1 Introduction and History

Lithium carbonate (Li_2CO_3) treatment is used worldwide for the prophylactic treatment of bipolar affective disorder. Although the molecular mechanism(s) of action remains uncertain, the efficacy is well-demonstrated and can be maintained by continued use of the drug. Lithium succinate is used to treat seborrheic dermatitis, a skin disorder. Other uses currently being explored include treating immunological disorders and cancers.[107,108] Schrauzer has proposed that lithium may be an essential trace element and has suggested a daily intake of 1.00 mg day^{-1}.[109]

Dr. J. F. J. Cade, an Australian psychiatrist, first reported on the beneficial use of a lithium compound for a psychiatric disorder, namely, manic behavior in 1949.[110] The early human trials were undertaken after initial experiments on rats, which became quite lethargic after treatment with lithium urate.[110,111] Fairly large doses were required for treating manic behavior and its use for this disorder has been displaced by organic drugs that carry less risk. His report, however, led to its current use as a treatment for bipolar affective disorder (also known as manic-depressive disorder).[112,113] Its use in the United States was curtailed for a decade and a half by the US. Food and Drug Administration (FDA), which based its decision on incidental poisonings due to overuse of a lithium-based table salt substitute, despite a safe record of controlled psychiatric applications in Europe.[114] It has been estimated that by 1985 lithium treatments had saved the world at least 17.5 billion in medical expenses and by reduction of lost productivity.[115]

6.2 The Element and Ion

Lithium (Z = 3) is the smallest of the alkali metals in group I (*see* ***Periodic Table: Trends in the Properties of the Elements***). It occurs naturally in brines and pegmatites and is found in river water at concentrations of $\sim 2\,\mu M$.[116] Plants accumulate it and transfer it to humans and animals at low concentrations.[109] Elemental lithium is a soft, pale silvery substance that can be cut with a butter knife and is easily deformed. Naturally occurring lithium consists of two isotopes, ^{6}Li and ^{7}Li, which are 7.42 and 92.58% abundant. The three additional isotopes that have been prepared synthetically, ^{5}Li, ^{8}Li, and ^{9}Li have half-lives of $\sim 10^{-21}$ sec, 0.86 sec, and 0.18 sec, respectively, which are too short to allow effective use as radiotracers in biological experiments. The ^{6}Li and ^{7}Li nuclei are both quadrupolar, $\mu_{^6Li} = 1$ and $\mu_{^7Li} = 3/2$, respectively. The ^{7}Li isotope has proved extremely useful for NMR experiments both in vitro and in vivo. Lithium forms a single stable ion, Li^+, by loss of a single electron from the outer 2s subshell. The very negative standard reduction potential indicates that oxidation to Li^+ is favorable:

$$Li^+ + e^- = Li^0 \qquad E_o^{\,2} = -3.045 \text{ volts.} \tag{8}$$

As a consequence, it is reactive toward air and forms lithium hydroxide by reaction with oxygen and moisture in the air, necessitating storage under oil or an inert environment. Its chemistry is that of the 1+ ion, since the inner core electrons are not easily removed. The very small ionic radius, 0.60 Å, causes Li^+ to be strongly hydrated in aqueous solution. Thus, the effective ionic radius increases to 3.40 Å in solution; the 5.6-fold increase from free ion to aqueous ion is far greater than for any other alkali metal ion. The large charge-to-radius ratio makes it atypical of the heavier alkali metal ions and more like magnesium in some of its chemical properties. For example, both tend to form polar-covalent organometallic species, RLi and RMgX, whereas the heavier group I and II elements form less stable and more reactive ionic species.

6.3 Psychiatric Uses

Manic depression currently affects up to 2 percent of the world's population. Clinical studies demonstrate proven effectiveness of lithium treatment for bipolar affective disorder.[113,117,118] Lithium is taken orally and has been used successfully by some patients for periods exceeding a decade. The action is prophylactic, meaning that it is able to prevent the occurrence of the manic and depressive mood swing phases of the disease once the patient has been

taking it for a period of time. It functions very well in typical cases of bipolar disorder and is more efficacious than the anticonvulsant carbamazepine (5H-dibenz[b,f]azepine)-carboxamide.[113,117,118] It is effective in cases with mood-incongruent psychotic features or with rapid cycling,[117] but may not be as effective as carbamazepine for cases with atypical manifestations.[118] A recent metaanalysis of previous studies confirms the efficacy of lithium therapy for relapse prevention and suggests that it prevents manic episodes more effectively than depressive episodes. On the other hand, there is a clearly documented reduction of suicides among patients receiving lithium treatments,[117,118] and Schou, who had an important role in the development and acceptance of lithium therapy, recommends it, on the basis of an extensive literature review, for patients at high risk of committing suicide.[117]

A double-blind, placebo-controlled trial of the use of lithium to augment antidepressant medication for treating unipolar major depression has shown it to be beneficial for patients receiving continuation therapy following acute therapy for a major depressive episode.[119,120] The 14 patients in the lithium-treated group suffered no relapses over 4 months, while seven of the 15 patients in the placebo-treated group experienced relapses including one suicide.[119]

A number of competing hypotheses have been proposed to explain the action of lithium against affective bipolar disorder. As with other metallodrugs that are widely distributed in the body, it is difficult to identify the causative biological activities when many systems and pathways are incidentally inhibited or stimulated. It is not clear that a single mechanism explains both the antimanic and the antidepressant activities that are observed clinically.[107,108,117] Three principal hypotheses for the mechanism of action are presently being investigated. Lithium inhibits the normal phosphoinositide signaling system, leading to depletion of inositol in the hypothalmus, and also inhibits adenylate cyclase, which in turn lowers cyclic-AMP levels. Both effects have been suggested to contribute to the clinical benefits.[107,108] It has been pointed out, however, that the brain levels of inositol in humans are higher than those in laboratory animal models, and that, therefore, the role of phosphoinositide signaling system may not be central to the action of lithium in affective bipolar disorder. Inhibition of Mg^{2+}-dependent G-protein activation has also been proposed as a mechanism of action, which would also affect cell signal transduction pathways in the brain.[121] The third proposed mechanism is based on a specific membrane disorder in bipolar disorders.[122] Interestingly, there is evidence for a genetic predisposition for responses to lithium therapy.[123]

6.4 Pharmacology

Following oral administration, lithium is widely distributed in the body with the largest accumulations in bones (>1 mmol kg^{-1} wet weight) and teeth (Figure 17) based on a metaanalysis of nine independent studies.[107] The kidney, thyroid, and adrenal glands accumulate between 0.3 and 0.4 mmol kg^{-1} wet weight, while the brain concentrations are somewhat below 0.2 mmol kg^{-1} wt weight.[107] Oral dosing of patients with lithium carbonate (250 mg in previously untreated subjects) leads to plasma levels of ca. 0.2 mmol L^{-1} after 1 to 4 hours, followed by a decay over the next 72 hours (Figure 18). Excretion is through the kidneys, and the decay is multiphasic, but has an approximate half-life of $t_{1/2} = 24$ hours. Dosage varies up to 2.0 g (~30 mmol) of lithium carbonate per day, and is typically in the range of 800 mg (~11 mmol) of Li_2CO_3, which is formulated with a binder such as guar gum or

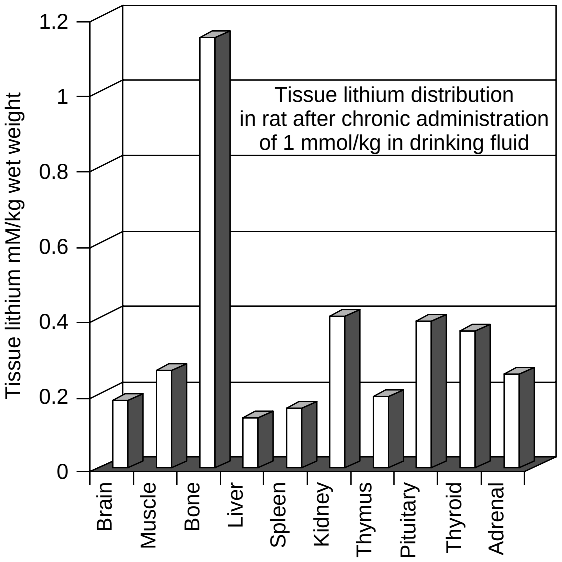

Figure 17 Distribution of lithium among organs of the rat after chronic ingestion 1 mmol kg^{-1} of lithium carbonate in the drinking water, normalized databased on a metaanalysis of 9 studies, as reported in Ref. 107. (Reprinted with permission from © 1999 American Chemical Society)

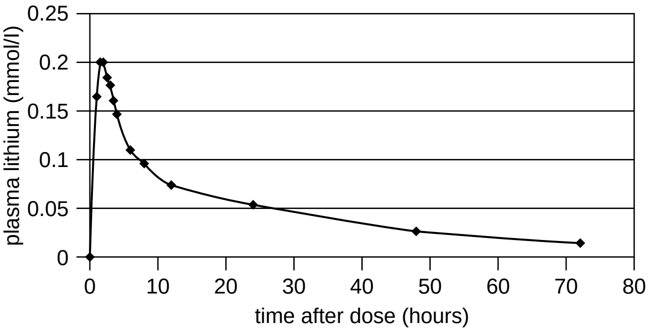

Figure 18 Plasma levels of lithium following a single dose of oral lithium carbonate (250 mg Li) in previously untreated subjects. (Reprinted with permission from Ref. 107 © 1999 American Chemical Society)

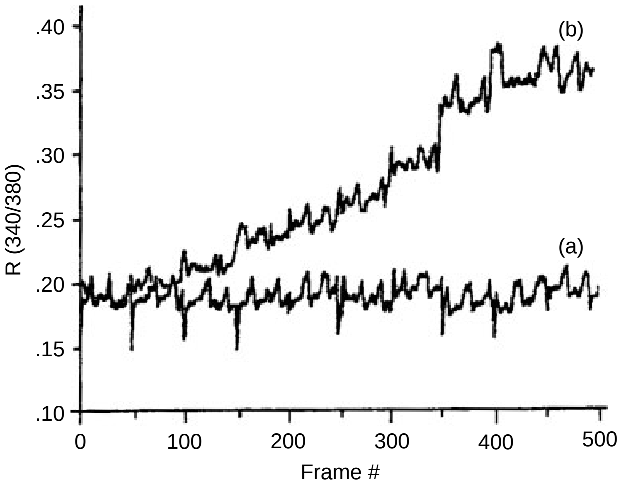

Figure 19 Time-dependent fluorescent monitoring of free Mg^{2+} in neuroblastomas cells demonstrates the Li^+/Mg^{2+} competition that releases bound Mg^{2+} (curve B) Li-perfused cells, compared to untreated cells (curve A). Each frame represents 0.33 seconds. (Ref. 124. Reproduced by permission of Biophysical Society)

methyl cellulose.[107] The target serum levels are in the range 0.4–0.8 mmol l^{-1}, which is achieved cumulatively after multiple, daily doses.

The ability of Li^+ to compete with Na^+ in cell membranes and with Mg^{2+} in a variety of sites has been well documented in biochemical and cellular systems. Fluorescence spectroscopy, using, for example, the dye furaptra, ^{7}Li NMR, and to a lesser extent ^{31}P NMR methods have all been applied to examining the competition.[124] Figure 19 shows fluorescent monitoring of the displacement of Mg^{2+} from cellular binding sites in the neuroblastomas cell line SH-Sy5Y after exposure to Li^+, leading to an increase in free Mg^{2+}. Similar results were obtained by ^{31}P NMR spectroscopic monitoring of the ATP α and β phosphate chemical shifts, which increase upon Li^+/Mg^{2+} exchange.[124] Table 8 compares the affinity of Li^+ and Na^+ for cell membrane sites in (unsealed) RBC ghost cells and cytoskeleton-depleted cells (csd-RBCs), studied by ^{23}Na and ^{7}Li NMR methods.

The cytoskeleton causes a reversal of the expected affinity of the monovalent cations for membrane binding sites, leading to the order $Na^+ > Li^+$, whereas its depletion causes the binding preference to revert to the electrostatically expected order, $Li^+ > Na^+$.[124]

Table 8 Li^+ and Na^+ binding constants for red blood cell membranes[124]

Constant	Unsealed RBC Membranes	csd-RBC Membranes
K_{Li}	209 M^{-1}	321 M^{-1}
K_{Na}	292 M^{-1}	262 M^{-1}

6.5 Topical Applications

Lithium succinate (Efalith)[125–127] and lithium gluconate[128] are effective topical treatments for seborrheic dermatitis, which affects the face and other oil-secreting areas of the body. The causative agent has been identified as the yeast, *Pityrosporum ovale*.[126,129] Two British multicenter double-blind, randomized studies and another in Belgium, which compared lithium succinate (8%) ointment to the vehicle, have demonstrated that the succinate successfully treats the majority of the patients.[129,130] The benefits are observed within days after onset of treatment and last significantly beyond the cessation of treatment. It has been found specifically useful for AIDS patients,[130] among whom a high incidence of infection is observed.[129,130] The action of the lithium succinate is apparently directed against the lipid metabolism of the yeast,[126] but not its growth,[127] and may exert an anti-inflammatory response in the patients.[130]

6.6 Potential New Uses

Lithium compounds are under investigation for a number of additional medical uses. Salzman has reviewed 21 additional potential uses of lithium in psychiatry that have been reported in the literature.[120] Lithium has been shown to inhibit herpes, pox and adenoviruses in vitro and lithium succinate ointment is useful in treating herpes simplex infections.[131] Interestingly, patients with dipolar disorder who are treated with oral lithium carbonate exhibit a reduction in the frequency of labial herpes recurrence.[132] Lithium reduces brain damage in animal models of certain neurodegenerative diseases and has been shown to inhibit expression of apoptotic proteins, p53 and Bax, which leads to the possibility that it may be useful in treating neurodegenerative diseases.[133]

7 OTHER METALLODRUGS – IN USE OR IN DEVELOPMENT

7.1 Introduction

This section briefly reviews a number of additional classes of metallodrugs that are of interest at the intersection of biological inorganic chemistry and modern medicine. Antimony and arsenic have important, life-saving antiparasitic activities, while bismuth is a key antiulcer treatment and useful for other gastrointestinal disorders. The success of cisplatin and its analogues has stimulated intensive searches for complexes of other metal ions with antitumor activity.[134–136] Although many promising candidates with suitable cytotoxicity and bioavailability have been identified, toxicity concerns, patent issues and other factors have kept most from reaching even Phase I clinical testing. The examples listed in Table 9 are discussed briefly in this section,

Table 9 Non-platinum metals under investigation as antitumor agents

Metal	Z	Examples	Refs.
Ruthenium	44	*trans*-$[Cl_4(Ind)_2Ru^{III}]^-$, *trans*-$[Cl_4Im_2Ru^{III}]^-$, *trans*-$[Cl_4(Me_2SO)ImRu^{III}]^-$	134,135
Gallium	31	$Ga(NO_3)_3$, [(8-quinolinolato)$_3$ Ga^{III}]	134,138,139
Gold	79	$[Au^I(Ph_2PCH_2CH_2PPh_2)_2]^+$, $[(damp)Au^{III}Cl_2]$	53,54
Titanium	22	*cis*-$[(CH_3CH_2O)_2(bzac)_2Ti^{IV}]$, $[(\eta^5\text{-}C_5H_5)_2Ti^{IV}Cl_2]$	134,140,141
Tin	50	$(n\text{-}Bu)_3Sn\text{-}S\text{-}CH_2\text{-}CH_2\text{-}NH_3^+$	134,142
Vanadium	23	$V^{IV}OSO_4$, NaV^VO_4, $[V^{IV}O(maltolato)_2]$	134
Arsenic	33	As_2O_3	143–146

except for gold antitumor agents, discussed in Section 2.6. Recent overviews of the metallodrugs under development as antitumor agents can be consulted for further detail.[134–137]

7.2 Ruthenium Antitumor and Nitrogen Oxide Scavenging Agents

Ruthenium complexes have shown considerable promise as antitumor agents, and some may act via mechanisms other than DNA binding.[134,135] Octahedral Ru^{III}polyam(m)ine (Am) complexes, $[Ru^{III}(Am)_nX_{6-n}]^{+/0/-}$ (Figure 20) exhibit favorable cytotoxicity in cell culture and are correspondingly active in animal models against a variety of tumor lines. Correlations between their DNA binding ability and biological activity have been observed. Trichloro and tetrachloro complexes exhibit the best activity. *mer*-$[Ru^{III}L^3Cl_3]$ complexes, where L^3 represents planar tridentate ligands such as terpyridine have activities comparable to cisplatin. Tetrachloro complexes such as *trans*-$[Ru^{III}Cl_4(Im)_2]^-$ (Im = imidazole) are typically more active against a wide variety of tumors, especially with ImH^+ as the counterion. The compound *trans*-$[Cl_4(Ind)_2Ru^{III}]^-$ (Ind = indazole; KP1019, Figure 20(c)) has entered clinical trials.[147]

The trinuclear ruthenium red complex, $[(H_3N)_5Ru^{III}ORu^{IV}(NH_3)_4ORu^{III}(NH_3)_5]^{6+}$ accumulates in the mucopolysaccharide coat of tumor cells and inhibits their growth.[134] Active,

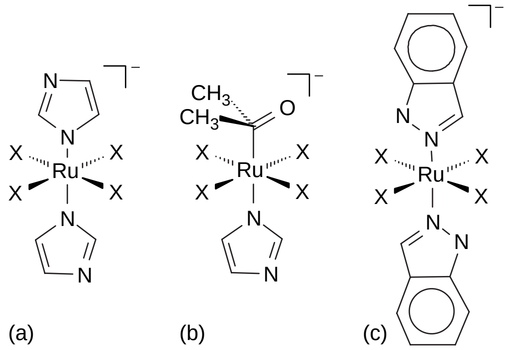

Figure 20 Structures of (a) *trans*-$[Ru(Im)_2X_4]^-$; (b) *trans*-$[Ru(DMSO)(Im)X_4]^-$ (Im = imidazole), the anionic constituent of NAMI and NAMI-A; (c) *trans*-$[Ru(Ind)_2X_4]^-$ (Ind = indazole) the anionic constituent of KP1019

octahedral Ru^{III} and Ru^{II} complexes of EDTA-like ligands (polyaminopolycarboxylates) damage and alter the conformation of DNA molecules, which inhibits DNA recognition. Pyrimidines bind via η^2 coordination of the C_5-C_6 double bond or by forming η^1 links to N_1 and N_3 positions. *cis*-$[Ru^{III}Cl_2(pdta)]$ stimulates the respiratory burst of neutrophil cells and the NADPH oxidase-dependent release of superoxide, which is potentially a second mechanism of cytotoxicity.

NAMI and NAMI-A, the respective imidizolium and sodium salts of *trans*-$[Cl_4(Me_2SO)(Im)Ru^{III}]^-$ (Figure 20(b)) show promise against metastatic tumors, which are generally refractory to treatment. They appear to act extracellulary rather than by DNA binding. The activity of metalloproteinases is lowered at the transcriptional level by down-regulating the levels of mRNA for the matrix metalloproteinase MMP-2 relative to that for TMP-2, an inhibitor for MMP-2. This, in turn, slows metastasis of tumors and may find use in postsurgical or postradiation therapies.[134,135]

Ruthenium complexes have also been explored as potential NO scavengers.[148,149] NO is generated in vivo by the constitutive nitric oxide synthetase enzyme (c-NOS) as a messenger in the course of normal physiological signaling processes (especially in vasodilation), but is also generated by an inducible nitric oxide synthase (i-NOS) in macrophage cells, which overproduces it in certain disease states (diabetes, arthritis, inflammation, epilepsy, which are chronic diseases, and septic shock, which is acute and sometimes fatal) (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***). $K[Ru^{III}(Hedta)Cl]$, JM1226, acts as a scavenger and has potential use in treating such disease states. It undergoes hydrolysis to the corresponding aquo species, $[Ru^{III}(Hedta)(OH_2)]$, which reacts by ligand exchange to form the nitrosyl complex, $[Ru^{II}(edta)(OH_2)NO]^+$, formally a ruthenium(II) species bound to the NO^+ ion.[148,149]

7.3 Gallium Antitumor and Hypercalcemia Treatments

Gallium (Z = 31) in group 3(A) of the periodic table (*see* ***Periodic Table: Trends in the Properties of the Elements***) is an effective antitumor agent for lymphomas and bladder carcinoma.[134,138,139,147] It is most often administered as a slow infusion of gallium nitrate, $Ga(NO_3)_3$. Although the fully aquated ion $[Ga(OH_2)_6]^{3+}$ is quite acidic and precipitates as amorphous hydroxides, it reacts with transferrin in vivo in the

blood serum almost completely, partially displacing iron, at the therapeutic concentrations of 10–15 μM.[134,138] The ability to mimic iron is important in the delivery of gallium to tumor cells by transferrin and also in the likely mechanism of action, as Ga^{3+} binds to and inhibits the iron-enzyme ribonucleotide reductase (*see* ***Iron Proteins with Dinuclear Active Sites***), which converts ribonucleotides to deoxyribonucleotides, thus depriving tumor cells of DNA precursor molecules needed for replication. Complexes of gallium have been explored as alternate means of administration and delivery to tumor cells. Complexation by the iron-siderophore, deferoxamine, inhibits cell growth and induces apoptosis. Chelating ligands such as citrate, 8-hydroxyquinoline and 3-hydroxy-4-pyrones increase bioavailability, in part by reducing the extent of hydrolysis. tris-(8-Quinolinolato)gallium(III) (KP46) has entered clinical trials.

Gallium nitrate is used clinically, at lower doses than for treating tumors, to treat hypercalcemia associated with bone cancers.[134,139] It incorporates into bone at very low levels and prevents calcium resorption, leading also to higher phosphate and collagen levels, and hence sturdier bone structure.[134,139]

7.4 Titanium Antitumor Agents

Titanium (Z = 22) is the lightest element of the group 4 (4B) triad of the periodic table (*see* ***Periodic Table: Trends in the Properties of the Elements***). Ti(IV) is the most stable oxidation state, but Ti(III) and Ti(II) complexes are also commonly encountered. The antitumor activity of titanium(IV) compounds has been investigated extensively,[134,140,141] Titanocene dichloride $[(\eta^5\text{-}C_5H_5)_2Ti^{IV}Cl_2]$ and budotitane (Figure 21) are among the few non-platinum metal compounds to enter clinical trials. They show activity against a variety of tumor types and are most effective against gastrointestinal tumors.[134,140,141] The titanocenes are the most active of a series of $[(\eta^5\text{-}C_5H_5)_2MX_2]$ complexes (M = Ti, V, Nb, Mo; X = halide) to exhibit significant activity. They are prodrugs that undergo rapid hydrolysis and subsequent acid dissociation,[134] not unlike cisplatin. The most acidic diaquo complex is diaquotitanocene, $pK_{a1} = 3.51$ and $pK_{a2} = 4.35$, which generates the neutral dihyroxo species, $[(\eta^5\text{-}C_5H_5)_2Ti(OH)_2]$, at physiological pH. Transferrin may play a role in delivering Ti^{IV} to tumor cells.[138] Titanocene dichloride blocks collagenase IV activity (a Zn-dependent matrix metalloproteinase enzyme) and may act by preventing angiogenesis.

Budotitane, $[(EtO)_2(bzac)_2Ti^{IV}]$, exists in solution as three equilibrating structural isomers resulting from differing orientations of the benzylacetonate ligands relative to the mutually cis ethoxy groups. The isomers are in thermal equilibrium: *cis-cis-cis*, Figure 21(b), 60%; *cis-trans-cis*, 21%; and *cis-cis-trans*, 19%. Only recently has one of the isomers, *cis-cis-trans*-budotitane with the acetate oxygens mutually trans, been isolated and crystallized.[150] The

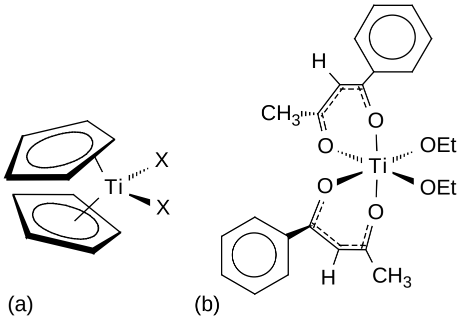

Figure 21 Structures of (a) titanocene dihydroxide, the dominant hydrolysis product of titanocene dichloride; (b) *cis-cis-cis*-budotitane (*cis-cis-cis*-$[(EtO)_2(bzac)_2Ti^{IV}]$), the dominant solution isomer in an equilibrium with the *cis-trans-cis*- and *cis-cis-trans*-isomers

availability of a single pure isomer may facilitate further clinical studies.

7.5 Tin Antitumor Agents

Many classes of organotin(IV) compounds (*see* ***Tin: Organometallic Chemistry***) have been tested for antitumor activity.[134,151] Organotin compounds have a wide range of biological activities and have had widespread use as biocides in paints, although their use as marine-antifouling agents has been curtailed.[142] The general order of toxicities is $R_3SnX > R_2SnX_2 > RSnX_3$. The nature of the R group affects their solubility and biological activity. The *n*-butyl group and to a lesser extent the phenyl and benzyl groups show the greatest promise in balancing solubility and lipophilicity. Serious neurotoxic effects, especially for shorter-chain trialkyltin complexes, and immunosuppressive effects are the most serious side effects. A wide variety of mono-, di-, and polydentate inorganic ligands have been tested. A series of tri- and di-*n*-butyltin cysteaminates and *N*,*N*-dimethylcysteaminates have been examined and found to have much lower ID_{50} values than cisplatin, etoposide, or 5-fluorouracil when tested against a panel of seven human tumor lines.[152]

7.6 Arsenicals Past and Present

Arsenic is in group 15 (VA) of the periodic table, lying between phosphorus and antimony (*see* ***Periodic Table: Trends in the Properties of the Elements***). Arsenic has two principle oxidation states, As(III) and As(V). It is a highly toxic element that is carcinogenic and also a classical poison (*see* ***Metal Ion Toxicity***). In some regions of the world, most notably Bangladesh, arsenic in the drinking water is a serious public health concern.[153] Solid forms of arsenic present in geological formations can be mobilized by prokaryotes that utilize oxyanions of arsenic for energy generation under

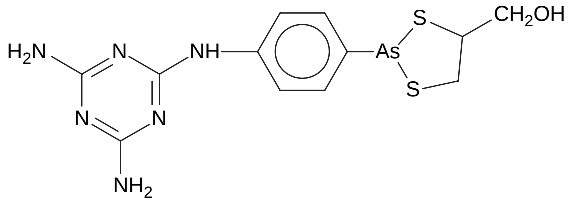

Figure 22 Melarsoprol contains a phenylarsine moiety coordinated by dimercaptopropanol (BAL) linked to a para-melamine functional group

anaerobic conditions and release the arsenic to the aqueous phase.[154]

Paul Ehrlich developed arsenicals in parallel efforts to cure syphilis and trypanosomiasis (African sleeping sickness), which is transmitted by mosquitoes. A considerable number of organoarsenicals, especially substituted phenyl derivatives were prepared and tested against these infectious diseases. Loevenhart and Stratman-Thomas's 1928 review of Ehrlich's work provides a fascinating view of medicinal chemistry in its early stages.[155] While syphilis is no longer treated with arsenicals, melarsoprol (Figure 22) finds continuing use in the treatment of the second stage of trypanosomiasis, when the trypanosomes reside in the cerebrospinal fluid, where they are no longer accessible to other treatments (pentamidine and suramin) that are effective in the earlier stage of infection.[156] The structure of melarsoprol is based on a phenylarsine moiety, in which the arsenic is coordinated by dimercaptopropanol (BAL) and a melamine functional group is para-substituted on the phenyl ring.

Arsenic trioxide (As_2O_3, ATO) had historical applications against leukemia, but was then set aside for a period of time. In the 1990s, it was shown to be effective against acute promyelocytic leukemia (APL),[143] and has been approved by the FDA (Trisenox™)[144] Its success in this therapy has led to testing against related tumors, notably myelodysplastic syndrome (MDS)[143] and multiple myeloma (MM),[145] which remains uncurable. Phase II clinical trials have demonstrated the effectiveness of As_2O_3.[145] Its actions include up-regulation of lymphokine-activated-killer (LAK) cells and degradation of the PML-RARalpha chimeric gene that blocks differentiation of the host-organism granulocytes, a class of immune cells.[146] At the molecular level, As_2O_3 reacts with thiols to inhibit a variety of enzymes related to the cancer growth. High concentrations act on mitochondria in a thiol-dependent manner to induce cell apoptosis.

7.7 Antimony Antiparasitic Agents

Antimony (Z = 51) lies between arsenic and bismuth in group 15 (*see* ***Periodic Table: Trends in the Properties of the Elements***). It has been used medicinally since the age of the alchemists. Like other members of its group it readily forms compounds of the +3 and +5 states. Although relatively little attention has been paid to this element by the inorganic biochemistry community, several compounds have important medicinal properties. Tartar emetic ($K_2[Sb_2(d\text{-}C_4O_6H_2)_2]\cdot 3H_2O$) has been used for over 300 years in the treatment of schistomiasis and leishmaniasis. The compound consists of two Sb(III) ions linked by two tartaric acid molecules. Sodium stibogluconate, which contains two Sb(V) ions linked to two gluconic acid molecules, remains an important treatment for leishmaniasis. As with other antibiotics, the evolution of resistant parasite strains is reducing the effectiveness of antimonicals in the tropical nations where its use is most important. Research on the mechanisms of induction of resistance and the structures of the proteins involved in resistance gives hope that cotreatment with an antimony compound and an inhibitor of either the induction mechanism or the resistance conferring proteins will allow effective treatments to continue.

7.8 Bismuth Antiulcer Complexes

Bismuth has a well-accepted role in the treatment of ulcers and other forms of gastric distress including diarrhea, dyspepsia, and general gastric distress. Indeed, bismuth might be rated the foremost of all metallodrugs based on (i) sheer mass of bismuth compounds consumed for medicinal purposes, over 700 tons per annum in just the United Kingdom and United States and (ii) the unusual validation by present-day scientific knowledge and medical practices of a treatment first reported in the 15th century. In complementary reviews, Sun and Sadler describe the inorganic basis of bismuth medicinal agents and their mechanisms of action as presently understood,[157] while Briand and Burford have impressively catalogued the literature on bismuth compounds and their formulations and uses, organized in a series of extensive tables that facilitate retrieval of over 1000 references.[158]

Bismuth (Z = 83) is the heaviest stable element in group 15 (VA) of the periodic table (*see* ***Periodic Table: Trends in the Properties of the Elements***). The ^{201}Bi isotope, which is 100% abundant, has a 9/2 nuclear spin. ^{212}Bi, an alpha emitter is used in nuclear medicine as a radiotherapeutic agent.[159,160] Bismuth has two stable oxidation states: Bi(V), corresponding to complete loss of the valence electrons, and Bi(III), a lower oxidation state that retains two valence electrons. Both oxidation states are diamagnetic. The latter is more stable and more common since Bi(V) has a large reduction potential:

$$\mathrm{Bi(V)} + 2e^- = \mathrm{Bi(III)} \qquad E^0_{1/2} = 2.03\ \mathrm{V} \tag{9}$$

Bismuth occurs in nature as Bi_2O_3 and as bismuth sulfide ores. This reflects the fact that Bi(III) is an intermediate acid in the Pearson's classification of hard and soft acids-bases (*see* ***Hard & Soft Acids and Bases***). Interestingly, over-the-counter drug formulations involve primarily oxygen-donor ligands such as salicylate, citrate, and nitrate, while in vivo reactions

include formation of bismuth metallothionein complexes, for which Bi–S ligation is extremely important. Bi(III) has a rich coordination chemistry with complexes ranging from three to ten-coordinate. Three-coordinate structures such as Me_3B and $Bi(SAr)_3$ are trigonal pyramidal owing to the presence of a stereochemically active lone pair, as found for the lighter group V elements such as nitrogen and phosphorus. The nonaaquo complex, $[Bi(OH_2)_9]^{3+}$ found in the trifluoromethylsulfonate salt is a tricapped trigonal prism,[161] but in aqueous solution a variety of oxo- and hydroxy-bridged species such as $[Bi_6O_6]^{6+}$, $[Bi_6O_4(OH)_4]^{6+}$, $[Bi_6O_6(OH)_3]^{3+}$ and $[Bi_6(OH)_{12}]^{6+}$ are present at various pH conditions. The triethylenetetraminehexaacetate complex contains a 10-coordinate Bi(III) ion.[162]

In the medicinal agents used to treat ulcers, Bi(III) is complexed to oxygen-donor ligands (Table 10). Bismuth-subsalicylate (BSS) is marketed as Pepto-Bismol™, CBS as De-Nol™ and RBC as Tritec™ and Pylorid™. Ranitidine is an organic H_2 antagonist that works synergistically with bismuth in RBC. Although the bacterium *Helicobacter pylori* had been known for over a century, it was discovered to be the causative agent for ulcers only in 1983. It uses two metalloenzymes, urease, which has two nickel ions at the active site (*see* ***Nickel Enzymes & Cofactors***), and a manganese-dependent catalase (*see* ***Manganese Proteins with Mono- & Dinuclear Sites***). The urease catalyzes cleavage of urea into ammonia and CO_2 thereby neutralizing its immediate environment in the normally acidic stomach mucosa, while the Mn-catalase catalyzes the disproportionation of H_2O_2 to oxygen and water to protect the bacterium against neutrophil cells activated by the immune system. The composition and structures of the bismuth antiulcer formulations are sensitive to pH and concentration effects and many variants can be identified by NMR and electrochemical studies of the solutions and by crystallization and X-ray structure determination.[157,158]

Newer agents under investigation include tris(tropolonato) Bi(III) and nitratobis(tropolonato)Bi(III); a host of bis (mercaptoethanol)Bi(III) complexes, which are formed with O,S-bidentate chelation, with and without deprotonation of the hydroxyl oxygen and usually having an axial fifth ligand; and sialic acid derivatives of Bi(III).[157] The interactions of Bi(III) and its compounds with metallothionein, serum albumin and transferrin have been studied by a variety of groups, as have a number of enzymes that may be related to the mechanism(s) of action of bismuth in treating ulcers.

In the 1930s and 1940s, bismuth formulations were used extensively to treat syphilis,[158] but they have since been supplanted by more effective antibiotics. More recently, bismuth complexes have been examined for antitumor activity,[163,164] Tiekink compared the literature results for antimony(III), antimony(V), and bismuth(III) with the conclusion that Bi(III) was most promising among these possibilities.[164]

8 CONCLUDING REMARKS

As a scientific discipline, metals in medicine (or inorganic medicinal chemistry) is healthy and active. Potential new metal-based drugs directed at a wide variety of pathological conditions are reported every year. Specialists in the field have developed an increasingly sophisticated understanding of how metal ion activity and toxicity can be targeted and modulated (or tuned) by altering the oxidation states and ligation of the metal ion. A variety of proteins (e.g. serum albumin, metallothionein, transferrin) that can alter the chemical state and bioavailability of metal ions and their complexes have been identified and characterized. Similarly, small molecule redox-active species and ligands are known and their reactions well characterized. The roles of oxidation-reduction reactions, ligand exchange reactions and aggregation in metallodrug metabolism have been identified. Useful screening models have been developed for many target diseases, but remain lacking for other, sometimes equally important diseases. Despite these advances, only a disappointingly small number of compounds have proceeded through clinical trials to approval by national drug agencies. This reflects in part concerns of large drug firms about toxicity and liability issues and conservatism on the part of regulatory agencies. Patent issues are also a concern since the greatest activity in the field remains in academic laboratories. One hopeful sign is the formation and evolution of small entrepreneurial companies that are targeting metallodrug discovery and development. With almost a hundred elements beyond carbon, nitrogen, oxygen, and phosphorus, the periodic table, in combination with many thousands of unique ligands, remains a relatively unexplored source of new compounds that may exceed the potential of the world's rainforests.

Table 10 Bismuth-based antihelicobacter pylori formulations[157]

Compound	Formula	Aqueous solubility	MIC_{50}/nM
Bismuth subnitrate	$Bi(O)NO_3$	Insoluble	0.45
Bismuth subgallate	$Bi(OH)C_7H_4O$	Insoluble	0.04
Bismuth subsalicylate	$Bi(O)C_7H_5O_3$	very low	0.09
CBS[a]	$K_3(NH_4)_2[Bi_6O_3(OH)_5(C_6H_5O_7)_4]$	soluble	0.04
RBC[a]	$[ranitidine]^+$ Bi(citrate)	soluble	0.011

[a]CBS = colloidal bismuth subcitrate; RBC = ranitidine bismuth citrate; approximate formulas.

1 INTRODUCTION

Radiopharmaceuticals are drugs that contain a radionuclide and are routinely used for diagnosis and treatment of disease. This entry discusses imaging agents that are useful for diagnosis (*see **Metal-based Drugs***), focusing on the growing class of metal-based imaging agents, wherein the radionuclide is a transition metal or posttransition metal. The most widely used radionuclide for radiopharmaceuticals is technetium-99m, ^{99m}Tc.[1–3] The radionuclides ^{67}Ga, ^{111}In, ^{210}Tl, ^{57}Co, and ^{51}Cr are used in the clinic as well.[4] There are a number of radioisotopes, including ^{64}Cu, ^{67}Cu, ^{68}Ga, that show promise for diagnostic purposes.[5]

1.1 Requirements for a Diagnostic Imaging Agent

The physical properties of the radionuclide are paramount for its use in diagnostic imaging (Table 1). First, the radionuclide should emit penetrating radiation, either gamma or positron emission, that is detected outside the body. γ-ray emission is the basis of Single Photon Emission Computed Tomography (SPECT), used for imaging radiopharmaceuticals based on ^{99m}Tc, ^{111}In, ^{67}Ga, or $^{123/131}$I. The energies of the emitted gamma photon should be in the range of 100–250 keV, the window of current gamma cameras. Radiopharmaceuticals for Positron Emission Tomography (PET) emit a positron (β^+) that results in the production of two 511 keV annihilation photons that are emitted at an angle of 180° (with respect to each other). PET scanners contain a circular array of detectors with coincidence circuits designed to specifically detect the 511 keV photons emitted in opposite directions. The most widely used PET radiopharmaceutical is ^{18}F fluorodeoxyglucose (FDG) for imaging glucose metabolism. Radiometal positron emitters for diagnostic imaging under investigation include ^{62}Cu, ^{64}Cu, and ^{68}Ga.

Other requirements for an effective radiopharmaceutical include a half-life that is long enough to synthesize, purify the radiopharmaceutical, inject the drug into the patient, allow it to localize and image the desired area with PET or SPECT instrumentation. The half-life should be commensurate with the procedure. For example, small molecule heart and brain perfusion-based agents require shorter half-lives because they reach the target quickly. Radionuclides with longer half-lives are generally required for imaging with monoclonal antibodies because they take longer to reach the target. Also, the radionuclide should decay to a relatively stable daughter without any accompanying α- or β-particle emission. Finally, the cost and availability of the radionuclide are important parameters as well. The development of parent–daughter generator systems, in which a longer-lived parent decays to a shorter-lived daughter that is eluted from a chromatographic column, has increased the availability of some radionuclides. The development of the ^{99}Mo/^{99m}Tc generator was instrumental in the widespread availability of the radionuclide ^{99m}Tc that is a mainstay in nuclear medicine procedures. Another generator system approved by the US Food and Drug Administration (FDA) for clinical use is the ^{82}Sr/^{82}Rb system, which is a direct-infusion generator allowing the use of ^{82}Rb that has a 76 sec half-life for myocardial imaging. Other generator systems with potential utility, discussed herein, are the ^{68}Ge/^{68}Ga and the ^{62}Zn/^{62}Cu systems.[1,5,6]

1.2 Diagnostic Radioisotope Production Methods

The two methods for production of radioisotopes that are used in imaging involve either an accelerator or cyclotron or application of a generator system. Production of radionuclides has been reviewed comprehensively.[5,6] Accelerator or cyclotron-produced radiometals are more expensive, since the cyclotron or accelerator can produce one isotope at a time. Targetry and separations (usually ion extraction or ion exchange) methods have to be worked out as well. The development of parent–daughter generator systems has increased the availability of some radionuclides. Parent–daughter generators are systems in which a longer-lived parent decays to a shorter-lived daughter that is eluted from a chromatographic column. A classic example of such as system is the ^{99}Mo/^{99m}Tc generator.

2 TECHNETIUM

2.1 Physical Properties

Technetium, as ^{99m}Tc, is the most widely used radionuclide in the nuclear medicine clinic and is used in over 85%

Table 1 Common γ- and positron-emitting radionuclides

Radionuclide	Half-life	Production methods	Maximum particle emission[a]	γ-emission (keV)
^{99m}Tc	6.2 h	$^{99}Mo/^{99m}Tc$ generator	IT	141
^{67}Ga	3.26 days	Cyclotron	EC (100%)	91,93,185,296,388
^{68}Ga	67.63 min	$^{68}Ge/^{68}Ga$ generator	1.899 MeV β^+ (90%)	1077 (3.3%)
			EC decay (10%)	511 (176%)
^{66}Ga	9.5 h	Cyclotron	4.153 MeV β^+ (57%)	2752 (23.5%)
			EC decay (43%)	1039 (38.4%)
				834 (6.1%)
				511 (117.3%)
^{62}Cu	9.74 min	$^{62}Zn/^{62}Cu$ generator	2.96 MeV β^+ (97.8%)	511
			EC decay (2.2%)	
^{64}Cu	12.7 h	Cyclotron	0.63 MeV β^+ (19%)	511
			EC decay (41%)	
^{67}Cu	2.58 days	Accelerator	0.577 MeV β^-	184.6 (46.7%)
				93.3 (16.6%)
				91.3 (7.3%)
^{111}In	2.83 days	Cyclotron	EC decay	245 (94%)
				171 (91%)

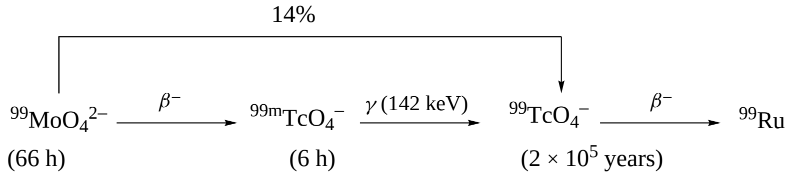
[a]IT = Isomeric transition; EC = Electron capture.

of nuclear medicine scans. The physical characteristics (γ ray = 142 keV, half-life = 6.02 h) of ^{99m}Tc are ideal for nuclear medicine scans to study organs lying deep in the body using current SPECT technology. The short half-life allows more activity to be injected with minimal radiation burden to the patient. ^{99m}Tc decays to ^{99}Tc, a very weak β^- emitter, that provides no interference or degradation of image quality. ^{99m}Tc is conveniently obtained from the $^{99}Mo \rightarrow {}^{99m}Tc$ generator using saline as an eluent (Scheme 1). The parent, ^{99}Mo (66 h half-life), as $^{99}MoO_4{}^{2-}$ adsorbed on an alumina column, continuously decays to the daughter, ^{99m}Tc (6 h half-life). The separation of ^{99m}Tc from ^{99}Mo is accomplished by selective elution of $^{99m}TcO_4{}^-$ with saline owing to the charge difference. The generator can be prepared at a production site and shipped to remote locations and will dispense eluate of suitably high activity for nuclear medicine scans for one week.

Sodium pertechnetate, $Na^{99m}TcO_4{}^-$ from the generator is the starting material for all radiopharmaceuticals based on ^{99m}Tc. The generator eluate, $^{99m}TcO_4{}^-$, is introduced into a 'radiopharmaceutical instant kit' containing the ligand, a reductant, usually stannous ion, and buffers. Incubation at room temperature or elevated temperature for a prescribed period of time, leads to the formation of the technetium imaging agents. The reaction to form the reduced ^{99m}Tc radiopharmaceutical must be quick and of high radiochemical purity.

2.2 Chemistry of Technetium

Technetium is a transition metal that lies in the middle of the transition series and possesses a diverse chemistry. Complexes are known where the range of Tc oxidation states is −1 to +7, having various coordination geometries (4–9) with a variety of ligands filling the coordination requirements. For production of radiopharmaceuticals, $Na^{99m}TcO_4$ must be reduced from the +7 oxidation state to a lower oxidation state for complexation with chelating ligands. Reduction of $TcO_4{}^-$ is most commonly accomplished by stannous chloride. The



Decay Scheme of $^{99}MoO_4{}^{2-}$ to $^{99m}TcO_4{}^-$: the chemistry of the ^{99m}Tc generator

Scheme 1

coordinating ligand has a profound effect on the oxidation state and the Tc core that is formed vide infra.

The concentration of Tc (both ^{99m}Tc and ^{99}Tc) eluted as pertechnetate from the generator is generally in the range of 10^{-7} to 10^{-10} M. These 'no-carrier-added' concentrations preclude characterization of its complexes using routine analytical techniques available to inorganic chemists. The long-lived ^{99}Tc isotope (β^-: 243 keV; $t_{1/2}$: 2×10^6 years) is available in macroscopic quantities and has enabled the use of standard methods of chemical characterization to determine the structure and chemistry and physiochemical properties of these Tc radiopharmaceuticals. Rhenium, the third row transition metal congener of Tc, has also been used for characterization. However, the kinetic inertness of Re compared to Tc, as well as the higher reduction potential, can result in significant differences in the chemistry and, using Re as a nonradioactive surrogate for Tc, should be practiced with caution. Most of the ^{99m}Tc based radiopharmaceuticals on the market since the 1980s have been characterized by performing the ^{99}Tc chemistry, characterization using routine analytical tools and relating back to the tracer radiopharmaceutical by high performance liquid chromatography (HPLC) concordance experiments.

2.3 Technetium Cores

The chelating ligands that are present upon reduction of TcO_4^- with stannous ion determine the coordination complex that forms. Complexes of a variety of oxidation states, structures, and ligand composition can form. Certain stable motifs, often called 'technetium cores' (Figure 1), form the basis of small coordination compounds and molecules that can be linked to biomolecules.

2.3.1 Tc=O^{3+} Core

The Tc=O^{3+} core is ubiquitous in radiopharmaceutical chemistry. This core forms upon reduction of pertechnetate in the presence of a diaminodithiol or N_3S tetradentate ligand and other ligands, including amine-oxime ligand systems. Generally, one or more amine or amide nitrogens deprotonate upon complexation forming strong bonds to the Tc^V. These complexes are square pyramidal with the Tc=O in the apical position. The strong bonds (thiolate S, amide N) to the Tc(V) render these complexes very stable and tetradentate N_2S_2 or N_3S ligands form a significant cohort of the ligands studied as bifunctional chelates (BFC). Diastereomers, wherein a substituent is syn or anti to the Tc=O group, commonly form when a chiral carbon is incorporated in the ligand.

2.3.2 O=Tc=O$^+$ Core

The O=Tc=O$^+$ core forms when pertechnetate is reduced in the presence of amines such as linear or macrocyclic tetraamines, such as cyclam and also phosphines. In this case, the donor atoms do not bond as strongly to the Tc^V.

2.3.3 Tc(Co)$_3^+$ Core

In the mid- to late 1990s, Alberto prepared water-soluble, air-stable $Tc(CO)_3(H_2O)_3^+$ species, both on the tracer, ^{99m}Tc, and on the macroscopic, ^{99}Tc, levels.[7–10] These species undergo ligand exchange in water to form stable octahedral complexes that possess the $Tc(CO)_3^+$ core. $^{99m}Tc(OH_2)(CO)_3^+$ is available in a kit formulation from Mallinckrodt, St. Louis, MO, where potassium boranocarbonate $K(H_3BCO_3H)$ is employed as the in situ

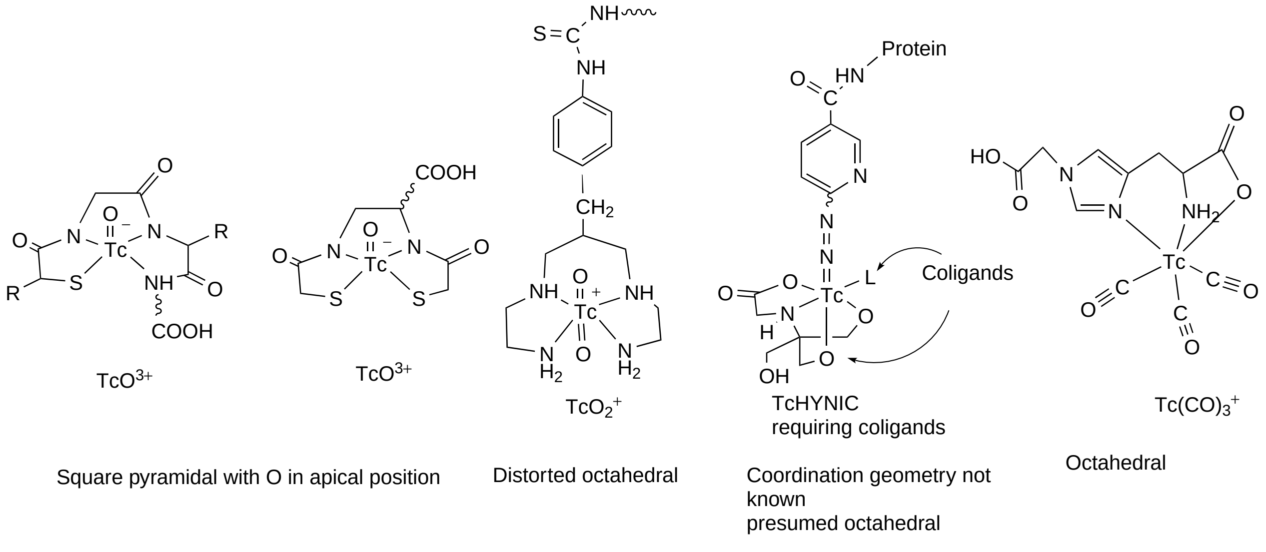


Figure 1 Technetium cores

CO source and $NH_3 \cdot BH_3$ serves as a reductant.[9] On the macroscopic scale, $MX_3(CO)_3{}^{2-}$ (M=^{99}Tc, Re), which forms the *fac*-$M(CO)_3{}^+$ unit in water, can be prepared via a low pressure synthesis.

The water molecules are substitutionally labile and the 'soft' $M(I)(CO)_3{}^+$ species reacts with ligands containing both hard and soft ligands, for example, thioethers, histidine, and carboxylates, to form kinetically stable octahedral complexes. In fact, histidine in a peptide is such a strong binding ligand that it often competes with the intended bifunctional ligand.

Ligands containing three donor atoms, including heterocyclic amines and carboxylate groups, provide the most stable ^{99m}Tc tricarbonyl complexes, and such tridentate ligands have been incorporated into peptides and receptor-specific molecules for successful radiolabeling with the $^{99m}Tc(CO)_3{}^+$ moiety.[11,12] Single amino acids that can be incorporated directly into peptide syntheses have been derivatized with N-heterocyclic tridentate ligands for complexation of $^{99m}Tc(CO)_3$.[13,14] A potential problem with the $^{99m}Tc(CO)_3{}^+$ core is the high affinity for histidine, often requiring 'prelabeling' procedures that are not amenable to radiopharmaceutical kit formulation.

2.3.4 Tc HYNIC Core

The N-hydroxysuccinimidyl hydrazinonicotinate (S-HYNIC) moiety forms a very stable ^{99m}Tc complex and provides excellent images.[15,16] HYNIC has been successfully coupled to peptides and antibodies for imaging thrombosis and sites of infection.[17,18] HYNIC also has been used for attachment to Annexin for in vivo imaging of apoptosis at the molecular level.[19,20]

The hydrazinopyridine moiety can bind to Tc using one or two coordination sites requiring the use of coligands, such as tricene, ethylenediaminediacetic acid (EDDA) and glucoheptonate. The advantage of using HYNIC as a bifunctional chelating agents(BFCA) is its high labeling efficiency and the choice of coligands allows easy modification of the hydrophilicity and pharmacokinetics of ^{99m}Tc-labeled small peptides. However, the difficulty that arises from multiple products and the lack of clarity as to the oxidation state of the Tc may impede the development of HYNIC-peptides into radiopharmaceutical kits.[17,21]

2.4 Technetium Radiopharmaceuticals

The development of the 'instant radiopharmaceutical kit' in the 1970s was followed by the development of technetium imaging agents for renal, skeletal, and hepatobiliary imaging. At that time, the coordination chemistry of technetium was not well understood and as a result, the early radiopharmaceuticals are not fully characterized. Studies of the coordination chemistry of technetium intensified in the late 1970s leading to the discovery of Tc brain, heart, and renal agents. These agents are considered 'Tc essential,' because the size, charge, and lipophilicity of the Tc complex (properties that result from the combination of Tc and the coordinating ligand) dictate the biological localization of the radiometal complex. Most of the early radiopharmaceuticals, and, indeed, the radiopharmaceuticals in clinical usage, are considered Tc essential.

Another category of Tc agents that have been under investigation from the mid-1980s to present are 'technetium tagged' radiopharmaceuticals. In this broad class, the Tc, bound to a ligand, is connected to a biologically active molecule via a linker (Scheme 2). Targeted technetium molecules distribute in the body according to a targeting vector, generally, an antibody targeted towards an antigen on a tumor site, or a peptide or hormone or small molecule targeted towards a receptor. The targeting vector is connected via a 'linker' to an organic ligand that forms a coordination complex with the metal ion, often called a metal chelate. The organic ligand and the linker are often called a bifunctional chelate.

2.4.1 Tc-essential Radiopharmaceuticals

The early technetium imaging agents have been reviewed in earlier versions of this Encyclopedia and in other references.[2,3] This section is intended to be an overview highlighting developments in technetium chemistry.

Brain Agents. ^{99m}Tc radiopharmaceuticals that penetrate the blood–brain barrier (BBB) are generally small, neutral, and lipophilic. Moreover, to be useful for imaging, the molecules must possess some mechanism of retention. Clinical brain imaging studies with ^{99m}Tc, aimed at detection of regional cerebral blood flow changes, are performed with D, L-^{99m}Tc-HMPAO, Ceretec™, or L, L-^{99m}Tc-ECD, Neurolite™ (Figure 2). Both are small, neutral molecules that cross the BBB and are retained in the brain.

^{99m}Tc ethyl-cysteine-dimer (ECD) is based on a tetradentate N_2S_2 chelate. ECD has two chiral centers and can be synthesized as the L, L-ECD or D, D-ECD isomers. Both form similar chiral, symmetric square-pyramidal Tc(V) oxo complexes that are neutral and lipophilic. However, the in

Figure 2 Brain imaging agents

vivo behavior is quite different; while both penetrate the intact blood–brain barrier, the L,L-isomer is stereoselectively hydrolyzed to the acid, forming a charged species that is trapped in the brain.[22] Other brain perfusion agents that have been studied in humans include the Tc-boronic acid adducts of dioximes (Tc-BATO), particularly the 2-methylpropyl derivative.

Heart Agents. Routine myocardial perfusion imaging in nuclear medicine started with ^{201}Tl thallous chloride. While $^{201}Tl^{+}$ is efficiently perfused into the myocardium, the long half-life and imaging characteristics are not optimal for nuclear medicine imaging and cationic ^{99m}Tc-based perfusion agents were desired.

The hexakis *tert*-butylisonitrile Tc(I) complex, $Tc(TBI)_6{}^{+}$, was the first complex to image human myocardial tissue; however, its high lipophilicity resulted in high lung and liver uptake. Optimization of the organometallic Tc(I) hexakis isonitrile family of compounds led to the development of hexakis(2-methoxyisobutylisonitrile)Tc(I), $Tc(I)(MIBI)_6{}^{+}$ (Cardiolite™ or sestamibi), an FDA-approved agent for clinical myocardial perfusion imaging (Figure 3).

Other lipophilic cations that have been approved as myocardial perfusion agents include a Tc(III) ^{99m}Tc-teboroxime cryptate, (Cardiotec™), the trans-dioxo technetium(V) bisphosphine complex, ^{99m}Tc-tetrofosmin (Myoview™) and the mixed ligand Tc(III) Schiff-base bisphosphine Tc-Q12 complex, ^{99m}Tc-furifosmin (TechneScan) (Figure 3).

Renal Agents. ^{99m}Tc MAG3 (TechneScan™; Figure 4) is used to assess renal function.[23,24] After intravenous injection, this tracer passes through the kidneys and is rapidly excreted primarily by active tubular secretion. ^{99m}TcMAG3 has no chiral centers and thus does not form diastereomers. On coordination of the MAG3 ligand to the Tc(V) center, the thiolate sulfur and three amide nitrogens each lose their protons to yield an anionic complex, exhibiting square-pyramidal geometry with the oxo group in the apical position. The carboxylate group is not coordinated to the metal. A free carboxylate group is necessary for efficient renal excretion of an anion. The MAG3 ligand and derivatives are used as bifunctional chelates to link Tc to biomolecules.

Agents for Hypoxia. Determining the oxygen status of solid human tumors and identifying viable versus hypoxic (low oxygen content) tissue following myocardial infarction, ischemia, and strokes is important to determine treatment regime. Hypoxic tissue can be differentiated from oxic tissue (normal oxygen concentrations) and necrotic tissue (dead or nonviable tissue) on the basis of differences in reduction potential within the cells. A hypoxic tissue radiopharmaceutical must be able to enter the cell and it must be selectively reduced in hypoxic tissue, but not normal tissue. Once inside the cell, the compound should be reduced and trapped in the hypoxic area.

Recent ^{99m}Tc-based imaging agents, shown in Figure 5, for hypoxic tissue are in development. These include nitroimidazole derivatives, BSM-181321 and BRU-59-2, based on the ^{99m}Tc-propyleneamine oxime (PNAO) complexes. Both contain the 2-nitroimidazole functionality, that is the active component of the oxygen mimetic molecule, ^{19}F-2-nitroimidazole,[25] and have been shown in vivo to localize in ischemic tissue. The BnAO chelate also displays uptake in hypoxic tissue. The mechanism is unknown, however, electrochemical studies show an irreversible reduction at biologically accessible potentials.

2.4.2 Receptor Specific Agents-technetium Tagged Radiopharmaceuticals

The mid- to late 1980s saw an increasing emphasis on designing technetium radiopharmaceuticals that have specific interaction with cellular proteins and/or receptors.

with ^{99m}Tc by direct labeling or with BFC conjugates. The long time required for mAbs to localize at their target antigen in vivo has hindered their widespread use for ^{99m}Tc agents. However, various ^{99m}Tc-labeled antibody fragments have been used clinically to image cancers and melanoma.[26] Also, ‘pretargeting’ strategies have been developed wherein the antibody, covalently linked to a molecule, such as streptavidin, is administered first and allowed to circulate and bind to antigen. Administration of a clearing agent, such as galactosylated protein, that has a high-affinity, noncovalent interaction with streptavidin will remove the mAbs from circulation, but allow them to remain in the tumor. A small effector molecule, for example, biotin linked to the chelated radiometal, is then administered. Pretargeting strategies allow the radiolabeled small molecule to bind to the tumor with rapid excretion of residual radioactivity.[27,28]

Labeling of ^{99m}Tc to annexin, a small 36 kDa endogenous protein that binds to phosphoserine headgroups in phosphatidyl serine with affinity of ca 10^{-9} M, has been used to detect apoptosis in vivo in animal models of transplant rejection, to visualize apoptotic cells and to assess chemotherapy of xenographs. The potential for using ^{99m}Tc labeled Annexin to visualize apoptosis in a wide array of pathologies is under investigation.[19,20,29,30]

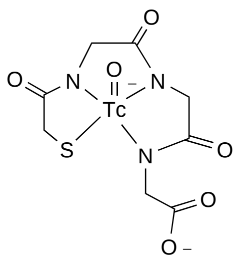

Figure 4 ^{99m}Tc MAG3

Receptor-specific Small Molecules. Receptor imaging in nuclear medicine has been performed with small receptor-specific molecules radiolabeled with ^{123}I (reactor produced),

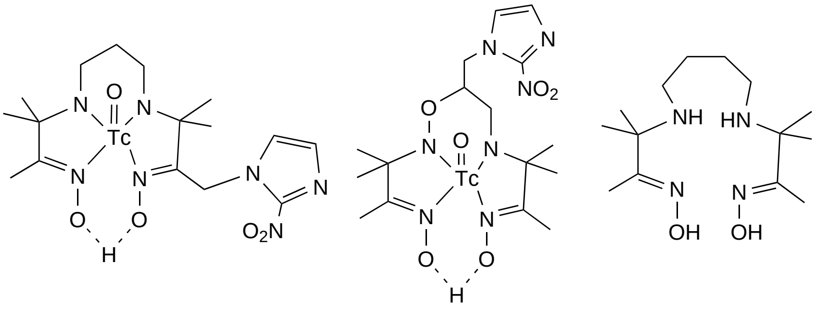

Figure 5 ^{99}Tc complexes for imaging hypoxic tissue

^{18}F, and ^{11}C (cyclotron produced). These isotopes can be incorporated into biomolecules with relative ease and with no or minor alteration of the structure of the biomolecule and, generally, the bioactivity remains the same or similar. The high costs and relative unavailability for routinely producing receptor-specific agents with these isotopes provided the impetus for developing similar agents labeled with ^{99m}Tc. Unlike ^{123}I, ^{18}F, and ^{11}C, labeling with ^{99m}Tc requires incorporation of a ligand or coordinating atoms within or appended to the molecular framework of the receptor ligand to stabilize ^{99m}Tc. Generally, the approach that is taken is to 'tag' the biologically active molecule with a ligand for complexation of ^{99m}Tc, although there are a few examples where the biologically active molecule is templated by ^{99m}Tc. These have been called the 'conjugate design' and 'integrated design,' respectively.[31,32]

The general design criteria applied in the development of these complexes, discussed in detail in previous reviews,[31,32] are dictated by (1) the location of the receptor in the organ or body and (2) the structure of the receptor and nature of its interaction with ligands. Some receptors, such as the integrin gpIIB/IIIA and somatostatin receptors, are located in the vascular or peripheral system and do not need to cross the BBB or cellular membranes to reach the target receptor. In these cases, there is more tolerance for the size and charge of the receptor-specific radiopharmaceutical. Receptor-specific ^{99m}Tc molecules for neurotransmitter receptors, located in the brain, must traverse the BBB. Receptor-specific molecules for intracellular steroid hormones need to cross plasma membranes.

The structure of the receptor and the nature of its interaction with the receptor-specific molecule will determine the degree to which large ^{99m}Tc molecules or ^{99m}Tc molecules with large substituents will be tolerated. Other important concerns include receptor density, affinity of the complex, and nonspecific binding of the complex.

Receptor-specific ^{99m}Tc labeled molecules can be divided into two broad categories: small molecules and peptides. The following discussion presents an overview of this large area with specific examples that are in clinical trials or on the market.

Small ^{99m}Tc Labeled Receptor-specific Organic Molecules

Neuroreceptors/Transporters[2,3,33]. Noninvasive neuroreceptor imaging could greatly aid in understanding, diagnosis, and monitoring various neurologic diseases. An important consideration in the design of these radiopharmaceuticals is that they must cross the blood–brain barrier. Thus, the complexes must be small, neutral, lipophilic, and stable in vivo as well as possess high affinity for the targeted receptor with minimal nonspecific binding to other proteins and receptors.

Two promising agents target the dopamine transporter (DAT) and have shown receptor-specific localization in primate and human brains. The DAT, located in high density on the presynaptic dopamine neurons concentrated in the striatum of the brain, plays a vital role in regulating endogenous dopamine concentration in the synaptic cleft. The DAT has been implicated in Parkinson's disease and schizophrenia. Several groups have targeted the DAT using tropane analogs, shown in Figure 6, that are derivatives of well-known DAT antagonists, β-CIT or β-CFT.

^{99m}Tc-TRODAT is a tropane derivative in which the diaminodithiol ligand is linked via a methylene group to the 2β-position of tropane. Two diastereomers form on coordination of the ligand to the TcO^{3+} core, both syn relative to the TcO group. Both diastereomers show nanomolar binding affinities for DAT in rat striatal homogenate. The tracer localizes in the basal ganglia consistent with DAT binding.[34] ^{99m}Tc-Technepine is also a tropane derivative which is conjugated to the amine nitrogen of a dithiol-amide-amine ligand coordinated to the TcO^{3+} core.[35,36] Two diastereomers, both syn relative to the TcO group, show nanomolar IC_{50} values for the DAT in cynomologous monkey brain homogenates. Modifications of the structures increase selectivity for the DAT versus the serotonin receptor.[3] A '3 + 1' ^{99m}Tc-tropanol is a motif wherein the Tc=O core is bound to a tridentate dithiol ligand and a monodentate thiol that is itself linked to the tropane moiety.[37] TROTEC is a tropane derivatized with the $Tc(CO)_3^+$ core.[38]

Alteration of serotonin receptors is implicated in a variety of anxiety disorders, depression, schizophrenia, and Alzheimer's disease. The 5-HT$_{1A}$ and 5-HT$_{2A}$ subtypes have received the most attention with respect to developing ^{99m}Tc-labeled receptor-specific complexes. These tracer complexes must also penetrate the BBB. Most of the ^{99m}Tc complexes investigated for serotonin 5-HT$_{1A}$ receptors are analogs of high-affinity antagonists at the 5-HT$_{1A}$ receptor that possess 1-(2-methoxyphenylpiperazine) (MPP) as the receptor-binding moiety (Figure 7). The diaminodithiol chelate linked to 2-methoxyphenyl piperazine via alkyl chains or via linkages that contain both a 2-pyridyl substituent and an aromatic

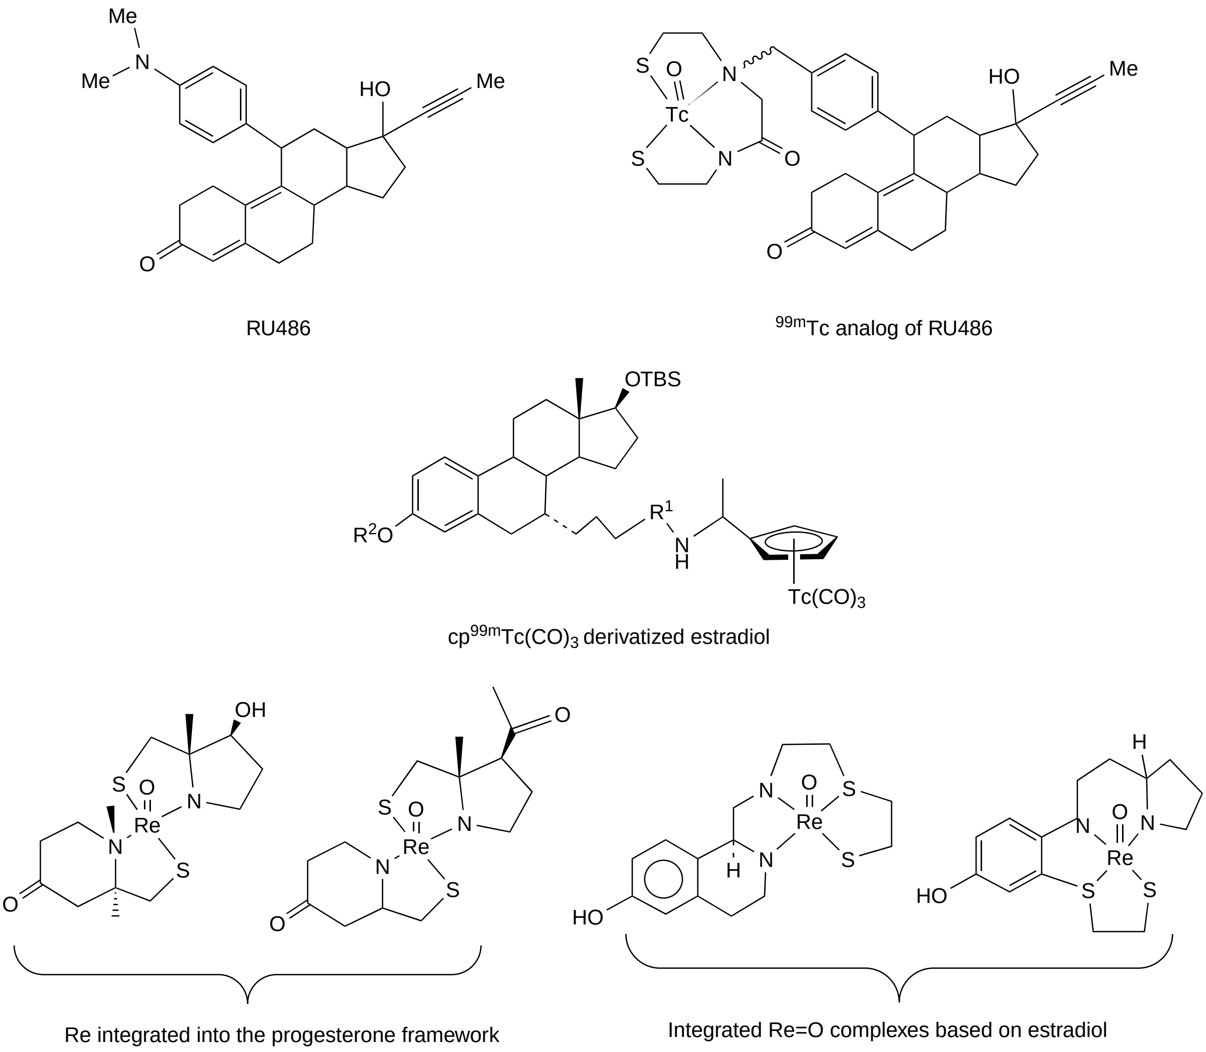

Figure 8 Tc and Re derivatives of progesterone and estradiol

benzamide show high affinity for the 5-HT$_{1A}$ receptor; however, brain uptake is low. Other MPP analogs have been reported, including one based on the Tc(CO)$_3^+$ core.[33]

Steroid Receptors. Steroid receptors such as estrogen, progesterone, and androgen receptors are overexpressed in breast, ovarian, and prostate cancers. Estrogen and progesterone receptors are present in about 65% of human breast cancers. The presence or absence of these receptors in cases of breast carcinoma assists the determination of the therapeutic strategy (hormonal or chemical) that is likely to be effective. The successful Tc complex must cross the membrane lipid bilayer of the cell, and thus, the size and lipophilicity of the complex must be balanced with receptor-binding affinity.

Katzenellenbogen and coworkers have done extensive research in the area of steroid receptor ligands.[31,32] Appending N_2S_2 chelates onto progestin at the 11β position, based on the drug RU486 (Figure 8), resulted in ^{99m}Tc complexes that showed moderate to high affinity for the progestin receptor. However, nonspecific binding and uptake in nontarget organs were observed.[39,40] Attempts to reduce the molecular mass and lipophilicity lead to design of integrated complexes wherein the Tc=O group is integrated within the ring system of 5-α-hydroxytestosterone or estradiol. The binding affinities were found to be low but this integrated approach where the ^{99m}Tc templates the structure of the overall complex appears to be a promising strategy.[41] Other designs where the tricarbonyl moiety have been tethered to estradiol have been examined.

Other Receptors. The above examples show the design criteria of stabilizing ^{99m}Tc either appended to or integrated within the framework of small receptor-specific molecules. There have been other receptors such as sigma receptors, muscareinic acetylcholine receptors, and dopamine D2

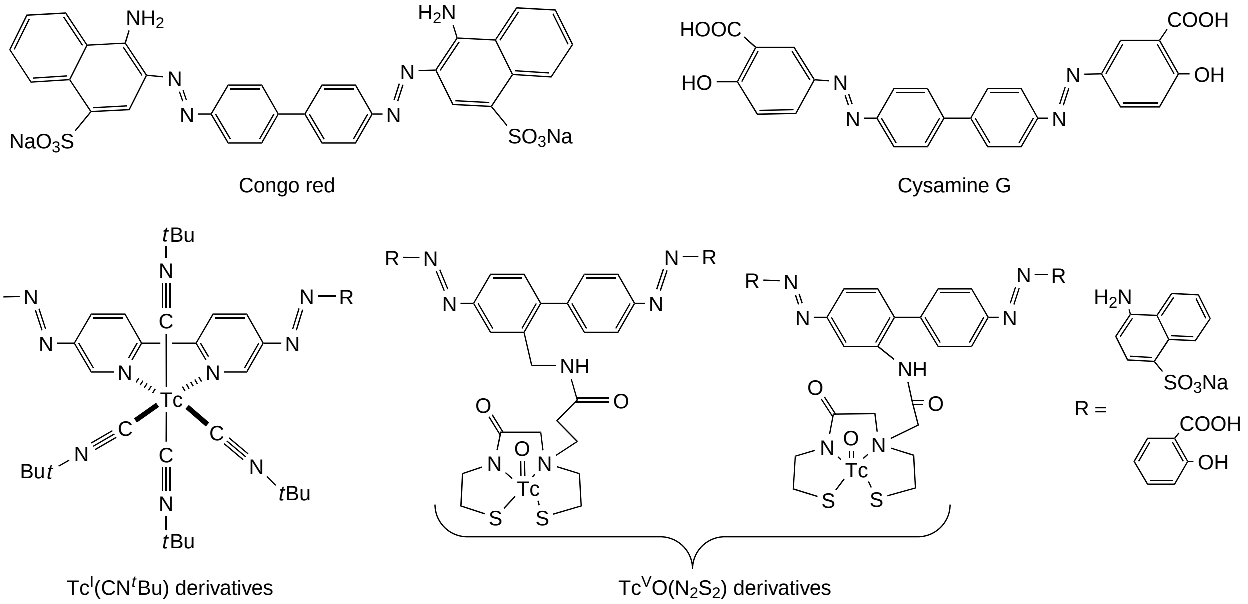

Figure 9 Tc complexes for binding to β-amyloid fibrils

receptors that have been targeted with ^{99m}Tc labeled small molecules. These can be found in recent reviews.[2,3,33]

Other Targets

Amyloid Plaque. Staining by aromatic azo dyes such as congo red and chrysamine G displays extensive amyloid deposits in postmortem brain tissues from Alzheimer's patients. Incorporating the basic dye structures within Tc complexes by an integrated approach in which a central bipyridyl group capable of bidentate coordination to Tc is introduced in place of the biphenyl group in the azo dyes results in Tc(I) complexes, shown in Figure 9, that display submicromolar binding affinity to β-amyloid fibrils.[42,43] The charges of the molecules preclude brain uptake. Alternative approaches using pendant amineamide chelates have been reported for these azo dyes as well as their uncharged ester derivatives. In vivo studies show low brain uptake even for neutral derivatives, perhaps due to their large size.[44,45]

Multidrug Resistance Targeting Molecules. Multidrug resistance (MDR) is a phenomenon in which cancer cells become resistant to chemotherapeutic drugs with differing modes of action. This is believed to be one of the primary reasons for treatment failure in cancer patients. The most well-characterized source of MDR arising from cancer cells is the P-glycoprotein (Pgp) expressed by the human MDR1 gene. Pgp is a transmembrane protein and is believed to confer drug resistance by pumping cytotoxic material out of the cell. Functional measurement of the MDR status in vivo by SPECT or PET would be useful in determining the resistance status of a tumor. ^{99m}TcMIBI, a myocardial perfusion agent, is a substrate for Pgp and thus does not accumulate in MDR-active cells and experiences increased washout rate from tumors expressing Pgp.[46,47] Other lipophilic cationic ^{99m}Tc complexes such as ^{99m}Tc-tetrofosmin and the ^{99m}Tc-Q complexes have also been shown to be substrates for Pgp in both in vitro and in vivo animal tumor models.[48] Efforts to optimize the differential uptake between drug-sensitive and drug-resistant tumors and to minimize nonspecific binding have identified variants of the ^{99m}Tc-Q series.

^{99m}Tc Labeled Receptor-specific Peptides.[17] The success of ^{111}In diethylenetriaminepentaacetic acid (DTPA)-octreotide (OctreoScan™), the first radiolabeled peptide in the nuclear medicine clinic (vide infra) stimulated the search for receptor-specific imaging agents based on ^{99m}Tc peptides. These ^{99m}Tc-labeled peptides target cell surface receptors. For example, tagging a ^{99m}Tc chelate to cyclic peptides targeted towards gpIIb/IIIa receptors have proven successful for imaging Deep Vein Thrombosis (DVT). A thrombus is an aggregate of fibrin, platelets, and red blood cells within blood vessels. In a rapidly growing thrombus, activated platelets express gpIIb/IIIa receptors that recognize peptides and proteins such as fibrinogen containing a tripeptide Arg-Gly-Asp (RGD) motif. The RGD unit has been incorporated into high-affinity antagonists of the gpIIb/IIIa receptor. Ligands that bind ^{99m}Tc have been appended to these high-affinity receptor-specific cyclic species. For example, DMP 757, an RGD containing conformationally constrained cyclic high-affinity gpIIb/IIIa antagonist, has been derivatized with the N_2S_2 ligand and the HYNIC moiety to give, upon labeling with ^{99m}Tc, the radiolabeled analogs, RP419 and DMP444, respectively (Figure 10). Both ^{99m}Tc-labeled agents show rapid uptake in thrombi and clear visualization 15–30 minutes after injection.

The first ^{99m}Tc-radiolabeled peptide in the nuclear medicine clinic was ^{99m}TcO apcitide (^{99m}TcO(P246); Figure 11), the technetium complex of the 13-amino acid apcitide, *cyclo*-(D-Tyr-Apc-Gly-Asp-Cys)-Gly-Gly-Cys(Acm)-Gly-Cys(Acm)-Gly-Gly-Cys-NH_2, where Apc is L-S-(3-aminopropyl)cysteine (an arginine mimetic) and Acm is the acetamidomethyl protecting group. ^{99m}TcO apcitide has high affinity and selectivity for the gpIIb/IIIa receptor.[49,50] Bibapcitide, a 26-amino acid, bis-succinimidomethyl ether-linked dimer of the peptide apcitide, has been formulated as a single-vial, lyophilized kit having the trade name AcuTect™. When sodium pertechnetate ($^{99m}TcO_4^-$) is added to the AcuTect™ radiopharmaceutical kit and the resulting kit is heated, ^{99m}TcO apcitide forms (Figure 11). The ^{99m}Tc is complexed to the terminal Gly-Gly-Cys of apcitide (N_3S donor set).[51]

The second ^{99m}Tc-labeled peptide to enter clinical use is ^{99m}Tc depreotide (^{99m}Tc P829, NeoTect™) for lung tumor imaging (Figure 12). The pharmacophore, cyclic-Tyr-D-Trp-Lys-Val receptor-binding sequence is restrained in

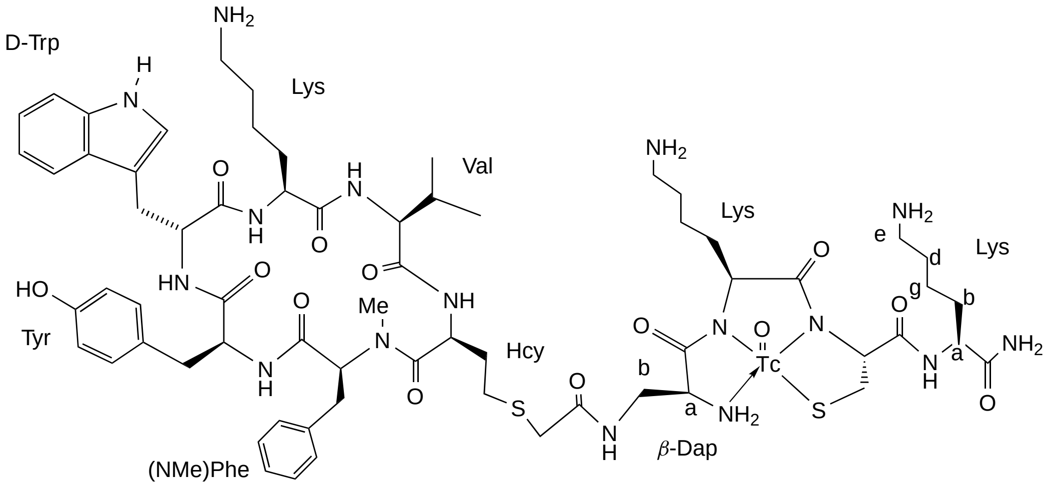

Figure 12 ^{99m}Tc depreotide (P829) NeoTect™

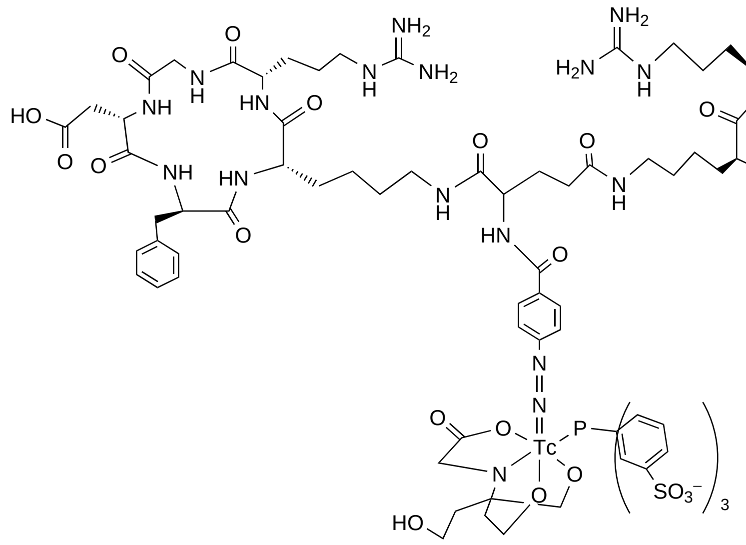

Figure 13 A ^{99m}Tc labeled vitronectin receptor antagonist for tumor imaging

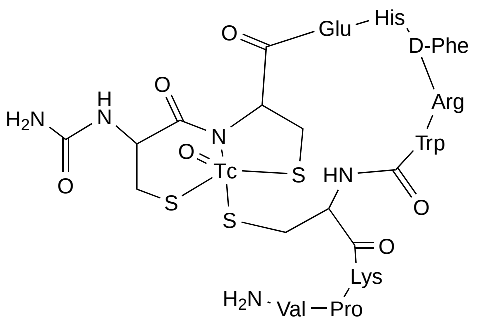

Figure 14 Cyclic ^{99m}Tc α-MSH analog

a cycle and tethered to a β-diaminopropionate-Lys-Cys-Lys that comprises the ^{99m}Tc binding region, shown in Figure 12. Two ^{99m}Tc-labeled depreotide diastereomers form upon treatment with $^{99m}TcO_4^-$ and stannous ion, where the pendant group (containing the cyclic pharmacophore) is disposed syn or anti to the Tc=O group. The diastereomers have nanomolar affinities for the somatostatin receptor.[52]

Many antagonists to the vitronectin receptor, an integrin receptor, inhibit tumor-induced angiogenesis and tumor growth. A dimeric vitronectin receptor antagonist, RP593, labeled with ^{99m}Tc (Figure 13) shows high affinity in vitro receptor assays and studies in animal tumor models indicate rapid blood clearance with tumor uptake.[53]

There are few examples of the integrated design in radiolabeled peptides. One example is found in the α-melanocyte stimulating hormone (α-MSH) receptor-binding peptides that are expressed on murine and human melanoma tumors. In this case, the ^{99m}Tc templates the cyclization of a tridecapeptide by binding to cysteine residues at the N- and C-terminals to produce enzymatically stable ^{99m}Tc (Figure 14) and ^{188}Re analogs that display significant tumor localization in vivo. This metal-cyclized peptide binds to the α-melanocyte stimulating hormone (α-MSH) receptor.[54–56]

3 OTHER METAL DIAGNOSTIC AGENTS

3.1 Gallium, Indium

^{67}Ga and ^{111}In are presently clinically used in diagnostic imaging. The positron-emitting ^{68}Ga ($t_{1/2} = 68$ min) is generator produced (^{68}Ge/^{68}Ga) and is potentially useful for PET imaging.

3.1.1 General Information

Ga(III) and In(III) (Group IIIB) have properties similar to Fe(III) except that their reduction potential to the +2 species is much lower and not attained under physiological conditions. Thus, the +3 oxidation state is exclusively observed in radiopharmaceutical chemistry. The formation of hydrolysis products and formation of transferrin complexes (Ga(III)-transferrin: log $K_1 = 20.3$;[57] In(III)-transferrin: log $K_1 = 18.74$[58]) must be considered in the design of radiopharmaceuticals based on Ga(III) and In(III) (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). Therefore, the majority of Ga(III) and In(III) coordination complexes used as radiopharmaceuticals or as BFCA, to link Ga(III) and In(III) to antibodies or

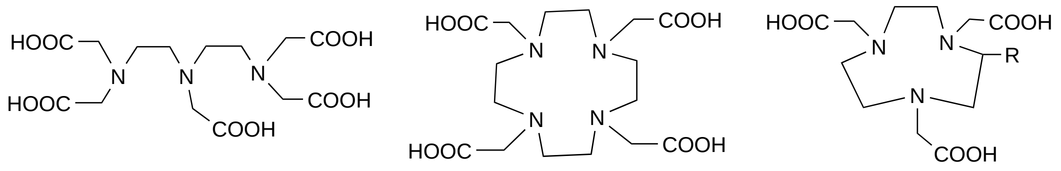

Figure 15 Ligands for Gallium(III) and Indium(III)

peptides, have very high thermodynamic stability and/or are kinetically inert to exchange with transferrin in vivo. Macrocyclic or linear aminocarboxylates (Figure 15) are typically employed although others have been and are studied. Ligand development for radiopharmaceutical use has been thoroughly reviewed.[6] The coordination chemistry, analytical chemistry, and radiopharmaceutical applications have been reviewed.[5,6,59]

3.1.2 *Radiopharmaceuticals Containing ^{67}Ga and ^{111}In Currently in Use*

Approved Radiopharmaceuticals for Imaging Based on Monoclonal Antibodies

The DTPA ligand is linked to antibodies via a carbohydrate-glycyl-tyrosyl-lysine linkage in the commercial products ProstaScint and OncoScint. ProstaScint is a whole IgG1, murine monoclonal antibody that was generated from a human prostatic cell line. This product is used to determine extent of prostate cancer. OncoScint is based on the monoclonal antibody B72.3 or CYT-103 directed against an antigen TAB-72 that is expressed on colorectal adenocarcinomas and ovarian cancers. Another commercially available product, MyoScint, is an anti-myosin Fab fragment antibody with an attached DTPA chelate that localizes in necrotic myocardial tissue and is used to detect myocardial infarcts.

Radiopharmaceuticals for Tumor and Infection Imaging

^{67}Ga-citrate has been used to image tumors since 1969 and infection since 1972. ^{67}Ga citrate scintigraphy is the best available functional imaging modality for evaluating patients with non-Hodgkin's lymphoma and Hodgkin's disease and is also in clinical use for diagnosis of lung cancer, malignant melanoma, and leukemia. The role of ^{67}Ga scintigraphy is primarily to assess the viability of tumors, that is, to differentiate between the presence of viable lymphoma, which requires further treatment, or benign tissues.

^{67}Ga citrate is not stable in blood and the actual radiopharmaceutical in vivo is ^{67}Ga transferring (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***).[60,61] The mechanism of ^{67}Ga-citrate/transferrin uptake into tumors has been debated. The most recent theory is that after intravenous injection of ^{67}Ga citrate, ^{67}Ga is transported in the blood bound to transferrin (an iron-transport protein). ^{67}Ga transferrin binds to transferrin receptors (CD71) that are increased and upregulated on tumor cells and is incorporated by receptor-mediated endocytosis into intracellular lysosomes.[62] The result is enhanced ^{67}Ga uptake in malignant cells.

^{67}Ga-citrate is also commonly used for imaging infection and inflammation.[63,64] At sites of inflammation, the gallium-transferrin complex leaks into the extracellular space and ^{67}Ga is transchelated from transferrin in blood to lactoferrin and siderophores (*see* ***Iron Transport: Siderophores***), which are released by leukocytes and bacteria. Imaging with ^{67}Ga takes place usually 24–72 h following injection.

^{111}In-labeled white blood cells (WBC) have also been clinically used for infection and inflammation imaging. The neutral, lipid-soluble ^{111}In(oxine)$_3$ (oxine = 8-hydroxyquinoline) complex penetrates cellular membranes and is used to label WBC.[65] After diffusing intracellularly, the ^{111}In(oxine)$_3$ complex dissociates and the ^{111}In is bound to nuclear and cytoplasmic proteins. Labeling of WBCs is done in plasma to avoid transchelation with transferrin in blood. The procedure consists of withdrawal of blood from patient, separation of red blood cells from white blood cells, purification of leucocytes, radiolabeling, followed by reinjection of the radiolabeled cells into the patient. The WBCs migrate to inflamed area and can lead to positive imaging.

Disadvantages of using ^{111}In-labeled WBCs include the laborious procedure, specialized equipment and the exposure to potentially contaminated blood that can lead to transmission of blood-born pathogens. An alternative to white blood cell labeling is labeling IgG, a nonspecific immunoglobulin, with ^{111}In using the chelator DTPA. ^{111}In-DTPA-IgG accumulates by binding to receptors present on inflammatory cells.[66] DTPA-IgG, formulated as an instant kit (MacroScint™, RW Johnson Pharmaceutical Research Institute) is used for detection of infectious bone and joint disease.

A disadvantage of ^{111}In-labeled IgG is the lengthy time between injection of radiopharmaceutical and imaging (generally 1–3 days). This problem has been addressed by a 3-step pretargeting procedure[67] as well as the use of faster clearing molecules such as chemotactic peptides,[68] that also bind to receptors expressed on white blood cells with high affinity. Chemotactic peptides show promise for imaging infection and inflammation although issues such as undesired biological activity may impede clinical development.[69]

Radiolabeled Receptor Ligands for Tumor Imaging

The first peptide-based receptor-binding radiopharmaceutical is ^{111}In-DTPA-octreotide, known as ^{111}In-OctreoScan™.[70,71] Octreotide (Figure 16) is a shortened peptide analog of somatostatin, a cyclic disulfide-containing peptide hormone of 14 amino acids that is present throughout the central nervous system. Somatostatin receptors (sstr) are overexpressed on many neuroendocrine tumors. Octreotide and metal-derivatized octreotide analogs exhibit high affinity for sstr2 receptors, one of the five different human somatostatin receptor types that has been cloned. Imaging and therapy of neuroendocrine tumors with octreotide and other small peptide somatostatin derivatives has been reviewed.[71–83]

^{111}In-DTPA-D-Phe-octreotide binds to sst receptors and is internalized via invagination of the plasma membrane and coated vesicles. Once in the cell, the receptor dissociates from ^{111}In-DTPA-octreotide and is externalized. The polarity of the DTPA-conjugated radiometabolites such as ^{111}In-DTPA-D-Phe prevents passage of the radioactivity out of the cell.[84]

Studies to improve receptor uptake and selectivity[85] and to tailor the peptide for other radiometals for SPECT and PET imaging followed the introduction of ^{111}In-DTPA-D-Phe-octreotide in the clinic. The differences in coordination chemistry of the radiometal may influence biological behavior. For example, the ^{67}Ga complex of DOTA derivatized Tyr^3-octreotide showed higher stability in human serum, high affinity to the somatostatin receptor and high tumor and low kidney uptake compared to the ^{111}In and ^{90}Y congeners. Gallium(III) is hexacoordinate, bound to four nitrogen atoms of the DOTA and two carboxylate oxygen atoms, while the In(III) and Y(III) analogs are seven-coordinate. It is likely that the free carboxylate group of the ^{67}Ga derivative contributes to the favorable handling of the radiopeptide by the kidneys.[86] ^{67}Ga labeled DOTA-Tyr^3-octreotate showed improved affinity for the sstr2 receptor.[87] The positron-emitting ^{68}Ga-DOTA-Tyr^3-octreotide showed high sensitivity in identifying carcinoid tumors in patients by PET compared to ^{111}In-octreotide. The combination of the high tumor to nontumor contrast, excellent clearance properties, and sensitivity of PET bode well for the use of ^{68}Ga in somatostatin receptor PET imaging.[88]

3.2 Copper

Copper offers many radionuclides of interest for diagnostic imaging and for radiotherapy. The positron-emitting ^{64}Cu has been investigated for labeling proteins, peptides, and molecules with long blood clearance. ^{60}Cu and ^{62}Cu are of interest for agents that reach their targets and clear the blood quickly.[89,90]

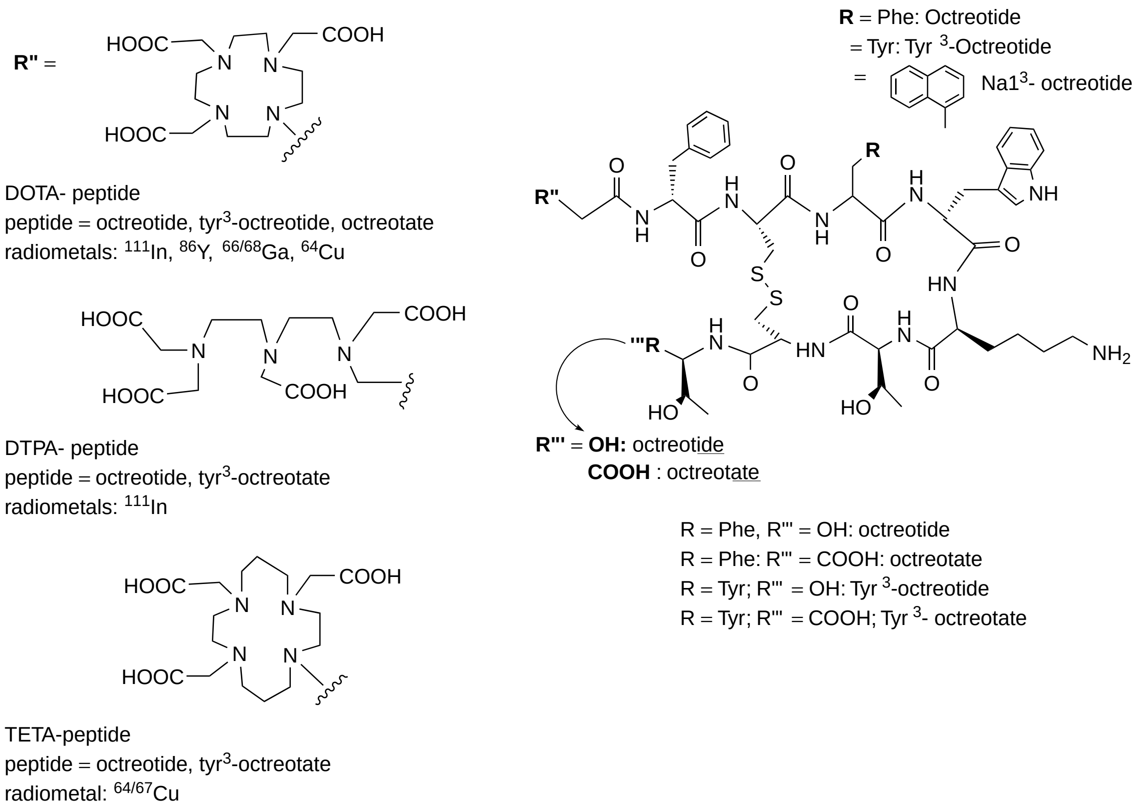

Figure 16 Octreotide and derivatives

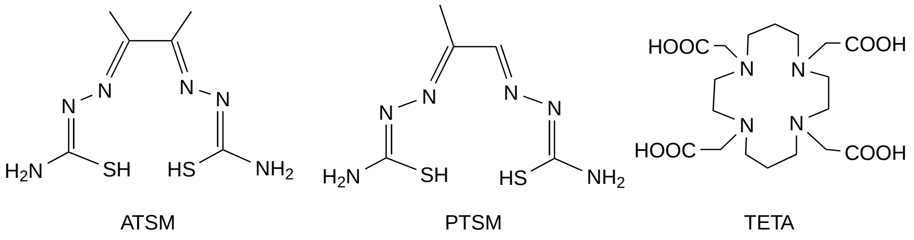

Figure 17 Ligands for Cu^{II}

Two classes of ligands, shown in Figure 17, have been extensively investigated for complexation of copper: bis(thiosemicarbazones), represented by diacetyl-bis(N4-methylthiosemicarbazone) (ATSM) and pyruvaldehyde bis-(N4-methylthiosemicarbazone) (PTSM) and macrocyclic ligands exemplified by 1,4,8,11-tetraaza-cyclotetradecane-N,N',N'',N'''-tetraacetic acid (TETA).

3.2.1 *Bis(thiosemicarbazones)*

ATSM and PTSM form small neutral, lipophilic square-planar complexes with radiocopper that can easily traverse the blood–brain barrier.[91–93] ^{67}Cu-PTSM is rapidly extracted into cells and the Cu(II) is reduced to Cu(I) by intracellular thiols, followed by dissociation of the resulting labile Cu(I)-PTSM and binding of the Cu(I) to intracellular proteins, thus constituting the trapping mechanism. Details of this process are discussed in a review by Blower.[89] The high lipophilicity of Cu-PTSM may preclude its use as a blood flow tracer.[94–96]

^{64}Cu-ATSM is selectively trapped in highly reducing hypoxic tissue but not in less reducing normal tissue. On the other hand, Cu-PTSM is reduced in both normoxic and hypoxic tissue. Hypoxia selectivity has been correlated to the reduction potential of the molecule that is in turn related to the alkyl group substitution.[97] The reduction potential of Cu-ATSM is about 100 mV lower than that of Cu-PTSM. Density Functional Theory and chemical reactivity studies attempt to correlate the structure and redox properties of bis(thiosemicarbazones) with the characteristics of the LUMOs (metal or ligand based) and chemical reactivity.[98] The fast and selective uptake of $^{64/62}$Cu-ATSM in hypoxic tissue will allow rapid quantitative and qualitative detection of hypoxic regions in tumors with PET before a radiotherapy or chemotherapy regime.[91,93,99,100]

3.2.2 *Macrocyclic Ligands*

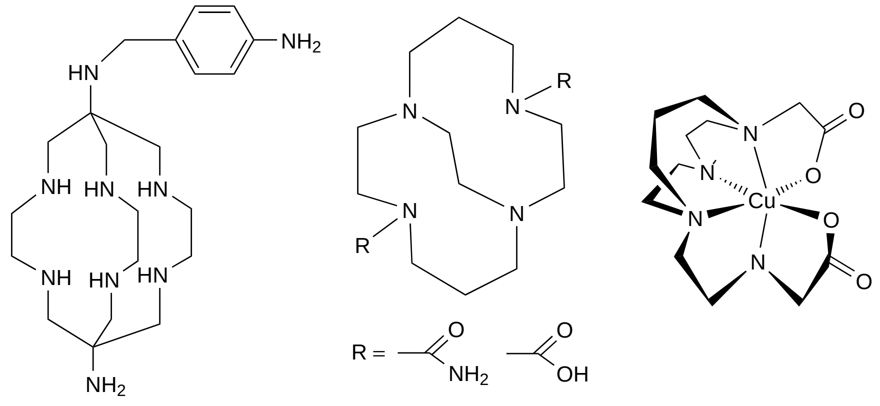
While acyclic polyaminocarboxylate (DTPA, ethylenediaminetetraacetic acid (EDTA)) complexes of copper(II) have high thermodynamic stability, these complexes are kinetically labile to ligand exchange. Cu(II) has been found to have much greater kinetic stability (and consequently greater serum stability) with macrocyclic chelates, such as TETA and DOTA, than with aliphatic ligands.[101] Consequently, TETA or DOTA have been used to conjugate radiocopper to biomolecules.[102] Many studies suggest that negatively charged complexes may have more favorable clearance properties when used as BFCs.

Studies over the last decade show that ^{64}Cu-TETA linked to antibodies shows tumor uptake and provides impetus for the use of PET in combination with ^{64}Cu for imaging of tumors.[103–105] Also, the β^- emissions of ^{64}Cu and ^{67}Cu have been used to advantage in radiotherapy applications when these isotopes are conjugated to antibodies.[106–108] Recent advances in genetically engineered fragments[109] and pretargeting strategies[110] show rapid access and high retention in tumor tissue combined with rapid blood clearance.

^{64}Cu has also been conjugated to octreotide and modified octreotide analogs using TETA and cyclam derivatives (Figure 16).[105,106] Biological studies show that tyrosine substitution in position 3 and replacement of the C-terminal alcohol with a C-terminal COOH enhance receptor-binding and tumor cell uptake with the addition of the C-terminal COOH contributing more.[106]

In analysis of the liver metabolism in rats treated with anti-colorectal carcinoma mAb 1A3 radiolabeled with ^{67}Cu through three different macrocyclic bifunctional chelates, it was apparent that the radiocopper was transchelated and bound to proteins such as superoxide dismutase (SOD; *see* ***Copper Proteins with Type 2 Sites***). Transchelation of the copper radiolabel appears to be a major factor for liver accumulation of the $^{64/67}$Cu-labeled BFC-1A3 conjugates.[111] After extensive evaluation, experimental results are consistent with in vivo transchelation of ^{64}Cu from TETA-octreotide to superoxide dismutase (SOD) in rat liver.[112]

New ligands that show improved biological kinetic stability are needed to form stable Cu(II) bifunctional complexes. For this purpose, a series of ligands that sequester radiocopper have been developed. 1-N-(4-aminobenzyl)-3,6,10,13,16,19-hexaazabicyclo(6.6.6)eicosane-1,8-diamine (SarAr, Figure 18) was designed for conjugation to proteins and complexes metals within 30 min at pH 6–8.[113] The ^{64}Cu(SarAr) is found to be kinetically inert to dissociation of the radiocopper and is rapidly excreted through the renal system; these qualities make it an attractive prospect for use in nuclear medicine.[113] Cross-bridged cyclam ligands (Figure 18) have been developed, have high stability with copper, and appear



SAR-AR | Cross-bridged cyclam | Cu^{II} complex of cross-bridged cyclam

Figure 18 Macrocyclic ligands for stabilization of ^{67}Cu, ^{64}Cu

to have improved kinetic stability.[114,115] Thus, these cross-bridged cyclam ligands may sequester Cu(II) appropriately for nuclear medicine applications.[116]

4 CONCLUDING REMARKS

Diagnostic imaging has grown significantly with the introduction of new metal-based imaging agents, including ^{99m}Tc agents for brain, heart, and renal imaging as well as the introduction of targeted peptide receptor-specific agents (both ^{111}In and ^{99m}Tc) in the clinic. An increased understanding of the requirements of small molecule receptor-specific interactions, coupled with the development of the coordination chemistry of ^{99m}Tc and other radiometals, result in new potential imaging radiopharmaceuticals, many of which are in clinical trials.

1 INTRODUCTION

Proteins perform many of the most essential functions in biology, from structure and recognition to catalysis and regulation, representing an extraordinarily diverse range of functions for a single family of molecules. This diversity is possible because of the unique organization of the folded polypeptide chain and the variety of functional groups provided by the 20 naturally occurring L-amino acids. The primary structure of the linear polypeptide chain is uniquely determined by its genetic template and the 'universal genetic code'. Expansion of the genetic code in certain special cases allows incorporation of at least two additional rare amino acids, selenocysteine (*see* ***Selenium Proteins Containing Selenocysteine***) and pyrrolysine, into proteins that utilize the unique reactivity of these groups in enzyme catalysis.

The functionality of protein structures may be further extended through posttranslational modifications to the polypeptide chain, generating novel amino acid residues. Some of these modified residues (like *m*-hydroxyphenylalanine (**1**), *o,o′*-dityrosine (**2**), dihydroxyphenylalanine (**3**)) bear a strong resemblance to familiar amino acids, while others form hyper-modified structures (like histidinomerdesmosine (**4**) and desmosine (**5**)). Generally these modifications can only be detected through direct analysis of the protein structure using high-resolution methods like X-ray crystallography or mass spectrometry, although in some cases (e.g. formation of a chromophore or a cross-link) the unusual behavior of the modified protein has allowed detection by more conventional biochemical techniques. There is a growing recognition that covalent modification of protein structure is important for biological function, and investigating these modifications is a rapidly emerging area in proteomics research.[1] Metal ions are known to participate in some way in many of the processing events giving rise to protein modifications. This overview focuses on these metal-dependent processing reactions, within which we will broadly distinguish among metalloenzyme-mediated protein modifications, metalloprotein self-processing reactions, and reactions of inorganic complexes leading to covalent modification of protein structure (Table 1).

2 METALLOENZYME-MEDIATED PROTEIN MODIFICATION

Enzymatic processing of proteins allows new functionality to be introduced in a highly selective fashion with one protein serving as a macromolecular substrate in the reaction. The inherent structural specificity of enzyme catalysis allows the recognition of individual amino acid side chains in a specific structural context for modification, and this type of processing is an important step in the maturation of many proteins, particularly those that are secreted into the extracellular space. Typical modification reactions include the oxygenation of amino acid side chains (by a class of enzymes known as oxygenases), oxidation of side chains (by oxidases), glycosylation of residues (by glycosyl transferases), and site-specific cleavage of polypeptide chains (by metalloproteases).

Table 1 Metal-mediated posttranslational modification of proteins

Mediating Complex	Metal	Modification product
A. Metalloenzyme-mediated modification		
Proline hydroxylase	Fe	γ-hydroxyproline
Lysine hydroxylase	Fe	δ-hydroxylysine
Peptidylglycine α-amidating hydroxylase	Cu	α-hydroxyglycine
Lysyl oxidase	Cu	α-aminoadipic δ-semialdehyde
Tyrosinase	Cu	dihydroxyphenylalanine
Peroxidase	Fe	dityrosine
Galactosyl transferase	Mn	galactosyl peptide
Peptidylamidoglycolate lyase	Zn	amidated peptide
Matrix metalloproteases	Zn	peptides
B. Metalloprotein self-processing		
Amine oxidase	Cu	trihydroxyphenylalanine (TPQ)
Lysyl oxidase	Cu	lysine tyrosyl quinone (LTQ)
Galactose Oxidase	Cu	cysteinyl-tyrosine
Hemocyanin	Cu	cysteinyl-histidine
Diphenol oxidase	Cu	cysteinyl-histidine
Cytochrome *c* oxidase	Cu	histidinyl-tyrosine
Nitrile hydratase	Fe,Co	cysteine sufenate/sulfinate
C. Modification by small complexes		
Artificial peptidases	Cu, Fe	peptides
Fenton reaction	Fe,Cu,Cr	nonspecific oxidation
Substitution-inert complexation	Cr,Co,Ru	complex conjugation

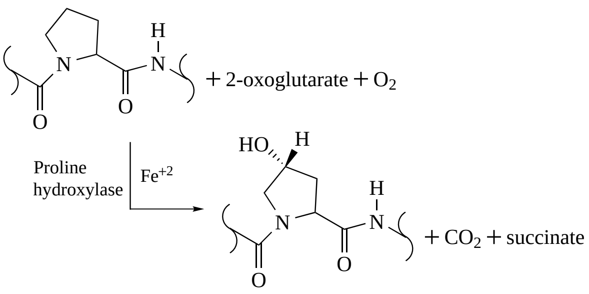
2.1 Oxygenases

Enzymes that insert oxygen atoms from molecular oxygen into unactivated C–C and C–H bonds are known generically as oxygenases (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***). Monooxygenases insert a single atom from dioxygen into substrate, reducing the other atom of oxygen to water. Dioxygenases, on the other hand, insert both atoms of dioxygen into products. All of the oxygenases that are known to be involved in protein modification contain essential metal cofactors.

2.1.1 Proline Hydroxylase [E.C. 1.14.11.2]

Hydroxylation of peptidyl proline residues is an essential step in the maturation of collagen, a proline- and glycine-rich structural protein that is the most abundant single polypeptide in the human body.[2–5] Collagen serves as the matrix material in bone and is the major polymer in tendon, skin, and blood vessels. The strength and flexibility of collagen is a consequence of its unique structure, a protein triple-helix formed by assembly of three polypeptides whose backbones are extensively interconnected by hydrogen bonding. This structure is further stabilized by hydrogen bonding between backbone amide groups and hydroxyl groups of hydroxyproline residues formed posttranslationally by oxygenation of proline residues in a (Gly-Pro-Pro)-sequence motif that is repeated many times within the protein. The enzyme that catalyzes the oxygenation reaction, proline hydroxylase, is a nonheme iron enzyme that requires 2-oxoglutarate as a reducing cosubstrate.[6]

Proline hydroxylase has been isolated and characterized and is known to contain a mononuclear nonheme ferrous iron center that is the catalytic active site of the enzyme, coordinated by two histidine and one aspartate side chains. The requirement for Fe(II) is reflected in the in vivo sensitivity of collagen formation to chelators specific for ferrous ion (e.g. 2,2′-dipyridyl). In addition to the catalytic metal cofactor, the reaction requires a reducing cosubstrate, 2-oxoglutarate, dioxygen, and the procollagen peptide (equation 1).



(**6**)

(1)

Hydroxylation primarily occurs at the γ-position of the proline ring to form γ-hydroxyproline (**6**), although β-hydroxyproline is also formed in smaller amounts. These two products apparently result from two closely related enzymes exhibiting distinct substrate regioselectivity.

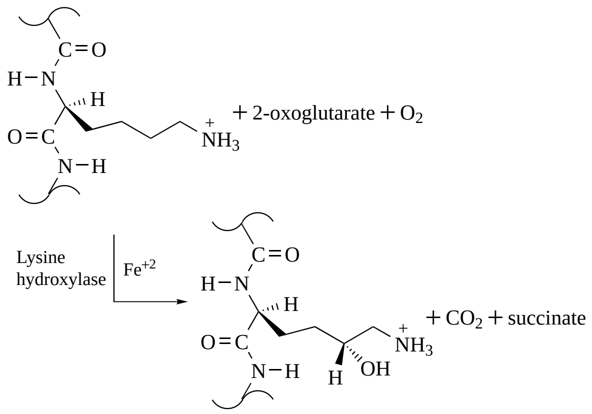
The active site metal center reductively activates dioxygen during the catalytic turnover cycle. Oxygenation of the ferrous [Fe(II)] metal center in the resting enzyme is

thought to generate a metal-bound peroxide adduct of 2-oxoglutarate whose decay results in transient formation of a highly reactive oxidized oxo-ferryl [Fe(IV)=O] species.[7] This aggressive oxo intermediate is capable of inserting an oxygen atom into unactivated C–H bonds. The specificity of the enzyme for C–H bonds in proline side chains in collagen is a consequence of substrate selectivity determined by the extended active site environment rather than the metal complex.

Although the reaction cycle returns the active site to the resting ferrous state during turnover, uncoupling between metal oxidation and substrate hydroxylation sometimes occurs, converting the enzyme to a catalytically inactive ferric complex. Ascorbate is required to maintain the protein-bound iron in the resting enzyme in the ferrous oxidation state. This ascorbate requirement of proline hydroxylase is expressed in the clinical connection between dietary ascorbate deficiency and scurvy, a disease resulting from incomplete collagen processing.[8] This example clearly illustrates the importance of metal ions in protein modification and biological function.

2.1.2 *Lysine Hydroxylase [E.C. 1.14.11.4]*

A second posttranslation modification that occurs in the maturation of collagen is the oxygenation of lysine residues to form *δ-erythro*-hydroxylysine, which serves as an anchor for attachment of carbohydrates in a glycosylation process (equation 2).



(**7**)

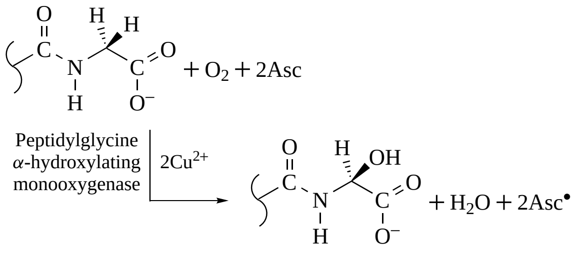
(2)

The enzyme that catalyzes this reaction, lysine hydroxylase, is, like prolyl hydroxylase, a Fe(II)/2-oxoglutarate dependent dioxygenase[6] but exhibits a distinct substrate specificity.

2.1.3 *Peptidylglycine α-hydroxylating Monooxygenase [E.C. 1.14.17.3]*

Many neuropeptides and peptide hormones are posttranslationally modified by C-terminal amidation, in which a C-terminal glycine residue is first hydroxylated, then cleaved to generate a carboxamido terminal group.[9] The amidated peptide does not serve as a substrate for carboxypeptidases (which recognize a C-terminal carboxyl group) and modification thus extends the lifetime of the peptide in circulation. The peptide hormones oxytocin and vasopressin exhibit this type of C-terminal amidation. The amidating reaction is performed by a bifunctional copper- and zinc-dependent protein-processing enzyme peptidylglycine α-amidating monooxygenase, which is comprised of an N-terminal monooxygenase domain (peptidylglycine α-hydroxylating monooxygenase) and a C-terminal lyase domain (peptidylamidoglycolate lyase)(*vide infra*).

Peptidylglycine α-hydroxylating monooxygenase is a copper metalloenzyme containing two Type 2 mononuclear copper sites (*see* ***Copper Proteins with Type 2 Sites***), each having a distinct coordination environment. X-ray crystallography shows that one copper ion has a [$(His)_2Met(H_2O)$] ligand set, while the other has [$(His)_3(H_2O)$] coordination. The oxidized [Cu(II)] centers in the resting enzyme are reduced to Cu(I) during turnover by two molecules of ascorbate (Asc), which are oxidized by one electron to semiascorbyl free radicals (Asc•). The Cu(I)-containing enzyme binds the peptide substrate and dioxygen to form a ternary complex within which the monooxygenation reaction occurs, inserting an oxygen atom into the unactivated C–H bond at the alpha carbon of the carboxy terminal glycine residue to form α-hydroxyglycine (**8**) (equation 3).



(**8**)

(3)

Amidating enzymes related to peptidylglycine α-hydroxylating monooxygenase are involved in regulation of a wide range of biological processes, including the vascularization of tissue (angiogenesis), which is recognized as an important target for cancer therapy. The copper-dependence of the glycine monooxygenase suggests the possibility of controlling tumor growth using metal-specific chelation. In fact, depletion of copper in tissues by treatment with a sulfide donor, tetrathiomolybdate, has been shown to have antitumor activity, possibly as a result of inactivation of amidating enzymes responsible for angiogenesis hormone processing.

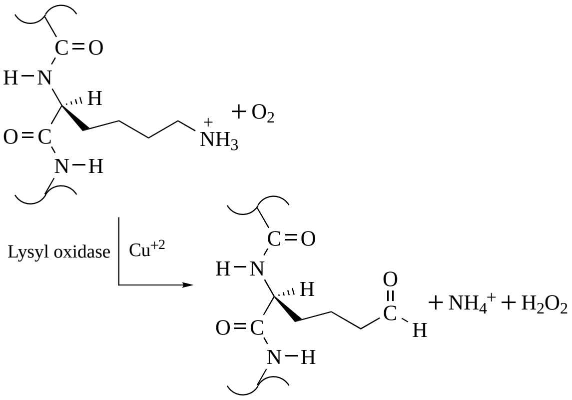
2.2 Oxidases

Oxidases are enzymes that catalyze oxidation–reduction processes that do not involve insertion of oxygen atoms. Modification of proteins by oxidases allows the introduction of covalent cross-links between polypeptide chains.

2.2.1 Lysyl Oxidase [E.C. 1.4.3.13]

Lysyl oxidases catalyze the oxidation of the ε-amino group in the side chain of lysine residues in proteins, producing a reactive aldehyde functional group, which can form Schiff-base adducts with unmodified lysine residues or undergo aldol addition, creating covalent cross-links between polypeptide chains.[10–12] Lysyl oxidases are widespread in nature, and have been isolated from organisms ranging from yeast to man.

Lysyl oxidase contains a single Type 2 copper center (*see* ***Copper Proteins with Type 2 Sites***) at the active site, bound by three histidine residues. The metal ion appears not to be redox active during turnover, and the oxidation chemistry is instead performed by a covalently attached cofactor, lysine tyrosyl quinone, derived from a tyrosine residue in the protein (*vide infra,* Section 3.1). The overall reaction involves oxidation of the primary amine group of a peptide-bound lysine residue, reduction of dioxygen to hydrogen peroxide, and release of ammonium ion (equation 4).



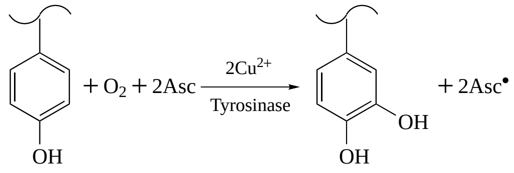
(**9**)

(4)

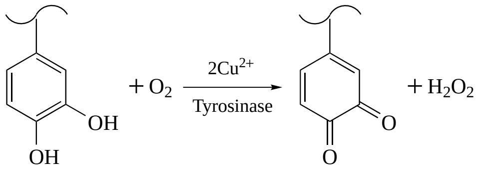
The peptidyl lysine substrate is converted to an α-aminoadipic δ-semialdehyde (allysine) residue in this process. This reaction is important in the maturation of the extracellular matrix proteins collagen and elastin, in which multiple allysine residues condense to form complex cross-links between polypeptide chains creating the unusual amino acids histidinomerdesmosine (**4**) and desmosine (**5**). The formation of these cross-links in collagen and elastin is important in determining their physical properties. Increasing the extent of cross-linking with age leads to loss of flexibility. Conversely, defects in cross-linking between chains may result in hyperextensible (rubbery) skin. Lysyl oxidases appear to have other, less well-characterized roles in tumor suppression, developmental control, and chemotaxis.

2.2.2 Tyrosinase [E.C. 1.4.18.1]

Tyrosinase (*see* ***Copper Proteins with Dinuclear Active Sites***), a copper metalloenzyme with a very broad phylogenetic distribution, is responsible for the browning of fruits and mushrooms.[13–15] Tyrosinase is a bifunctional phenol oxidase that is able to both hydroxylate monophenols like tyrosine (monooxygenase reaction, (equation 5)) and subsequently oxidize the diphenol product to the corresponding quinone (oxidase reaction, (equation 6)) at a single Type 3 binuclear copper active site.



(5)



(6)

(**10**)

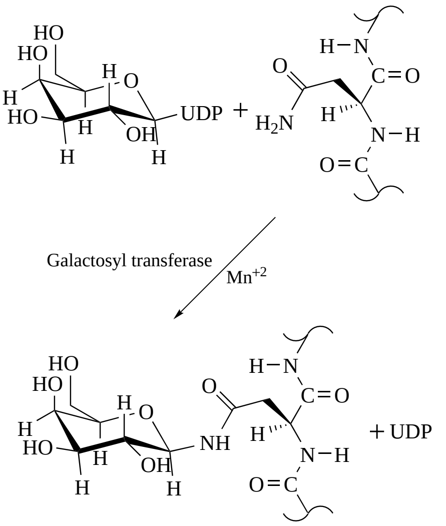
While tyrosinase substrates are generally small molecule phenolic compounds, the enzyme also appears to be responsible for the formation of dihydroxyphenylalanine (dopa) in molluscan proteins, including adhesive proteins (‘mussel glue’) that allow barnacles, limpets, and mussels to anchor themselves to wetted surfaces.[16] The presence of dopa residues in these polyphenolic proteins leads to cross-linking (probably *via* a peptidyl tyrosyl *o*-quinone (**10**) intermediate) forming an extremely strong polymeric resin. This unique bioadhesive is currently being investigated for potential biomedical applications.

2.3 Transferases and Lyases

2.3.1 Galactosyl Transferase [E.C. 2.4.1.44]

Many extracellular proteins are glycoconjugates, containing covalently bound polysaccharides that contribute to stability of the protein and may have a signaling function in cellular targeting. Carbohydrate residues are attached to proteins during secretion from the cell by specialized glycosyl transferases localized in the secretory pathway

(equation 7).

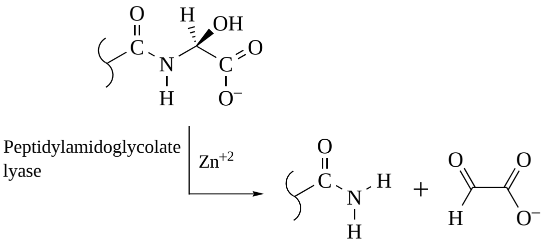


(7)

Many of these enzymes are known to be manganese dependent (*see* ***Manganese Proteins with Mono- & Dinuclear Sites***), containing a mononuclear divalent manganese ion in their active site.[17] The structures of a number of glycosyl transferases have recently been solved by X-ray crystallography, revealing a metal ion bound in mixed amine/carboxylate $[(Asp)_2(His)_1]$ coordination. The divalent metal ion is strictly required for activity, possibly functioning to activate the phosphorylated substrate. Further evidence for the importance of manganese-mediated glycosylation is provided by observation that mutational inactivation of the golgi manganese ion transporter (Pmr1p) in yeast results in aberrant processing of secretory proteins and 'supersecretion' behavior.

2.3.2 Peptidylamidoglycolate lyase [E.C. 4.3.2.5]

Peptidylamidoglycolate lyase completes the peptide amidation process initiated by peptidylglycine α-hydroxylating monooxygenase (*vide supra*, Section 2.1.3).[9] This zinc-dependent function converts the hydroxyglycine containing peptide to the amidated form and releases glyoxalate (equation 8):



(**11**)

(8)

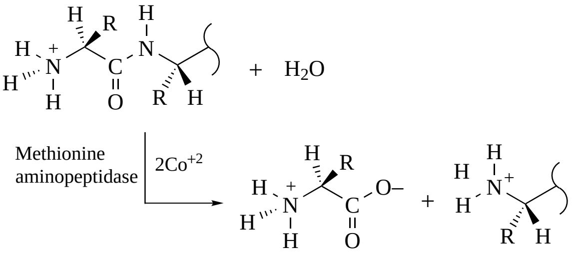
The role of the zinc ion in this reaction is not clearly understood, but might involve activation of coordinated water serving as a specific base in the reaction.

2.4 Metalloproteases

Proteolytic cleavage (peptide bond hydrolysis) is another way that metal-mediated posttranslational modification of proteins may occur.[18–21] Site-specific cleavage of polypeptides is essential for maturation of the protein and conversion of prohormones and cytokine precursor proteins to their biologically active forms, and proteolysis is also an important mechanism for regulating the protein activity through irreversible degradation.

2.4.1 Methionine Aminopeptidase [E.C. 3.4.11.18]

Virtually all proteins expressed in cells undergo processing to remove the N-terminal methionine residue encoded by the 'start codon', ATG. Cleavage of this initiation methionine from newly formed polypeptide chains is catalyzed by the enzyme methionine aminopeptidase (equation 9).



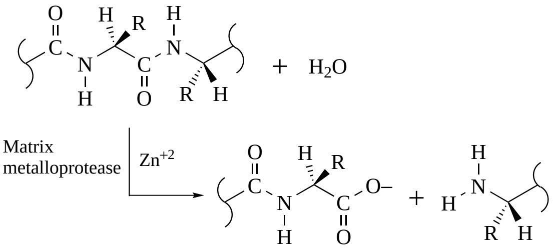
(9)

The active site of methionine aminopeptidase contains a binuclear cobalt complex that is required for activity, although a number of divalent metal ions support turnover to varying degrees. X-ray crystallographic studies on the enzyme in complexes with transition state analogs suggests that the binuclear metal cluster serves to stabilize the tetrahedral intermediate in peptide hydrolysis.[21]

2.4.2 Zinc Metalloproteases

Zinc metalloproteases (*see* ***Zinc Enzymes***) form an important class, distinguished by a strict requirement for a tightly bound mononuclear zinc ion cofactor. The role of the zinc ion in the hydrolytic mechanism is to polarize and activate both the coordinated peptide carbonyl and a coordinated solvent nucleophile, stabilizing the tetrahedral intermediate

(equation 10).



(10)

The central role of proteolytic processing by metalloproteases is illustrated by the essential functions in which they are involved. Carboxypeptidase A is a degradative enzyme that is important for recycling proteins, cleaving the C-terminal peptide bond to release free amino acids. The angiotensin converting enzyme (ACE) membrane secretase, which is responsible for the release of a peptide (angiotensin) that is involved in regulation of blood pressure, is a zinc metalloprotease that is an important target for pharmaceuticals aimed at controlling hypertension. Matrix metalloproteases are a family of zinc enzymes that have important roles in cellular regulation. Collagenase and elastase are involved in remodeling tissues during development. The ADAMs (‘a disintegrin and metalloproteinase’) family of zinc enzymes includes secretases and enzymes that process prohormones for release from cells. These enzymes are responsible for activating cytokines (bioactive cellular messenger molecules) including pro-TNF-α (tumor necrosis factor α), a peptide that is involved in programmed cell death. One of the matrix metalloproteases (disintegrin) has been implicated in the cleavage of β-amyloid precursor protein leading to Alzheimer’s plaque formation. The specific zinc requirement of this family of proteases makes them sensitive to metal chelators (EDTA, 1,10-phenanthroline) and hydroxamate substrate analogs, features that are taken advantage of in the design of new pharmaceuticals targeting these enzymes.[18–20]

2.5 Peroxidase Coupling

Peroxidases are heme metalloenzymes (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***) that catalyze oxidation of a variety of substrates coupled to reduction of hydrogen peroxide to water. During the catalytic cycle, hydrogen peroxide oxidizes the heme to an oxy-ferryl porphyrin π cation radical species [$(P^{+\bullet})Fe(IV)=O$] known as Compound I, which undergoes two 1-electron reduction steps. As a result, peroxidases are able to efficiently oxidize organic substrates to free radical products. Typically, the substrates for these enzymes are small organic molecules, but peroxidases have also been shown to catalyze the formation of cross-links in proteins in vitro, producing o,o'-dityrosine (**2**) dimers through a free radical coupling mechanism.[22] Dityrosine has been used as a biomarker for pathological protein oxidation. Covalent cross-links between tyrosine residues have been found in the egg coat proteins of certain invertebrates, suggesting the possibility of a structural role for dityrosine in biology.

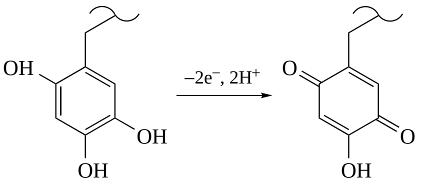
3 METALLOPROTEIN SELF-PROCESSING

The simple coordination chemistry characteristic of the majority of protein–metal interactions is replaced in certain cases by irreversible covalent modifications of the protein mediated by the metal ion. These modifications are essential for the function and are templated by the structure of the protein, as no other proteins are required for the reaction to occur. These self-processing reactions result in the biogenesis of redox cofactors in some enzymes (amine oxidases, galactose oxidase, cytochrome *c* oxidase) and activation of hydrolytic sites in others (nitrile hydratase). The active sites of all of these enzymes are bifunctional, directing not only the catalytic turnover reaction of the mature enzyme but the modification steps required for maturation.

3.1 Quinocofactors

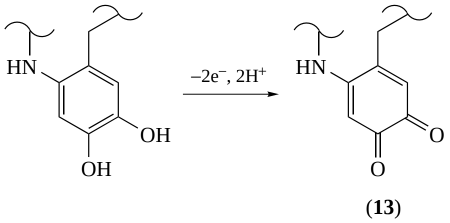
Enzymes that perform oxidation–reduction catalysis generally require some type of cofactor to store electrons (and protons) during the catalytic cycle. The cofactors are usually low-molecular weight species that reversibly bind to the enzyme, but in some cases are intrinsic elements of the protein structure. For example, *quinoenzymes* contain covalently bound quinones derived from tyrosine or tryptophan residues in the protein. These *quinocofactors* represent a striking extension of protein side-chain reactivity.[23–27]

There is a great deal of interest in understanding how the quinocofactors are formed. The mechanisms for the biogenesis of the tyrosine-derived quinocofactors, 2,4,5-trihydroxyphenylalanine quinone (TPQ, (**12**)) and lysine tyrosylquinone (LTQ, (**13**)) have been most extensively studied.



(11)

(**12**)



(12)

(**13**)

3.1.1 Topaquinone

Amine oxidases [E.C. 1.4.3.6] are a family of enzymes that are distributed over both prokaryotic and eukaryotic life, with the enzymes from bacteria (*Escherichia coli*, *Arthrobacter globiformis*) and plants (pea seedling) being most extensively studied (*see* ***Copper Proteins with Type 2 Sites***). All of these enzymes contain a mononuclear copper ion and a TPQ quinocofactor (**12**) that serves as both a redox center and an electrophile in the oxidation of primary amines (equation 11). Peptide mapping and gene sequencing have proven that the cofactor is derived from a tyrosyl residue in the protein, which undergoes posttranslational oxygenation to form the quinone.[28–30]

The protein is expressed in a precursor form, lacking both copper and quinocofactor. In vitro experiments have demonstrated that only copper and O_2 are required for the biogenesis reaction to occur. X-ray crystallographic studies on the self-processing reaction of *A. globiformis* amine oxidase have taken advantage of the availability of diffraction-quality crystals of the precursor apoprotein and the possibility of performing the cofactor biogenesis reaction within the crystal. The crystals are exposed to Cu^{+2} and dioxygen under controlled conditions, and the progress of the reaction followed using microspectrophotometry. The crystals are freeze-trapped for structure determination, yielding X-ray snapshots of species formed during the biogenesis of the quinocofactor.[31] This approach has provided important structural characterization of processing intermediates, as a basis for the biogenesis mechanism, illustrated in Scheme 1.[24–36]

The reaction is thought to be initiated by binding Cu^{+2} ion to the apoprotein, forming a complex in which the metal ion is coordinated by three histidine side chains and the phenolate form of the tyrosine residue that forms the cofactor (**14**). In a twist from the usual metalloprotein chemistry, dioxygen is thought to bind at a nonmetal site within the protein (**15, 16**). The presence of O_2 is thought to somehow induce a shift in the electron delocalization within the tyrosinate-Cu^{+2} charge transfer complex, stabilizing the phenoxyl radical species (**16**). The phenoxyl radical is expected to react readily with triplet dioxygen, yielding a peroxide adduct (**17**) that can lose the elements of water to form a peptidyl-dopaquinone that initially binds to the metal ion (**18**) and then dissociates (**19**). This first oxygenation product has been detected as an early intermediate in the X-ray snapshots.

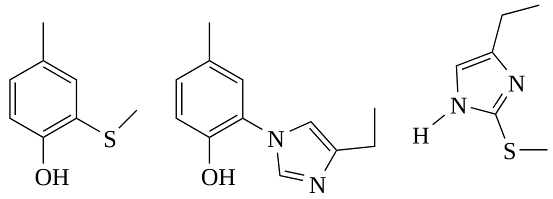
The second hydroxyl group is introduced into the tyrosine side chain through attack by a metal-activated solvent molecule rather than dioxygen. Hydroxide attack at the open para-position yields trihydroxy phenylalanine (**20**), which undergoes oxidation by dioxygen to form the mature quinocofactor-containing protein (**21**) (equation 11).

3.1.2 Lysine Tyrosylquinone

The active site of lysyl oxidase contains a chromophoric quinocofactor that is distinct from, but related to TPQ.[23–26] Structural characterization (by mass spectrometry) has shown that in lysyl oxidase, a lysine side chain adds to the quinocofactor forming a covalent cross-link within the protein. This novel cofactor, which has been given the trivial name lysine tyrosyl quinone (LTQ) (**13**), is immobilized by this linkage, and exhibits an altered pattern of reactivity, forming an *o*-quinone (equation 11) rather than the *p*-quinonoid structure stabilized by TPQ (equation 12).

3.2 Cross-linked Amino Acids

Covalent linkage between two amino acid side chains within a single polypeptide chain appears to be a surprisingly common modification that may serve a function in the structure or reactivity of the protein. In addition to the cross-linked *o,o′*-dityrosine dimers (*vide supra*, Section 2.5) and the quinocofactor, LTQ (*vide supra*, Section 3.1.2), a number of other covalent structures have been identified, mainly by X-ray crystallography. These cross-linked amino acid derivatives include cysteinyl-tyrosine (**22**), histidyl-tyrosine (**23**), and cysteinyl-histidine (**24**).

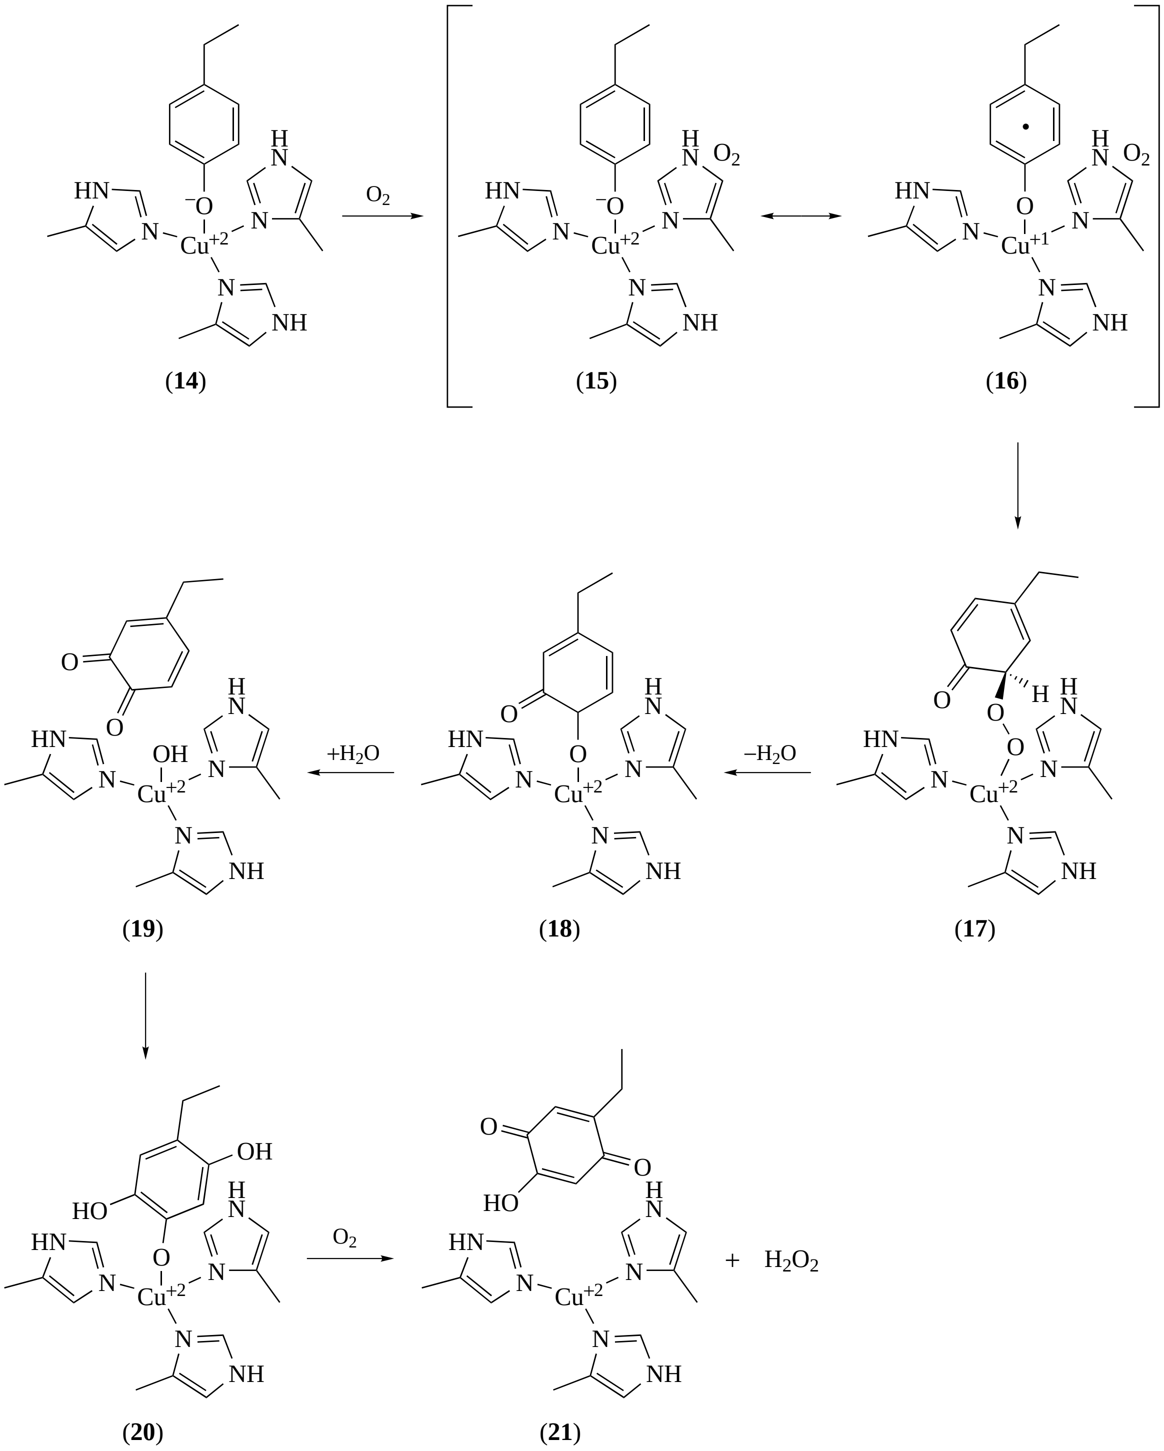


(**22**) (**23**) (**24**)

3.2.1 Cysteinyl-tyrosine Cofactor

The radical copper oxidases (*see* ***Copper Proteins with Type 2 Sites***), including galactose oxidase [E.C. 1.1.3.9] and glyoxal oxidase, have active sites that contain a nonquinone redox cofactor formed by covalently cross-linking cysteine and tyrosine residues to create a thioether-bridged structure, cysteinyl-tyrosine (**22**).[37,38] Unlike the TPQ cofactor in quinoproteins, the cysteinyl-tyrosine cofactor is restricted to one-electron oxidation–reduction chemistry, stabilizing a protein-free radical in the catalytically active form of the enzyme. The radical serves as a ligand to the Type 2 Cu^{+2} metal center, forming a two-electron redox unit that transfers electrons from reducing substrates (generally alcohols or simple aldehydes) to dioxygen, generating hydrogen peroxide. The presence of a modified tyrosine residue in galactose oxidase that functions as a free radical site in catalysis was recognized initially from spectroscopic studies, and the novel thioether linkage of one of the tyrosines in the active site was subsequently revealed by X-ray crystallography (Figure 1).[37,38]

The origin of the cysteinyl-tyrosine cofactor is intriguing, and early studies showed that a precursor form of the enzyme,



Scheme 1

lacking the cross-link, could spontaneously form the cofactor in the presence of copper and dioxygen, without assistance from any other proteins.[39] This indicates that, as seen for the amine oxidases, the active site is able to direct all of the chemistry required for cofactor biogenesis. Recent in vitro studies on the mechanism of cofactor biogenesis in galactose oxidase, using recombinant precursor protein, have demonstrated that it is a Cu^{+1}-dependent reaction.[40] Although Cu^{+2} also supports cofactor biogenesis in galactose oxidase, the reaction is >4000-fold slower when oxidized metal ion is used, and may still require slow reduction of Cu^{+2} by adventitious reductants for the reaction to proceed.

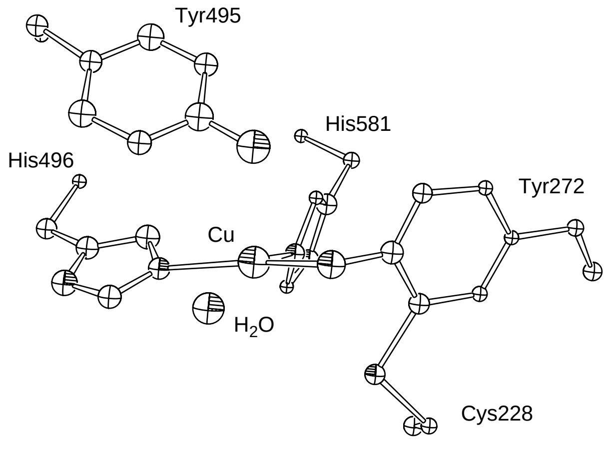


Figure 1 The active site of galactose oxidase, showing the covalent cross-link between Cys228 and Tyr272. Heteroatoms (N,O,S) are indicated by a shaded quadrant. [ortep-III view based on PDB ID 1GOG]

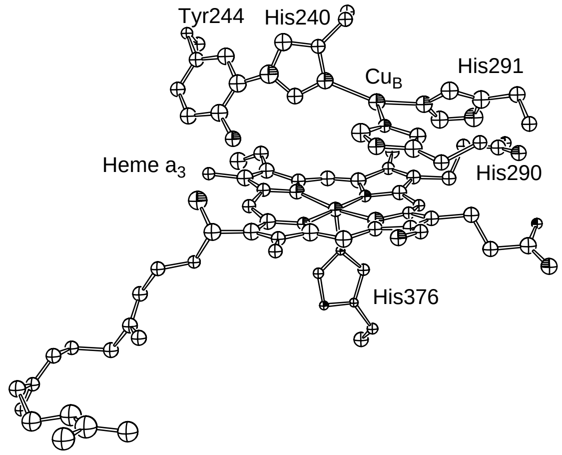

Figure 2 Oxygen-reducing Heme a_3-Cu_B active site of fully reduced bovine cytochrome *c* oxidase, showing the covalent cross-link between His240 and Tyr244. Heteroatoms (N,O) are indicated by a shaded quadrant. [ortep-III view based on PDB ID 1OCR]

The mechanism for cysteinyl-tyrosine cofactor biogenesis in galactose oxidase is outlined in Scheme 2.[40] The metal-free precursor protein (**25**) binds Cu^{+1} in the active site (**26**) and reacts with dioxygen to form an oxygenated species related to Cu^{+2}-superoxide adduct (**27**). This reactive complex may abstract a hydrogen atom from cysteine thiol to form a thiyl radical (**28**) or oxidize the tyrosine residue to form a phenoxyl radical (**29**). Reaction of either of these radical species would generate a covalent adduct (**30**). Loss of a proton restores the conjugation of the aromatic ring system and at the same time reduces the metal ion. This mature, cross-linked Cu^{+1} complex (**31**) represents the reduced form of the active enzyme, and subsequent reaction with O_2 completes the biogenesis process, forming catalytically active, free radical containing active enzyme as the product (**32**).

3.2.2 Histidyl-tyrosine

The dioxygen reduction site of the key respiratory enzyme, cytochrome *c* oxidase [E.C. 1.9.3.1], is a bimetallic catalytic center comprised of a heme iron adjacent to a Type 2 mononuclear copper center (*see* ***Cytochrome Oxidase***). The recent solution of the X-ray crystal structure of this enzyme revealed an entirely unanticipated covalent modification of the protein structure, a cross-link between a histidine and tyrosine side chain (**23**) within the active site (Figure 2).[41] This extraordinary posttranslational modification has been confirmed by peptide mapping and mass spectrometry, and has been detected as a conserved element in cytochrome *c* oxidases isolated from organisms ranging from bacteria to cows.[42,43] The role of the cross-linked structure in the function of cytochrome *c* oxidase is still controversial.[44–46] A number of possibilities have been suggested, including a role in modulating the acidity of the active site tyrosine hydroxyl group, stabilizing a possible phenoxyl free radical intermediate during turnover, stabilizing an unusual oxidation of copper, or a structural role as rigid scaffolding supporting the metal coordination spheres. The mechanism for formation of this feature is at present entirely unknown, but is likely a self-processing reaction of the protein mediated by the metal ions.

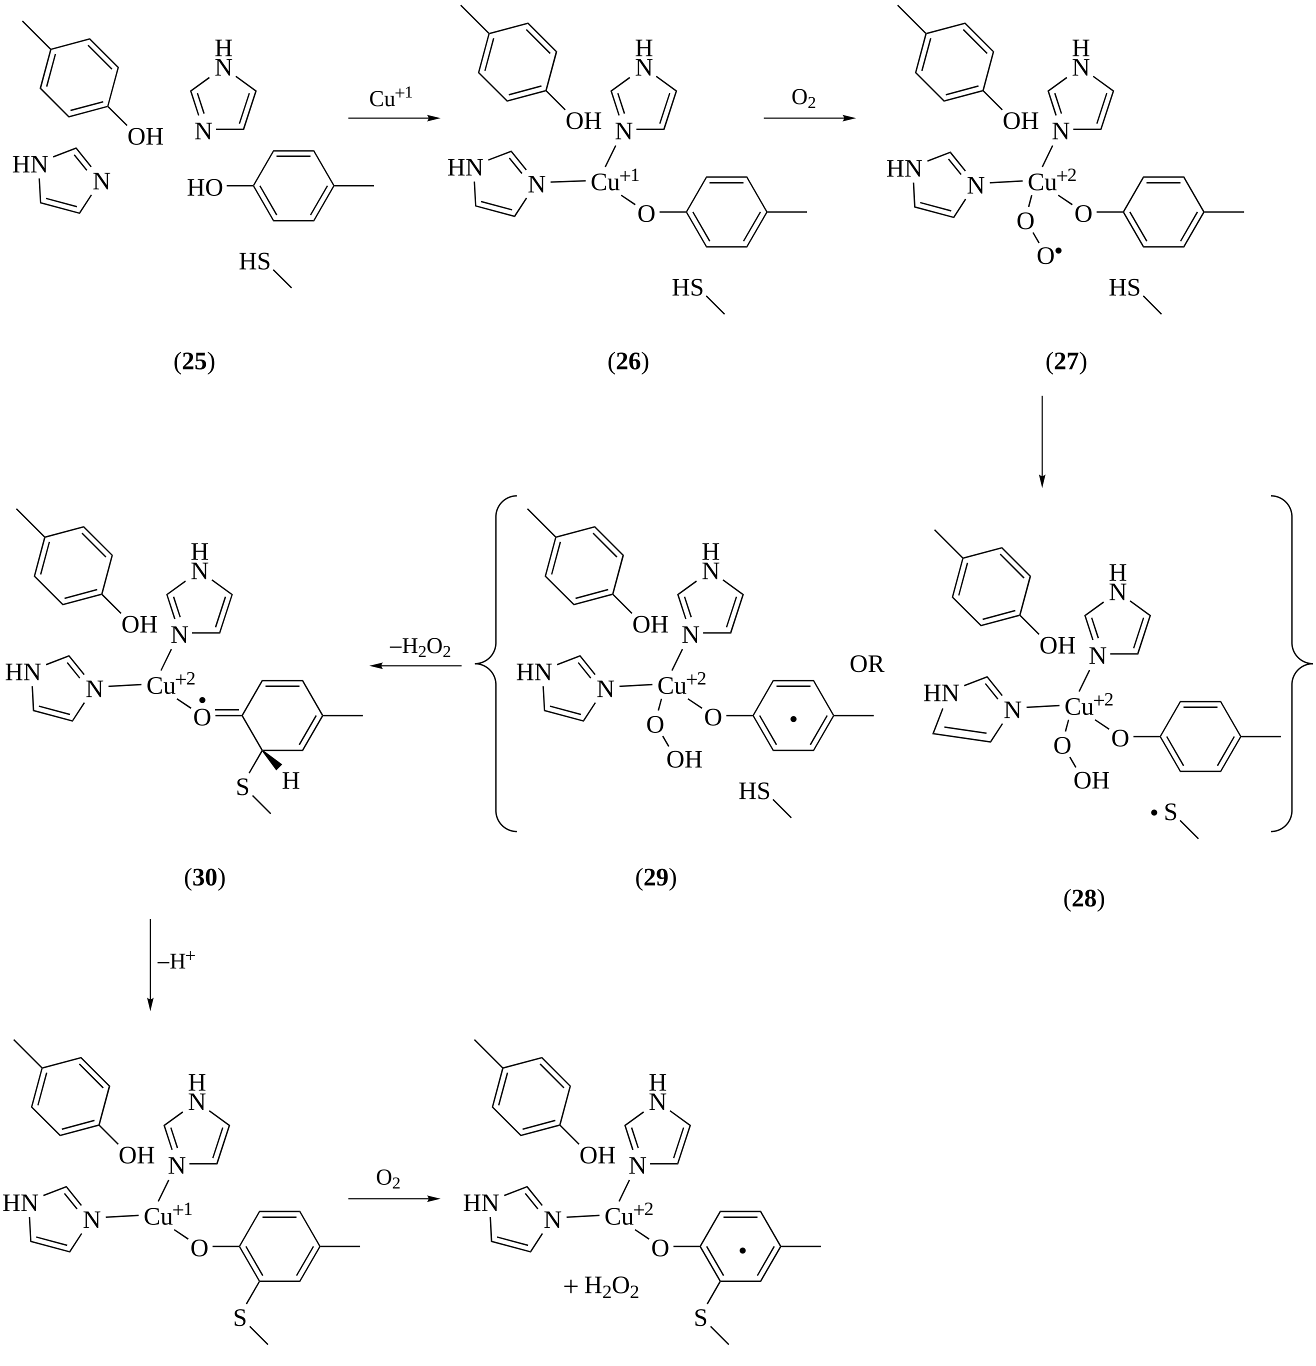
3.2.3 Cysteinyl-histidine

Cysteinyl-histidine (**24**) was first identified as a posttranslational modification of tyrosinase, detected during protein sequence analysis.[47] Like cysteinyl-tyrosine (**22**), it contains a thioether linkage, the sulfur being attached to the imidazole δ-carbon within the histidine side chain. Subsequent studies have identified cysteinyl-histidine in hemocyanin, the oxygen carrier protein of arthropods and molluscs that, like tyrosinase, contains a dinuclear copper site[48] (*see* ***Copper Proteins with Dinuclear Active Sites***). The X-ray crystal structures of the octopus oxygen transport protein hemocyanin and sweet potato catechol oxidase (Figure 3) have revealed that this protein modification is associated with the redox-active binuclear copper metal cluster, suggesting a metal-mediated origin for cysteinyl-histidine.[49,50]

3.3 Hydrolytic Sites

3.3.1 Nitrile Hydratase [E.C. 4.2.1.84]

Nitrile hydratase is a key enzyme involved in the microbial degradation of nitriles in the environment, catalyzing the hydration of a nitrile to an amide (*see* ***Iron Proteins with***



Scheme 2

Mononuclear Active Sites). This reaction has important commercial applications, and nitrile hydratase has been used industrially for enzymatic production of acrylamide from acrylonitrile. The enzyme contains a mononuclear Fe(II) (or Co(II)) active site, the metal ion being bound in a highly unusual coordination involving two deprotonated peptide amides together with three cysteine side chains (Figure 4). The two cysteines that are bound trans to the peptide ligands have been found (by X-ray crystallography) to be modified by oxygenation to cysteine-sulfenic acid (Cys-SOH (**34**)) and cysteine-sulfinic acid (Cys-SO_2H (**35**)) derivatives.[51]

Enzyme lacking these modifications is catalytically inactive, and the oxygenation occurs spontaneously when the anaerobically prepared precursor protein is exposed to O_2. The

4 MODIFICATIONS MEDIATED BY SMALL COMPLEXES

4.1 Artificial Proteases

The understanding of the mechanistic principles underlying the catalytic chemistry of metalloproteases has been applied in the design and synthesis of a number of biomimetic metal complexes that function as artificial proteases. These complexes include mononuclear water-activating complexes, and multinuclear complexes that combine carboxyl terminal recognition, peptide carbonyl polarization, and water nucleophile activation functions.[52]

Surprisingly, the most successful artificial proteases operate by a completely nonbiomimetic mechanism, using peroxide activated by metal complexes for peptide bond cleavage. Iron chelate-mediated protein cleavage may operate through a number of different mechanisms, involving bound oxygen species or diffusible hydroxyl radicals. This approach has been refined as a tool for mapping protein–protein interactions, using tethered cutting reagents to footprint the contact surfaces between two proteins.[53]

4.2 Fenton Chemistry

Proteins are susceptible to attack by a wide variety of metal-associated oxidants resulting in covalent modifications that impair, rather than enhance, their biological function. This observation has given rise to a view that many aspects of human health (disease, aging, and cancer) are linked to oxidative stress induced by reactive oxygen species (ROS) including superoxide radical ($O_2^{-\bullet}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($HO^{\bullet}$), products of partial reduction of dioxygen by metal complexes.[54,55] The one-electron reactivity characteristic of transition metal complexes makes them especially potent mediators of these oxidative modifications.

The reaction of dioxygen with reduced metal complexes generates the entire series of reductively activated dioxygen species, ultimately forming the very aggressive hydroxyl radical. The aggressive oxidation chemistry associated with reductive cleavage of hydrogen peroxide by metal complexes was first reported by Fenton more than 100 years ago and these

reactions are often loosely described as ‘Fenton chemistry’ (equation 13).[56]

$$Fe^{+2} + H_2O_2 \xrightarrow{H^+} Fe^{+3} + HO^{\bullet} + H_2O \qquad (13)$$

In the presence of reductants (such as ascorbate), the oxidized metal complex is rereduced and is able to support redox cycling, catalytically forming ROS. The hydroxyl radical formed in this reaction is highly reactive, and can insert unselectively into virtually any C–H bond in a protein. The lack of specificity in this modification tends to make the products of protein attacked by ROS extremely heterogeneous. Biomarkers used to monitor protein oxidation include *o,o′*-dityrosine (**2**), dopa (**3**), *o*-tyrosine, methionine sulfoxide, cysteine sulfenic (**34**) and sulfinic (**35**) acids, cysteic acid (Cys-SO_3H), and kynurenine (from tryptophan).[57] Iron and copper complexes are particularly well-suited for this type of chemistry, accounting for the biological safeguards imposed on the intracellular trafficking of those metal ions.

4.3 Oxidation by Metal Complexes

In some cases, proteins react directly with metal complexes. This type of metal-mediated modification is particularly common for metals in higher oxidation states, and is thought to contribute to the toxicity of high-valent chromium [Cr(VI)] in the environment (*see* ***Chromium: Biological Relevance***). Protein side chains that are relatively easily oxidized (including tyrosine, tryptophan, and cysteine) may form free radicals. Subsequent reaction of these radicals with O_2 forms reactive oxygen species, driving Fenton chemistry (*vide supra*, Section 4.2). Copper has been implicated in biomedically important protein oxidative modifications, including oxidation of low density lipoprotein leading to atherosclerosis, and damage to neurofilaments leading to nerve cell death.[58] It is not generally possible to resolve the contributions of the metal in direct oxidation and redox cycling in vivo.

4.4 Conjugation with Substitution-inert Metal Complexes

While the majority of metal-mediated protein modifications covered in this survey involve activation of small molecules (e.g. O_2, H_2O) by metal complexes, there are some instances in which complexation of the metal ion itself serves as the mechanism of modification. Complexes with low-valent cobalt and chromium undergo relatively rapid ligand exchange, permitting solution complexes to coordinate with exposed amino acid side chains (e.g. histidine) on the surface of proteins. Oxidation of this adduct converts the complex to a substitution-inert species. The extreme inertness of Cr(III) and Co(III) complexes toward ligand-substitution reactions may be understood as a consequence of the strong ligand field stabilization of the fully coordinated ground state relative to the lower coordinate complex that corresponds to the transition state for ligand exchange. The extreme stability of these adducts (exchange lifetime >10 days) results in an essentially permanent alteration of the protein. The biological consequences of this type of modification are less severe than similar modifications of DNA, which are mutagenic, but extensive protein modification will always have a deleterious effect on cells, contributing to concerns about the widespread use of Cr(III) dietary supplements[59,60] (*see* ***Chromium: Biological Relevance***). In vitro, the stability of substitution-inert metal complexes can be used to engineer protein–metal conjugates and to introduce photochemically reactive groups for special applications.[61]

1 INTRODUCTION

Although metalloproteins have been characterized intensively for decades, investigators have only recently focused on the mechanisms of biological metallocenter assembly.[1,2] Here, we briefly describe several recurring themes (summarized in Table 1) that are used, often in a combined manner, for cellular synthesis of metal sites. This summary draws from a recent, more comprehensive treatment of this subject.[3] In the simplest situation, metal binding to a biological ligand occurs by reversible thermodynamic control. The prevalence of buried metallocenters, the exceedingly low concentrations of free metal ions within cells, and the sophisticated structures of many metal-containing active sites provide evidence that alternative approaches also must exist. In some cases, metallochaperones are used to deliver the metal of interest to an apoprotein. In other cases, the target protein undergoes posttranslational modification at the metal-binding site, either prior to or after the metal is bound. Many metallocenters contain additional components that are added along with the metal ion or used to form an independent metal-containing cofactor, perhaps with the assistance of a scaffolding protein. Electron transfer reactions involving the metal, an added compound, or the protein ligand can participate in activation. Finally, molecular chaperones that bind to and alter the conformation of the target apoprotein may be utilized. In many cases, the function of the molecular chaperone is coupled to nucleotide triphosphate hydrolysis. Additional complications of metallocenter biosynthesis exist within cells, but are not highlighted here: uptake of metal ions,[4] sensing and controlling of cellular metal levels (*see* ***Metalloregulation*** and ***Metallochaperones & Metal Ion Homeostasis***),[5] and intercompartmental trafficking of metals and metal-containing proteins.[6]

2 REVERSIBLE METAL ION BINDING

The interactions between some biological macromolecules (L) and their requisite metal ions (M^{n+}) are governed simply by thermodynamic control, such as that illustrated in equation (1).

$$L + M^{n+} \rightleftharpoons L{\cdot}M^{n+} \qquad (1)$$

In these situations, the ligand's specificity and affinity for the metal ion as well as the metal ion's coordination geometry depend both on the metal ion properties and on factors associated with the macromolecular ligand.[7,8] Metal ions vary in their charge, radius, ligand exchange lability, ligand preference (e.g. hardness/softness; *see* ***Hard & Soft Acids and Bases***), and position in the Irving-Williams series. Similarly, the fold of a protein or other biological macromolecule, its rigidity, and the properties of its side chains (e.g. pK_a, polarizability, and location in a particular secondary structure) dictate its interactions with the metal ions.

Intracellular Ca-regulated proteins (*see* ***Calcium-binding Proteins***) provide a nice illustration of reversible metal ion binding.[9] For example, calmodulin, a small acidic protein involved in the regulation of selected phosphatases, kinases, and other enzymes, reversibly binds four Ca^{2+} ions.[10] Each of the hard Ca^{2+} ions is coordinated by 7 hard oxygen ligands contributed by amino acid side chains that comprise the so-called 'EF hand' helix-loop-helix motif. Analogous sites are found in troponin C, parvalbumin, calbindins, and additional Ca-binding proteins. For calmodulin, the reversible interaction shown in equation (1) is oversimplified because binding of the first two Ca^{2+} ions occurs in a cooperative manner with an average binding constant of approximately $2 \times 10^5\,M^{-1}$ whereas the third and fourth ions are associated with binding constants of about $3 \times 10^4\,M^{-1}$. The binding of calcium ions leads to the exposure of hydrophobic sites

Table 1 General mechanisms of metallocenter biosynthesis[a]

Mechanism	Equation(s) representing the indicated mechanism[b]
1. Reversible metal ion binding	$L + M^{n+} \rightleftharpoons L{\cdot}M^{n+}$
2. Metallochaperone delivery of metal ion or cofactor	$L_1{\cdot}M^{n+} + L_2 \rightleftharpoons L_1 + L_2{\cdot}M^{n+}$
3. Enzymatically catalyzed posttranslational modification to create a metal-binding site	$L \longrightarrow L^*$ *and* $L^* + M^{n+} \rightleftharpoons L^*{\cdot}M^{n+}$
4. Synergistic binding of metal with another component	$L + M^{n+} + X \rightleftharpoons L{\cdot}M^{n+}{\cdot}X$
5. Synthesis of metal-containing cofactors and use of scaffold proteins	$Y + M^{n+} \longrightarrow Y{\cdot}M^{n+}$ *and* $Y{\cdot}M^{n+} + L \rightleftharpoons L{\cdot}Y{\cdot}M^{n+}$
6. Metal incorporation coupled with electron transfer	$L + M^{n+} \longrightarrow L{\cdot}M^{(n+)+1} + e^-$ *or* $L + M^{n+} + X^{y+} + z\,e^- \longrightarrow L{\cdot}M^{n+}{\cdot}X^{y+(-z)}$
7. Requirement for an apoprotein-specific molecular chaperone	$C{\cdot}L + M^{n+}(+NTP) \longrightarrow L{\cdot}M^{n+} + C(+NDP + P_i)$

[a]These mechanisms are not mutually exclusive. Many examples of metallocenter synthesis utilize multiple mechanisms. In addition, it is important to note that metallocenter assembly can be driven by nucleotide hydrolysis reactions, typically involving mechanism 7.
[b]L, protein ligand; L*, covalently modified ligand; X, non-metal component of a metallocenter; Y, component required for the synthesis of a metal-containing cofactor; C, molecular chaperone.

on calmodulin, likely responsible for its interaction with the calmodulin-associated proteins listed above.

Investigators studying metallocenter properties can exploit such thermodynamic control to substitute alternate metal ions into selected proteins.[11] In this process, the original metal ions are removed by chelation, often using extreme conditions such as low pH/denaturants, and the resulting apoproteins are incubated with high concentrations of the desired metal ions to obtain the metal-substituted species. For example, the metal sites of many Zn-containing enzymes (*see* ***Zinc Enzymes***) have been replaced by Co to facilitate spectroscopic analyses. Five-coordinate Co^{2+} often exhibits intense ligand-to-metal charge-transfer transitions, and Co^{2+} is paramagnetic so that EPR spectroscopy can be used to monitor the metal site. While such an approach can help define the properties of selected metallocenters, this method of metal incorporation may have little relevance to the in vivo mechanism of metallocenter assembly.

Significantly, thermodynamic control cannot explain many metal ion–protein interactions.[12] This point is highlighted by the Cu-containing proteins (*see* ***Copper Proteins with Type 1 Sites***) that form despite the reported absence of free copper ions in the cell.[13,14] This claim is based on the measured zeptomolar (10^{-21} M) sensitivity of the *Escherichia coli* copper regulatory protein CueR and on the estimation of less than 10^{-18} M Cu in yeast, determined on the basis of superoxide dismutase activity measurements; for comparison, one atom of free Cu per yeast cell (10^{-14} liters) would correspond to a concentration of 10^{-10} M. An analogous situation may well exist for Zn,[15] where the intracellular concentration is estimated at 10^{-11} M.[16] It is still unclear whether Fe, Mo, Ni, Co, and other biologically important metal ions exist at significant concentrations as the ''free'' species (i.e. the hydrated metal ions) in the cell.[12] Not unexpectedly, expression of genes encoding metal transporters and permeases that accumulate these ions are tightly regulated (*see* ***Metalloregulation***).[5] In this way, cells strike a balance in which metal concentrations are maintained at levels sufficient for growth while preventing deleterious effects. The low concentrations of free metal ions observed within cells imply that reversible metal ion binding to ligands is unlikely to account for the synthesis of most metallocenters. Furthermore, the metallocenters of many proteins are buried within a rigid framework. This finding demands that the metal ions must bind to the ligand during the folding process, an unlikely scenario, or that an alternative mechanism exists for incorporating the metal (Sections 3 through 8).

3 METALLOCHAPERONE DELIVERY OF METAL ION OR COFACTOR

Metallochaperones (*see* ***Metallochaperones & Metal Ion Homeostasis***) are metal-binding proteins (L_1) designed to deliver the appropriate metal ion or metal cofactor to a target ligand (L_2), as illustrated in equation (2).

$$L_1{\cdot}M^{n+} + L_2 \rightleftharpoons L_1 + L_2{\cdot}M^{n+} \quad (2)$$

It is important to note the distinction between metallochaperones and molecular chaperones that assist in protein folding. The best-studied protein chaperones, such as GroEL, Hsp70, and Hsp40,[17] prevent the misfolding or stimulate the refolding of a wide range of proteins by processes that generally require nucleotide triphosphate hydrolysis. These generalized or 'housekeeping' protein chaperones are certain to play a role in the synthesis of many metalloproteins. In addition, Section 8 describes a subset of metalloprotein-specific molecular chaperones that bind to a target apoprotein and confer an appropriate conformation needed to bind a metal ion or cofactor. Nucleotide triphosphate hydrolysis is carried out by a subset of these chaperones, presumably to provide a driving force for their reactions. In contrast to such molecular chaperones

that bind proteins, metallochaperones bind metal ions or metal cofactors and deliver them to their highly specific targets.

Perhaps the clearest examples of metallochaperones are small, cytoplasmic proteins (e.g. Atx1 in yeast, Atox1 (or Hah1) in humans, or CopZ in bacteria) that function to deliver Cu^{1+} to secretory pathway ATPases.[6,18–22] Three-dimensional structures are known for these three proteins and for domain 4 of a target protein (the Menkes disease protein, Mnk4) in various metal-bound states. Both the metallochaperones and the target proteins bind Cu^{+1} using two Cys residues found in a MT/HCXXC motif, and a model of the Hah1:Mnk4 complex identifies other critical residues likely to be needed for protein:protein interactions. The mechanism of Cu^{1+} transfer between the metallochaperone and the target domain is proposed to involve ligand exchange reactions with two- and three-coordinate intermediates. Significantly, reversible Cu^{1+} transfer between the two proteins occurs with an equilibrium constant near unity. This equilibrium does not provide enough thermodynamic driving force for efficient metallocenter assembly; thus, these metallochaperones are hypothesized to function like enzymes that provide kinetic control. The mechanism by which Cu^{+1} initially becomes bound to the metallochaperones has not been elucidated.

Other copper metallochaperones exhibit a range of more complex behaviors. For example, a protein often considered to be a mitochondrial copper metallochaperone, Cox17, contains a polynuclear copper site coordinated by thiolate ligands,[18,19] as opposed to a single metal ion binding site. The copper chaperone for superoxide dismutase (CCS) has three domains: domain I is related to Atx1, domain II structurally resembles the target enzyme, and domain III contains a critical Cys-X-Cys motif. Cu/Zn superoxide dismutase (SOD1) activation likely initiates by the swapping of domain II in dimeric CCS with one subunit of dimeric Zn-containing SOD1, yielding two molecules of the heterodimer. Domain I of CCS obtains Cu^{1+} from an unknown source and transfers the metal ion to domain III. Domain III then rotates its position to deliver Cu to the SOD1 active site. Of note, this transfer involves a change in Cu coordination from Cys ligation to binding by His ligands and appears to require an oxygen-dependent step.[19] A reasonable scenario is that this step involves both oxidation of the metal and oxidation of Cys229 in CCS and Cys55 of SOD1 to form a disulfide bond, thus propping open the active site, followed by disulfide exchange to yield a Cys55-Cys144 disulfide in SOD1. The CCS:SOD1 complex has been structurally characterized.[19]

Three Ni-containing enzymes (*see* ***Nickel Enzymes & Cofactors***) appear to utilize Ni metallochaperones for enzyme activation.[23,24] UreE appears to function in Ni^{2+} delivery to urease. The *Klebsiella aerogenes* protein binds ~6 Ni per dimer, whereas that from *Bacillus pasteurii* binds a single Ni per dimer. The metal content differences arise from a His-Asp-His sequence near the middle and a histidine-rich region at the carboxyl terminus of the former protein. Truncated *K. aerogenes* UreE protein, missing the His-rich region, and UreE variants lacking the His-Asp-His motif also function in urease activation. Structures of the truncated *K. aerogenes* protein and full-length *B. pasteurii* UreE reveal nearly identical protein folds, with a conserved Ni binding site located at the dimer interface. Surprisingly, the Ni-binding domain of UreE closely resembles the fold of the Cu-binding Atx1 metallochaperone. The UreE proteins contain a second module that structurally resembles a domain of an Hsp40-type molecular chaperone protein.[23] It may be that the chaperone-like module participates in UreE docking to its partner protein while the metal-binding domain transfers Ni to urease apoprotein. The metallochaperone functions even in the presence of chelators, indicating that UreE is not simply a reversible carrier of Ni in this process. HypA and HypB can be considered to serve as Ni metallochaperones for hydrogenase activation. HypA binds stoichiometric levels of Ni and forms a complex with HypB.[25] In some microorganisms, HypB also binds multiple Ni atoms using an *N*-terminal histidine-rich motif, reminiscent of the situation for some UreE proteins involved in urease activation. Finally, carbon monoxide dehydrogenase appears to use a Ni metallochaperone (CooJ) for enzyme activation.[23,24]

Metallochaperones alternatively can bind metal cofactors rather than metal ions, as illustrated by the heme chaperone involved in synthesis of *c*-type cytochromes.[26] Biosynthesis of cytochrome *c* in *Escherichia coli* requires the products of eight cytochrome *c* maturation (*ccm*) genes as well as several multipurpose proteins.[27] The apoprotein is secreted across the cytoplasmic membrane into the periplasmic space by the Sec system, and the apoprotein thiols are reduced in order to react with the heme vinyl groups. Meanwhile, the heme is transported across the membrane by a still poorly understood process that might involve CcmA and CcmB. Within the periplasm, heme is covalently bound to a His residue of CcmE, acting as a heme chaperone.[28] CcmC is essential for heme attachment, but CcmD, CcmA, and CcmB facilitate this process. In the last step of biosynthesis, heme is transferred from CcmE to the reduced cytochrome *c* apoprotein. This process appears to use CcmF as a bacterial heme lyase, perhaps in association with CcmG and/or CcmH. The thioether linkages of heme to the protein ensure that cytochrome *c* remains a stable redox cofactor.

4 ENZYMATICALLY CATALYZED POSTTRANSLATIONAL MODIFICATION AT THE METAL-BINDING SITE

Some proteins tightly bind their cognate metal ion only after the nascent apoprotein (L) undergoes a covalent modification reaction (producing L*), as shown in equations (3) and (4).

$$L \longrightarrow L^* \qquad (3)$$

$$L^* + M^{n+} \rightleftharpoons L^*{\cdot}M^{n+} \qquad (4)$$

Several blood clotting factors, other plasma proteins, and bone proteins are modified at selected glutamyl groups by the action of a vitamin K-dependent carboxylase.[29,30] The resulting γ-carboxyglutamic acid residues chelate Ca^{2+} and aid in maintaining protein:protein and protein:membrane interactions. Similarly, a specific interaction with Ca^{2+} occurs in proteins containing enzymatically derivatized epidermal growth factor domains, such as those present in coagulation factors, complement proteins, and transforming growth factors.[30] Specific aspartyl and asparaginyl groups in these proteins are hydroxylated by an α-ketoglutarate-dependent dioxygenase to produce β-hydroxyaspartyl and β-hydroxyasparaginyl residues that bind the metal ions. Calcium ions also interact tightly with dentin or bone phosphoproteins that are very rich in phosphoserine residues.[31] These promote deposition of calcium phosphate or calcium hydroxylapatite during tooth and bone development. As a final example, the egg yolk protein phosvitin contains adjacent phosphoserine residues that form a tight complex (binding constant near $10^{18}\,M^{-1}$) with Fe^{3+}, important for trace metal ion storage during embryonic development.[32]

A related type of posttranslational modification accompanying metal binding involves proteolysis. An excellent example of such a situation is associated with hydrogenase activation.[23,33,34] In this case, a protease recognizes the Ni-containing large subunit precursor and proteolysis leads to a conformational change that buries the metallocenter. A similar proteolysis-based process may function in the stable incorporation of manganese into the oxygen-evolving complex.[35]

Posttranslational modifications alternatively can occur after a metal ion binds to a protein (*see* ***Metal-mediated Protein Modification***), in some cases involving a change in metal redox state or chemical transformations of another component. The resulting modifications may impart a specific enzymatic activity to the protein, tune the reactivity of the protein metallocenter, stabilize metal ion binding, or inactivate the enzyme. Often, the modifications derive from autocatalytic reactions directly involving the bound metal; however, accessory enzymes may be needed to recognize the metal-bound form of the protein and catalyze the chemical changes. Galactose oxidase contains a tyrosyl side chain linked by a thioether bond to a cysteine residue. The tyrosine that becomes modified first binds Cu^{1+} and is oxidized to a tyrosyl radical (as the metal is oxidized to Cu^{2+}) then reacts with the cysteine side chain.[36,37] Cytochrome *c* oxidases (*see* ***Cytochrome Oxidase***) contain a crosslink between tyrosine and histidine side chains, where the histidine is a ligand to Cu. The precise role of this modification is controversial, but its presence in enzymes from both bacteria and higher eukaryotes highlights its importance. Various other types of oxidations can occur on tyrosine[38,39] or cysteinyl[40] side chains after metal ion binding. In addition, self-hydroxylations of aromatic amino acids near the active sites of many nonheme iron oxygenases are known to occur,[41] often accompanied by enzyme inactivation.

5 SYNERGISTIC BINDING OF METAL WITH ANOTHER COMPONENT

The interaction of metal ions with some proteins is accompanied by the binding of another nonmetal component (X), as illustrated in equation (5).

$$L + M^{n+} + X \rightleftharpoons L{\cdot}M^{n+}{\cdot}X \qquad (5)$$

The identity of the accessory compound can range widely, as shown by the following examples. The metallocenter of ribulosebisphosphate carboxylase/oxygenase is comprised of both Mg^{2+} and an activating CO_2 molecule.[42,43] Assembly of this site proceeds in a stepwise fashion with CO_2 reacting with the ε-amino group of a specific lysyl residue to form a carbamate that serves as one of the metal ligands. Analogous CO_2-dependent metal-binding reactions occur during activation of a number of dinuclear hydrolases including phosphotriesterase[44] and urease.[45] In these enzymes, the carbamate bridges the two metal ions bound to the active site. The metallocenter of transferrin consists of both ferric ion and the carbonate dianion, with the carbonate acting as a bridge between the protein and the metal.[46] Kinases and phosphotransferases often bind their required metal ions concurrently with their substrate (e.g. the MgATP complex). Proteins containing Fe–S clusters[47–49] require a source of inorganic sulfur and this is provided by accessory proteins. In pioneering studies, the *Azotobacter vinelandii* NifS was shown to be a pyridoxal phosphate-dependent L-cysteine desulfurase that creates an enzyme-bound persulfide for use in the production of Fe–S clusters in nitrogenase proteins (*see* ***Nitrogenase Catalysis & Assembly***).[50,51] Essentially all organisms subsequently have been shown to possess homologous activities for use in the Fe–S cluster synthesis.[52,53] As a final example, Fe-only hydrogenases[34,54] and NiFe-hydrogenases[23,33] possess Fe sites with bound cyanide and carbon monoxide molecules. Cyanide synthesis involves HypF and HypE proteins for *E. coli* hydrogenase.[55,56] Critical insight into this process was obtained by experiments with an *E. coli carAB* mutant, deficient in carbamoylphosphate synthesis, that requires carbamoylphosphate for hydrogenase activation. Purified HypF transfers the carbamoyl group from carbamoyladenylate to the carboxyl terminus of HypE.[56,57] HypE dehydrates the protein-bound thiocarbamate to yield an enzyme thiocyanate which, after reduction, provides the cyanide ligand.[56] CO ligands may derive from similar chemistry with an added hydrolysis step. The activation of these enzymes requires that both the metal ions and the diatomic molecules be incorporated.

6 SYNTHESIS OF METAL-CONTAINING COFACTORS AND USE OF SCAFFOLD PROTEINS

Activation of selected metalloproteins requires the prior synthesis of a cofactor that contains both metal and an additional organic or inorganic component (Y), as shown in equations (6) and (7).

$$\mathrm{Y} + \mathrm{M}^{n+} \longrightarrow \mathrm{Y{\cdot}M}^{n+} \tag{6}$$

$$\mathrm{Y{\cdot}M}^{n+} + \mathrm{L} \rightleftharpoons \mathrm{L{\cdot}Y{\cdot}M}^{n+} \tag{7}$$

Perhaps the best-characterized example of this mechanism involves the synthesis of heme cofactors and their subsequent incorporation into various hemoproteins (*see* ***Iron: Heme Proteins & Electron Transport***). Succinctly, enzyme-catalyzed reactions convert either succinyl-CoA or glutamate into δ-aminolevulinic acid. This molecule is further converted through a series of intermediates to form protoporphyrin IX, the metal-free cofactor, into which Fe is inserted by ferrochelatase.[58] Analogous reactions are required for the synthesis of other tetrapyrrole macrocycles such as the cobalamins (*see* ***Cobalt: B_{12} Enzymes & Coenzymes***), various types of chlorophylls, and the methanogen coenzyme F_{430} (containing Co, Mg, or Ni, respectively). Co- and Mg-chelatases have been described for insertion of these metals into the appropriate tetrapyrrolic ring structures.[59,60]

Molybdenum-containing enzymes (*see* ***Molybdenum: Organometallic Chemistry***), with the exception of nitrogenase described below, possess a complex with Mo coordinated to one or two molecules of a tricyclic pyranopterin (also known as molybdopterin, MPT) forming the molybdenum cofactor (Moco).[61–63] Moco biosynthesis has been extensively detailed in *Escherichia coli* by using a combination of biochemical, genetic, and structural approaches, and additional insights are provided by studies in other microorganisms and eukaryotes. The first step involves the conversion of GTP or a closely related compound into precursor Z by MoaA and MoaC. In this remarkable reaction, the C-8 carbon of the guanine base is inserted between the 2′ and 3′ carbons of the ribose ring. The detailed mechanism of this reaction is unknown, but the sequence of MoaA indicates similarity to members of the 'radical SAM' family of proteins that catalyze radical-based reactions using *S*-adenosylmethionine and Fe–S clusters.[64] The role of MoaC in the reaction is unclear, but its structure has been elucidated. The second phase of Moco synthesis involves conversion of precursor Z to MPT in reactions catalyzed by MoaD, MoaE, and MoeB. Biochemical and structural studies involving complexes formed by MoeB plus MoaD and MoaD plus MoaE reveal that MoeB activates the *C*-terminus of MoaD by adenylation, and activated MoaD is modified by a sulfur transferase using cysteine-derived sulfur, resulting in a protein ending in a thiocarboxylate. The sulfur atoms from two MoaD thiocarboxylates are transferred by MoaE onto precursor Z to form the dithiolene group of MPT. MogA, a potential MPT carrier,[65] has been structurally characterized. MoeA appears to facilitate incorporation of Mo into MPT.[65,66] Its structure reveals four domains including one that resembles MogA, consistent with a role in MPT or Moco binding. In most prokaryotic Mo-containing enzymes, Moco is further modified by conversion to the guanine, cytosine, or hypoxanthine dinucleotide forms. For example, MobA transforms Moco into molybdopterin guanine dinucleotide. The structure of MobA has been determined and the biochemical properties of this reaction unraveled. These enzymes appear to be structurally and functionally similar to previously characterized nucleotide diphospho sugar transferases.

Some metallocenters are first synthesized on a scaffold protein and subsequently incorporated into the target enzyme. For example, the iron-molybdenum cofactor (FeMoco) of nitrogenase (*see* ***Nitrogenase Catalysis & Assembly***) is first assembled on NifEN (i.e. the products of the *nifE* and *nifN* genes) and then transferred into the NifDK enzyme apoprotein.[50,67] Notably, the two scaffold proteins are structurally related to the nitrogenase subunits. Scaffold proteins need not always be related in sequence to the final protein targets as demonstrated by accessory protein components involved in the synthesis of Fe–S cluster proteins (*see* ***Iron–Sulfur Proteins***).[52,53] A series of proteins (e.g. NifU, IscU, IscA, SufA) accept sulfur from L-cysteine desulfurases and appear to function as scaffolds for Fe–S cluster synthesis. Various biophysical approaches have been used to demonstrate that the sulfur donor and cognate sulfur acceptor proteins form complexes.[51,68] Questions remain about the precise types of interactions occurring between the donor/acceptor proteins, the source of Fe, and the possible types of clusters that can be generated in the scaffold proteins. Nevertheless, the overall pattern is conserved, with these proteins being acceptors of the Fe and S for cluster synthesis.

7 METAL INCORPORATION COUPLED TO ELECTRON TRANSFER

The synthesis of some metallocenters is coupled to one or more electron transfer reactions. Depending on the example, the redox step may involve the metal, another component, or a side chain of the protein. Direct metal oxidation during metallocenter assembly (equation 8) is nicely illustrated by synthesis of the ferrihydrite core of ferritin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***) or formation of the tetramanganese cluster in the oxygen-evolving photoreaction center (*see* ***Manganese: The Oxygen-evolving Complex & Models***).

$$\mathrm{L} + \mathrm{M}^{n+} \longrightarrow \mathrm{L{\cdot}M}^{(n+)+1} + \mathrm{e}^- \tag{8}$$

Ferritin is an iron storage protein comprised of 24 subunits (a mixture of H subunits with M_r 22–24 kDa and L subunits with M_r 20–22 kDa) that associate to form a hollow sphere capable of binding up to 4500 iron atoms.[69,70] Nucleation of the iron core is initiated at a ferroxidase site that binds two Fe^{2+} ions, reacts with oxygen to form a transient peroxodiferric species,[71] and releases H_2O_2 while yielding a μ-hydroxo (or oxo) diferric precursor. After its nucleation, the core grows primarily by oxidative processes on the surface of the mineral particle. In contrast, the water-oxidizing complex of photosystem II is formed by stepwise binding and oxidation of four Mn^{2+},[72] with the electrons transferred to other components of the photosynthetic system. More generally, synthesis of Cu^{2+} and Fe^{3+} sites in proteins often involves initial binding of Cu^{1+} and Fe^{2+} followed by oxidation to stabilize the metal ions.

Other examples illustrate how reduction of an accessory component may be required for metallocenter synthesis (equation 9).

$$L + M^{n+} + X^{y+} + z\,e^- \longrightarrow L{\cdot}M^{n+}{\cdot}X^{y+(-z)} \qquad (9)$$

For example, incorporation of nickel into carbon monoxide dehydrogenase of *Rhodospirillum rubrum* requires the prior reduction of an Fe–S cluster.[73] Structural studies of this protein reveal that the added Ni completes a unique [1Ni-4Fe-4S] center that is required for activity.[74] Another example of a reductive activation step occurs during NiFe-hydrogenase biosynthesis, perhaps involving participation of the Fe–S cluster in HypD.[55] Yet a third example from the Ni-enzyme literature involves the synthesis of methyl-*S*-coenzyme M reductase, a methanogen enzyme that contains the Ni-tetrapyrrole cofactor F_{430}.[23] Formation of active enzyme requires both the reduction of Ni^{2+} to Ni^{1+} and reduction of a C=N bond in the organic macrocycle.[75]

The third redox-dependent process involved in metallocenter assembly requires changes to the protein, typically involving cysteine residues. For example, disulfide bonds that are spontaneously generated or enzymatically formed in periplasmic proteins must be reduced to create metal-binding thiolates or for cytochrome *c* biosynthesis. The opposite reaction, oxidation of cysteines during metallocenter assembly appears to be required for SOD1 activation.

8 REQUIREMENT FOR AN APOPROTEIN-SPECIFIC MOLECULAR CHAPERONE

Several metalloproteins incorporate their metal centers by processes that appear to involve apoprotein-specific molecular chaperones (C). These proteins stabilize a required conformation of the target apoprotein, often catalyze nucleotide triphosphate hydrolysis, and dissociate after activation (equation 10); thus, they bind the apoprotein but are not part of the final holoprotein.

$$C{\cdot}L + M^{n+}(+NTP) \longrightarrow L{\cdot}M^{n+} + C(+NDP + P_i) \qquad (10)$$

These apoprotein-specific molecular chaperones target only their particular apoprotein partners, but otherwise resemble in function the well-studied molecular chaperones such as GroEL, Hsp70, and Hsp40 that bind to and prevent misfolding or stimulate refolding of a wide range of proteins.[17,76]

UreG and HypB are putative GTP-dependent apoprotein-specific molecular chaperones for urease and hydrogenase.[23] GTP-dependent urease activation requires a nucleotide-binding site located within UreG. Hydrogenase biosynthesis involves the HypB- and GTP-dependent insertion of Ni into a $Fe(CO)(CN)_2$-containing HypC:pre-HycE complex. Of interest, HypB is related in sequence to UreG and exhibits low levels of GTPase activity.[33]

Apoprotein-specific chaperones also are implicated in the biosynthesis of Fe–S cluster proteins and Moco-containing enzymes. Hsc20 and Hsc66, encoded by genes within the *isc* (iron–sulfur cluster biosynthesis) operon, are related to the known molecular chaperones DnaK and DnaJ. Surface plasmon resonance and titration calorimetry approaches reveal that a scaffold protein containing an Fe–S cluster forms a complex with Hsc20, which directs it to Hsc66.[77] This interaction stimulates Hsc66 ATPase activity by 480-fold via interaction with the Hsc66 substrate binding site.[78] The incorporation of Moco and its modified forms into molybdoenzymes often requires an additional protein component, as first noted for maturation of nitrate reductase where NarJ participates after Moco synthesis was complete.[61,62] NarJ and related proteins (e.g. TorD involved in activation of trimethylamine *N*-oxide)[79] are suggested to play molecular chaperone-type roles in the activation process.

At least two molecular chaperone-like activities are associated with nitrogenase biosynthesis. In one case, the γ or NifY proteins form complexes with nitrogenase lacking its FeMoco.[50,67] These proteins prop open and allow access to the enzyme active site, bind and insert FeMoco, and then dissociate from the nitrogenase holoprotein. Formation of the complex between γ or NifY proteins and FeMoco-free nitrogenase is achieved by action of the second nitrogenase-related chaperone, dinitrogenase reductase, in an ATP-dependent manner.[50] Of interest, the [4Fe-4S] center of dinitrogenase reductase is required for its function in electron delivery to nitrogenase, but not for its action as a chaperone.

A final example of an apoprotein-specific molecular chaperone involved in metallocenter activation is associated with *Streptomyces* tyrosinase. Insertion of Cu into the tyrosinase apoprotein (encoded by *melC2*) requires complex formation with the product of *melC1* that stabilizes an appropriate apoprotein conformation, inserts the metal, and assists in secretion of the active enzyme.[80]

Glossary

ATX1: copper chaperone for the Cu transporting P-type ATPase in the Golgi
CCS: copper chaperone for the largely cytosolic Cu/Zn superoxide dismutase
Copper transporting P-type ATPase: a membrane transporter for copper that uses energy derived from ATP hydrolysis to drive copper transport
COX17: copper carrying molecule for the mitochondria
IMS: intermembrane space of mitochondria, lying between the inner and outer membranes of this organelle
Metal chaperone: molecule that binds a specific metal and helps insert this ion into the metal binding site of a metalloprotein
Metalloprotein: protein that binds a specific metal ion and requires that metal ion for proper function
Metal transporter: transmembrane protein responsible for the translocation of metal ions across a lipid bilayer
MTM1: mitochondrial inner membrane transporter needed for activating SOD2 with manganese
SCO: Copper carrying molecule, possibly the copper chaperone or copper insertion factor for cytochrome oxidase
SMF2: intracellular metal transporter essential for manganese trafficking
SOD1: copper and zinc containing form of superoxide dismutase, a superoxide anion scavenging enzyme
SOD2: manganese containing form of superoxide dismutase localized in the mitochondrial matrix

1 INTRODUCTION

1.1 The Notion of 'Metal Trafficking'

The proteins that require metal ions as cofactors are numerous and are assorted in diverse cellular locations. How is it that these vastly different proteins all acquire their partner metal ion in an accurate and efficient manner? The process is quite complex and involves the cooperation of membrane transporters and metal carrying metallochaperones.

In order for a metal ion to reach its intracellular protein target, a number of complex barriers must be crossed. First, the metal existing in the extracellular environment must traverse the plasma membrane of the cell. The lipid bilayers of cellular membranes are generally impermeable to metals and cellular uptake of the ion requires the action of metal transport proteins. A host of membrane transporters reside at the cell surface, some of which are specific for certain ions (e.g. only copper or only zinc), while others are more promiscuous in their choice of metal ion substrate (e.g. can transport both copper and zinc). But all are designed to ensure that cells acquire proper levels of the essential heavy metal ions such as copper, zinc, iron, and manganese.

Once inside the cell, the metal is subjected to one of several fates. For example, the ion may be directly shuttled to metal requiring enzymes in the soluble cytosol. But many metalloproteins reside within membrane bound organelles (e.g. the Golgi or mitochondria) and the metal needs to traverse an additional membrane. As with cell surface transport, the translocation of metals across intracellular membranes is facilitated by heavy metal transporters.

In addition to the membrane bound transporters, the delivery of certain metals to their cognate metalloprotein involves the action of highly specific 'metal chaperone' or 'metallochaperone' proteins. These metal carriers are often soluble, as opposed to membrane associated, and act to directly insert the metal into the proper site of the metalloprotein.

Overall, a metal ion is not permitted to freely move about within a cell, but instead is personally escorted to its destination through the combined action of metal transporters and metal chaperones working in concert. This process of moving metals inside cells is commonly referred to as 'metal trafficking'. And many such highways exist in eukaryotic cells (reviewed in[1]).

1.2 Why do Metals Need Trafficking?

The requirement for metal ion trafficking is not intuitively obvious, as it might seem less energy intensive to move the ion by random diffusion. In a test tube setting, a metal ion will

generally insert itself into the correct site of a metalloprotein with ease; most metalloproteins in fact exhibit a high affinity for their partner metal ion. However, the situation inside a living cell is not so simple. Although metals may accumulate in cells to concentrations that far exceed the binding affinity of their cognate metalloprotein, the fraction of the total metal which is actually bioavailable is extraordinarily low. Through elegant studies in the laboratory of Tom O'Halloran, it has been estimated that in spite of the micromolar quantities of copper or zinc accumulated by a cell, not a single atom is freely available to react in the cytoplasm.[2,3]

Metals such as zinc, copper, iron, and manganese are not only essential for life, but are potentially toxic and if left unchecked, these ions can cause much havoc to the cell. In fact, all organisms are equipped with a host of metal detoxification pathways that act to sequester or remove metals, thereby preventing these ions from reacting with biomolecules. An example of one such metal detoxification system is the metal binding metallothionein protein (MT). Genes that encode the MTs are induced under metal toxicity conditions and the encoded MT proteins serve to 'mop up' excess metals, preventing toxicity from these ions. With such efficient metal scavenging systems, it seems quite a challenge for metalloproteins to find their cognate cofactor. This challenge is overcome in part through the action of metal trafficking proteins, specifically the aforementioned metal chaperones that act to spare a few ions from detoxification and ensure the safe delivery of metals to metalloproteins. It would then appear that the metal detoxification and metal trafficking pathways are at odds with one another. While the detoxification systems protect the *cell from the metal*, the metallochaperones protect the *metal from the cell*.

2 METAL TRAFFICKING PATHWAYS INVOLVING COPPER

Much of the current state of knowledge regarding metal trafficking pathways has emerged from studies on copper. Copper is a redox-active metal that can readily donate or accept electrons, and as such, serves as an ideal catalytic cofactor for reactions involving oxygen chemistry.

In eukaryotes, extracellular copper can enter the cell via a cell surface high affinity transporter for the metal. The first of this type of copper transporter, known as CTR1, was originally discovered in baker's yeast by Andrew Dancis.[4] Homologues exist in humans and other eukaryotes as well. A mouse containing a homozygous deletion in CTR has been created in the laboratory of Dennis Theile and this mouse exhibited profound developmental defects and embryonic lethality.[5] Hence this single pathway of high affinity copper uptake is essential for mammalian development and viability.

Once copper has entered the cell, it is subject to one of several fates. When the metal is readily abundant or present in excess, a large fraction of copper is subject to detoxification, largely by sequestration within MTs (Figure 1). This is thought to represent a dead-end fate of the metal. However, a separate pool of the metal is spared from detoxification and enters one of three major copper trafficking pathways. These pathways independently supply copper to proteins in the secretory pathway, in the cytoplasm, and in the mitochondria (Figure 1). These three pathways will now be discussed independently.

2.1 Delivering Copper to Enzymes in the Secretory Pathway

A number of copper requiring enzymes are located at the cell surface or are exported into the extracellular milieu. Examples of such 'secretory Cu-enzymes' include copper requiring ferroxidases that function in iron transport (e.g. ceruloplasmin, CP), enzymes for neurotransmission (peptidyl amidating enzyme and dopamine β hydroxylase), an extracellular superoxide dismutase (SOD) that functions in antioxidant defense and enzymes for formation of connective tissue (lysyl oxidase), and pigments (tyrosinase) (reviewed in[6]). En route to their designated location, each of these enzymes passes through a specialized compartment of the late Golgi where copper insertion takes place.

Copper enters the late Golgi compartment through the action of a specialized membrane copper transporter. This transporter is a member of a family of so-called 'P-type' ATPase transporters that derive energy from ATP hydrolysis to translocate copper from the cytoplasm across the Golgi membrane into the lumen of the Golgi. Two such copper transporters have been identified in humans and these are known as the Wilson disease and Menkes disease proteins (*see* ***Metalloregulation***).[6] Mutations in the corresponding genes have been linked to inherited disorders of copper transport and metabolism in humans. Homologues to these transporters have been identified in virtually every eukaryotic cell and in each case, the transporter protein contains at its amino terminus, a repeat of 2–6 short protein domains that have the capacity to bind copper.

The copper that serves as the substrate for the copper transporting ATPase finds it way to the transporter via the action of a cytosolic copper chaperone known as ATX1 (yeast)[7] or ATOX1/HAH1 (mammals).[8] We originally identified ATX1 in 1995 as a potential antioxidant protein in yeast, hence the name ATX1. Yet in follow-up studies, it became clear that this small copper binding protein actually serves to shuttle cytosolic copper to the copper transporting ATPase in the Golgi.[9] In fact, ATX1 exhibits significant homology to the aforementioned copper binding repeats found at the N-terminus of the copper transporter. In all these ATX1-like protein domains, there exists a single copper binding motif CXXC (C = cysteine copper binding ligand and X = any amino acid). Since both the donor (ATX1) and recipient (Cu ATPase) for copper transfer harbor this novel copper binding site, copper is able to move from one site to the other by rapid

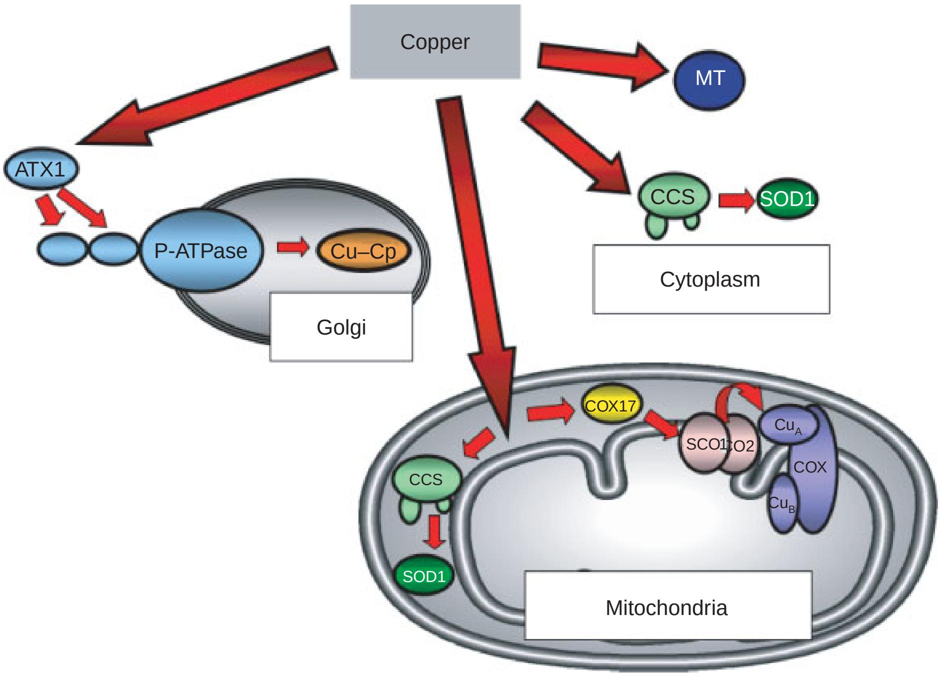

Figure 1 Metal trafficking pathways involving copper. Shown is a cartoon of a typical eukaryotic cell with various pathways of copper trafficking, indicated in red arrows. Much of the metal is sequestered by detoxification factors such as metallothioneins ('MT'). Alternatively, the metal can be delivered to two copper chaperones in the cytosol: (1) ATX1 (in light blue) which carries the copper to the P-type copper transporting ATPase ('P-ATPase') in the Golgi. This transporter pumps copper into Golgi lumen for activation of copper enzymes in the secretory pathway, such as ceruloplasmin (CP); (2) Cytosolic CCS (light green) also captures copper, which is then delivered to the copper/zinc superoxide dismutase (SOD1). Copper may also be delivered by some unknown mechanism to the mitochondrial IMS, where it can be taken up by a mitochondrial localized CCS that in turn activates mitochondrial SOD1. IMS copper that is destined for cytochrome oxidase is first captured by soluble COX17, then delivered to SCO1 (or SCO2) in the inner membrane, and finally inserted into the Cu_A site of cytochrome oxidase (COX)

exchange of its cysteine ligands. This was the first mechanism of copper transfer reported for any copper chaperone and was originally proposed by Thomas O'Halloran and colleagues in 1997.[9]

2.2 Delivery of Copper to the Cytosol: The Copper Requiring Superoxide Dismutase Enzyme

Another pathway of copper trafficking functions specifically to deliver copper to a single enzyme in the cytoplasm, the copper and zinc containing SOD1 (*see* ***Copper Proteins with Type 2 Sites***). SOD1 acts to catalytically disproportionate two molecules of superoxide to oxygen and hydrogen peroxide, and it is the redox cycling of copper at the active site that drives the chemistry. By removing toxic superoxide anion radicals, SOD enzymes represent the first line of defense against oxidative damage. SOD1 is ubiquitously expressed among eukaryotes and in certain cells, this enzyme can represent as much as 1% of the total cellular protein.

The vast majority of SOD1 ($\geq$95%) localizes to the cytosol and therefore, there is no intracellular membrane barrier for delivering copper to this enzyme. However, owing to the virtual absence of available copper in the cytosol, SOD1 relies on a copper chaperone for acquiring the metal. This molecule has been denoted as CCS, for copper chaperone for SOD1.

We first identified CCS in 1997 by genetic studies in the baker's yeast *S. cerevisiae*;[10] CCS was subsequently found to be well conserved throughout eukaryotes. CCS is a rather large copper chaperone, consisting of three domains (I, II, III) that serve distinct functions in inserting copper into SOD1.[11] The N-terminal domain I of CCS exhibits extensive homology to the ATX1 copper chaperone and contains the signature CXXC copper site. However, unlike ATX1, the CXXC of CCS is not essential for inserting copper into SOD1, rather this sequence appears important for capturing copper under conditions of copper limitation. In the central region of CCS, a larger domain II exhibits strong homology to SOD1, but lacks the SOD1 copper site. This homology facilitates the formation of a transient heterodimer between CCS and SOD1 that is the prelude to copper transfer. The structure of this heterodimer has been solved by X-ray crystallography and most notably, the interactions between CCS domain II and a monomer of SOD1 very closely mirror the interactions stabilizing the homodimer of SOD1 itself.[12] Lastly, the extreme carboxyl terminus (domain III) of CCS harbors a short copper binding site (CXC) that facilitates copper insertion into

SOD1. In fact, in the crystallographic analysis of CCS-SOD1 heterodimer, domain III is closely juxtaposed to the active site of SOD1. Interestingly, one of the CCS CXC cysteines forms an intermolecular disulfide bridge with an essential cysteine in SOD1, perhaps representing an intermediate in the copper transfer process.[12]

Unlike ATX1, where the chemistry of copper transfer is well understood, the mechanism of copper transfer from CCS to SOD1 remains unclear. For example, a dramatic change in metal ion coordination chemistry must accompany the copper transfer process in this case. Copper is bound to CCS in the reduced Cu(I) form via sulfhydral ligands, while in SOD1, copper is oxidized to the cupric Cu(II) state and is coordinated in an all-nitrogen environment to four histidines. The driving force for this large change in coordination chemistry is still poorly understood, but may involve an external oxidant, such as the superoxide substrate itself.

2.3 Delivery of Copper to the Mitochondria

The inner membrane of mitochondria is the site of respiratory electron transport and within the inner membrane and the intermembrane space (IMS) of mitochondria are two important copper containing enzymes. First, cytochrome c oxidase (COX) represents the terminal electron acceptor in the respiratory chain and two subunits of this large complex enzyme contain copper sites. A second enzyme in the mitochondria that requires copper is SOD1, as described above. Although the vast majority of SOD1 is cytosolic, a small fraction of this enzyme enters the IMS of the mitochondria where it is believed to directly scavenge superoxide anions produced as a by-product of the electron transport chain.

The copper that is trafficked to the mitochondrial IMS for SOD1 and COX must first cross the outer membrane of the mitochondria. The mitochondrial outer membrane has large pores that could accommodate the transport of solutes and small molecules. However the molecular state of the copper as it transits the outer membrane and enters the IMS is not understood. Once copper does enter the IMS, it is known to be captured by two copper binding proteins that facilitate delivery of the metal to the copper requiring SOD1 and COX enzymes. These copper capturing molecules include the mitochondrial form of CCS (described above) and the copper carrier for COX, known as COX17.

2.3.1 The Mitochondrial Form of CCS

Approximately 5% of the total cellular CCS can enter the mitochondria and this serves to metallate the fraction of SOD1 that resides in the IMS.[13] The exact mechanism by which CCS and SOD1 enters the IMS is unknown, but our studies indicate that apo SOD1 can move freely in either direction across the outer membrane, presumably through the outer membrane pores. But once this enzyme is metallated by CCS in either the cytosol or the IMS, the copper containing enzyme is trapped in the respective compartment (Figure 2). Indeed, increasing the metallation of SOD1 by mitochondrial CCS serves to shift the equilibrium of SOD1 towards the mitochondria. As such, CCS not only plays an important role in inserting copper into SOD1, but also in influencing the cellular location of this enzyme (Figure 2).[14]

2.3.2 Copper Delivery to Cytochrome Oxidase

As described above, COX of the respiratory chain has two subunits that require metallation with copper: the Cu_A site in subunit 2 contains 2 copper ions, while subunit 1 of the enzyme harbors a single copper atom in the Cu_B site. The Cu_A site acquires copper through two sets of accessory proteins in the mitochondria: COX17 and SCOI/SCOII. Assembly of the Cu_B site involves separate accessory factors including mitochondrial COX11. In this review, we shall specifically focus on assembly of the Cu_A site.

As is the case with the ATX1 and CCS copper chaperones, all the assembly factors for the Cu_A site of COX were originally discovered by genetic studies in baker's yeast, through work largely pioneered by Glerum and Tzagoloff in 1996.[15]

COX17 is a small cysteine rich protein that can bind copper in the form of a binuclear cuprous-thiolate cluster.[16] The COX17 protein has been localized to both the cytoplasm and mitochondria, and because of this dual location, COX17 was proposed to shuttle copper ions between these two compartments. However, work by D. Winge has shown that only the mitochondrial form of COX17 is needed for copper activation of cytochrome oxidase.[17] The role of the cytoplasmic form is not understood. In any case, mitochondrial COX17 is believed to capture IMS copper and then transfer the metal to a second set of accessory proteins for the Cu_A site of cytochrome oxidase: SCO1 and SCO2.

SCO1 and SCO2 are two homologous molecules that lie in the inner membrane of the mitochondria.[18] The copper binding site of these molecules bears striking resemblance to the target of copper delivery in cytochrome oxidase. The SCO1 and SCO2 proteins are believed to accept copper from COX17 and then transfer the metal to the Cu_A site of cytochrome oxidase (see cartoon of Figure 1) (reviewed in[19,20]). It is noteworthy that in humans, mutations in *SCO2* have been associated with a fatal disease in infants, hypertrophic cardioencephalomyopathy.[21]

3 METAL TRAFFICKING PATHWAYS INVOLVING MANGANESE

By far the greatest amount of information involving metal trafficking has surfaced from studies on copper. But more

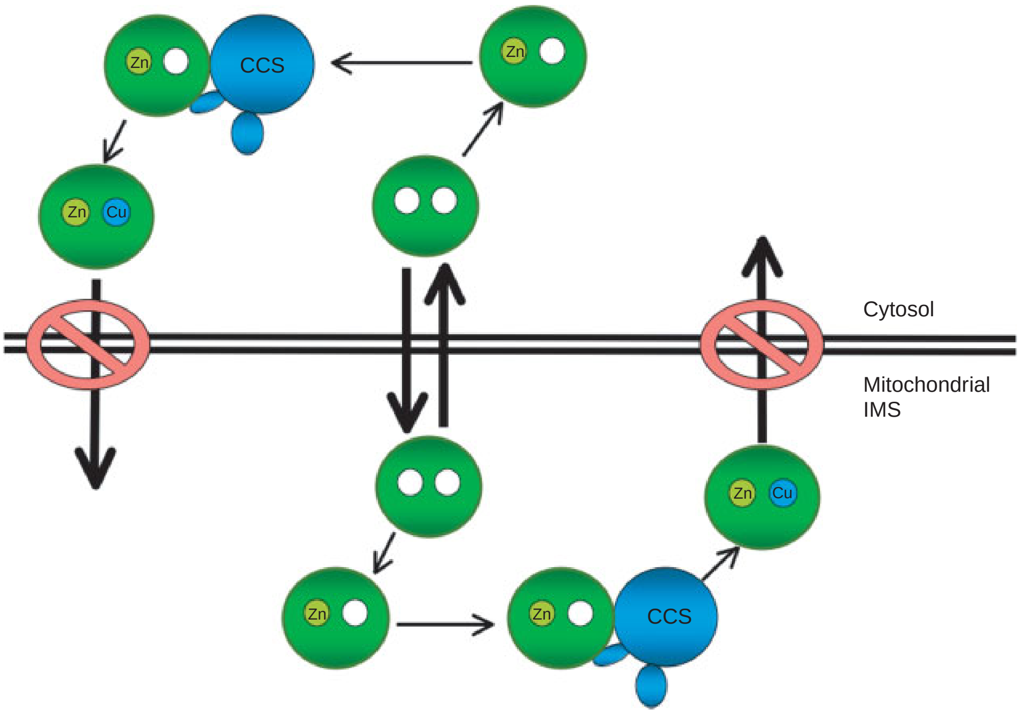

Figure 2 Partitioning SOD1 between the mitochondria and cytosol via the action of CCS. The double line represents the outer membrane of the mitochondria. Light arrows indicate maturation steps in the metallation of SOD1, whereas heavy arrows indicate movement of SOD1 across the outer mitochondrial membrane. The apo or unmetallated form of SOD1 can readily traverse the membrane in either direction. Once copper is inserted via CCS, SOD1 can no longer cross the membrane and becomes trapped within the corresponding compartment, either the cytosol or intermembrane space (IMS) of the mitochondria as indicated. This model shows zinc loading of SOD1 prior to copper metallation, but the exact order by which this occurs in vivo is not clear

recently, findings have emerged regarding the movement of manganese ions within the cell (reviewed in[1]). For the purposes of this discussion, we shall focus on studies completed in the baker's yeast *S. cerevisiae* that address the delivery of manganese ions to a manganese containing SOD2 (*see* ***Manganese Proteins with Mono- & Dinuclear Sites***) in the mitochondria.

Like the copper containing SOD1, SOD2 in the mitochondria serves to remove toxic superoxide anion radicals. SOD2 is strictly localized to the matrix of the mitochondria and acts to scavenge superoxide released on the matrix side of the respiratory chain. Our recent studies have shown that SOD2 can only obtain manganese when the protein is in the mitochondria. Therefore, there must exist a specific pathway for routing manganese ions to the heart of the mitochondria where the metal can activate SOD2.

3.1 Transmembrane Transporters for Manganese

Virtually all that is known regarding the transport and trafficking of manganese has come from studies in yeast and it is anticipated that similar mechanisms exist in higher eukaryotes including humans. Manganese that originates in the extracellular environment is first taken up by the cell via high affinity transport systems on the cell surface. One such system is represented by the yeast SMF1 transporter. SMF1 is a member of the Nramp family of divalent metal/proton symporters that have been well conserved from bacteria to humans. Yeast SMF1 primarily functions in the uptake of extracellular manganese under conditions of manganese limitation (reviewed in[1]). Once inside the cell, the metal is delivered to an intracellular vesicle where it then serves as the substrate for a second Nramp transporter, known as SMF2. SMF2 bears striking homology to SMF1, but never resides at the cell surface, only in intracellular vesicles. In one model of manganese transport, the metal is sequentially passed down from SMF1 at the cell surface to the SMF2 containing vesicles.[22] SMF2 then acts to transport the metal out of the vesicle for eventual delivery to other sites in the cell, including the mitochondria (see cartoon of Figure 3).

The metal ion transported by SMF2 is indeed utilized by the mitochondria for activation of SOD2. Yeast cells lacking SMF2 express a SOD2 polypeptide that is virtually devoid of manganese ions.[22] However, the role of SMF2 in delivering manganese to SOD2 is not direct. Rather SMF2 acts far upstream in the trafficking pathway. Other transporters or metal chaperones that operate downstream of SMF2 serve to pass the metal on to the mitochondria for utilization by SOD2. Once such downstream molecule is MTM1.

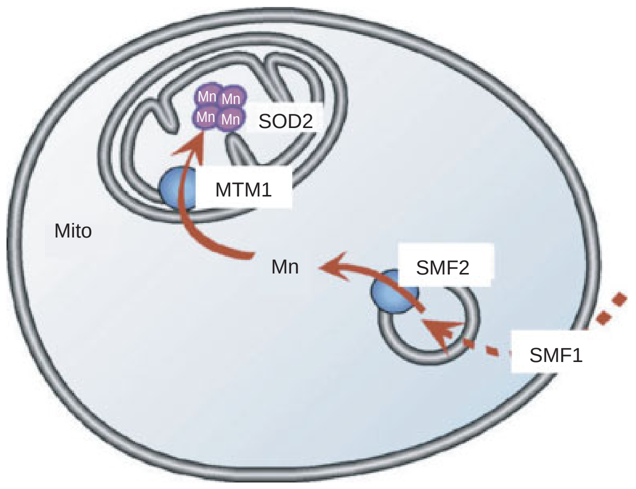

Figure 3 Pathway of trafficking manganese to mitochondrial SOD2. The model shown is based on factors identified in the baker's yeast *S. cerevisiae.* Extracellular manganese can enter the cell by a high affinity manganese transporter, SMF1. The metal is then trafficked to intracellular vesicles and then exported via a second manganese transporter known as SMF2. The metal that exits the SMF2-containing vesicles can then be escorted to the mitochondria where it is ultimately inserted into SOD2. The MTM1 transporter of the mitochondrial inner membrane is essential for activating SOD2 with manganese and may itself transport manganese or facilitate activation of SOD2 by transporting another mitochondria solute

3.2 The MTM1 Mitochondrial Factor for Activation of SOD2 with Manganese

We identified yeast MTM1 as a protein of the mitochondrial inner membrane that is needed to activate SOD2 with manganese.[23] MTM1 is a member of a large family of mitochondrial solute transporters known as MCF, for mitochondrial carrier family. All eukaryotic organisms express 30–40 distinct MCF molecules that serve to transport solutes in and out of the mitochondria. Substrates include ATP/ADP, precursors and products of the TCA cycle, and so on. Although the precise substrate for transport by MTM1 is not known, manganese is a likely candidate. Yeast cells lacking MTM1 show a deficiency in manganese incorporation into SOD2, although the mitochondria organelle itself is not deficient in manganese.[23] Therefore, if MTM1 indeed transports manganese, it must be specific for delivering manganese directly to SOD2. In one model, MTM1 or an accessory protein interact with SOD2 molecules and directly insert the metal ion cofactor (see Figure 3).

4 PERSPECTIVES

The findings presented here on metal trafficking have been limited to copper and manganese ions. However, it is conceivable that analogous pathways will emerge for other metals as well. Metals such as iron and even zinc are known to be toxic, but essential nutrients. As such, it is critical that cells maintain strict guidance and regulation of these ions to ensure accurate incorporation into metalloproteins without metal ion toxicity.

1 INTRODUCTION

Metalloproteins play important roles in biology. They account for about 1/3 of structurally characterized proteins and about 1/2 of all proteins.[1] The availability of different metal ions with various redox states, ligands, and geometries about the metal ion allows for fine-tuning of the reactivity of proteins at the highest level. As shown in other sections of this encyclopedia, studies of native metalloproteins and their variants have provided numerous insights. Design and engineering of metalloproteins can serve as a touchstone whereby the principles obtained from the studies are tested, and help determine whether the *necessary* features identified from the studies are *sufficient* to confer the structure and function of the proteins. Since it is a bottom-up approach of building the proteins that is complementary to the top-down approach of native protein studies, it can offer new insights. Furthermore, it is possible to design metalloproteins with unprecedented structural and functional properties. Finally, most designed proteins are smaller than the native proteins, making them easier for practical applications.

A number of excellent reviews on metalloprotein design and engineering have appeared in the literature.[2–28] This review will focus mainly on advances in creating new metal-binding sites in proteins.

2 RATIONAL DESIGN: CONSENSUS SEQUENCE/STRUCTURE APPROACH

Metalloproteins always contain highly conserved amino acid residues around the metal-binding sites, including the ligands to the metal ions. The consensus sequence/structure approach often involves a sequence homology search of a large number of proteins in the same family, identification of conserved sequences responsible for common metal-binding motifs, and then application of this knowledge to the design.

2.1 Design of Metallopeptide Models

Metallopeptide models refer to systems that are mostly unstructured in solution in the absence of metal ions.[21] It is applicable to design of metal-binding sites whose conserved residues appear mostly in a single peptide that is often much shorter than the whole protein. Designing metalloproteins using only the peptide with the consensus sequence, often called a motif, represents the minimalist approach in its purest sense. These motifs typically contain His, Cys, or both residues. In addition, metalloporphyrin-containing peptides have also been made to mimic basic features in heme proteins.

2.1.1 Metallopeptide Models with His-Containing Motifs

An interesting example of designed metal-peptide models is based on the amino terminal Cu^{II} and Ni^{II}-binding motif found first in serum albumin, and then later in other proteins such as neuromedins C and K, human sperm protamine P2a, and histatins.[29,30] The motif contains a simple tripeptide Xaa-Xaa-**His** (where Xaa is an α-amino acid, and amino acid side chains that are ligated to metal ions are shown in bold) with a free NH_2-terminus. This peptide binds Cu^{II} and Ni^{II} specifically through the histidine imidazole nitrogen, two intervening deprotonated amide nitrogens, and the terminal α-amine (Figure 1a). While the histidine at the third position is required, the identity of the first two amino acids seems to exert little effect on metal complexation at or above physiological pH. Based on this motif, a number of Cu^{II} and Ni^{II}-binding peptides have been designed. The designed motifs, either alone or incorporated into a protein, are effective cleavage agents for nucleic acids and proteins. Another interesting finding is that the Ni^{II}·Xaa-Xaa-**His** metallopeptide can target either the minor groove of B–form DNA or loop regions of structured RNA molecules.

While the Xaa-Xaa-**His** motif can bind metal ions and form a stable structure alone, almost all other metal-binding motifs have to be associated with either a peptide, a de novo designed protein, or a native protein scaffold. For example, the **His**-X_3-**His** motif (Figure 1b), common to zinc finger proteins (*see* ***Zinc: DNA-binding Proteins***), hemocyanin (*see* ***Copper: Hemocyanin/Tyrosinase Models*** and ***Copper Proteins with Dinuclear Active Sites***), and the EF-hand calcium-binding motif, found in calcium proteins (*see* ***Calcium-binding Proteins***), are often designed as part of another protein domain instead of as an individual unit alone. They will be covered in the Section 3.1 (Rational Design: Modular Approach) below.

2.1.2 Metallopeptide Models with Cys-containing Motifs

The **Cys**-Xaa-Xaa-**Cys** motif, occurs in rubredoxins, ferredoxins (*see **Iron–Sulfur Proteins***), and metallothionins (*see **Metallothioneins***). Based on the consensus sequence of ferredoxins, -**Cys**-$(Xaa)_2$-**Cys**-$(Xaa)_2$-**Cys**-$(Xaa)_{10-50}$-Cys, a 16-amino acid peptide (LysLeu**Cys**GluGlyGly**Cys**IleAla**Cys**Gly Ala**Cys**GlyGlyTrp) has been designed and shown to incorporate a ferredoxin-like [4Fe-4S] cluster under physiological conditions (Figure 1c).[31] This sequence was later truncated to seven amino acids (**Cys**IleAla**Cys**GlyAla**Cys**) that still maintain most of the spectral features of ferredoxins. This motif has been incorporated into de novo designed four α-helical bundles to formal mixed ferredoxin-heme-containing center, or bridged $[Ni^{II}\text{-}(\mu_2\text{-}S_{Cys})\text{-}Fe_4S_4]$-containing assembly (see Section 3.2). A rubredoxin-like $Fe^{II/III}$(**Cys**)$_4$ has also been designed using two β-hairpin peptides with each containing the **Cys**-Xaa-Xaa-**Cys** motif.[32] Instead of relying strictly on conserved primary sequence alignment, the authors designed the rubredoxin-like metallopeptide based on the three dimensional structure of native rubredoxin, through which they identified the minimal structure unit around the metal-binding site and incorporated it into the 11-mer peptide. Design of peptide models for blue copper proteins has also been reported.[33,34] Finally, an NMR study of the GlyMetThr**Cys**AlaAla**Cys** motif, commonly found in heavy metal-binding and transporter proteins such as MerP (*see **Metallochaperones & Metal Ion Homeostasis***), showed that the structure of the motif in an 18-mer peptide is similar to that in the 72-residue MerP protein (Figure 2).[35] This result suggests that carefully designed metal-binding sites in metallopeptides can maintain the same structure as in native proteins.

2.1.3 Metallopeptide Models with His and Cys-containing Zinc Finger Domains

The metallopeptides discussed above, although stable in solution, are mostly part of an overall structural unit in proteins. A few other metallopeptides, on the other hand, can fold into separate structure units (called domains), which are different from other parts of the proteins. Zinc finger domains (*see **Zinc: DNA-binding Proteins***) are a primary example of metal-binding domains, with the Cys_2His_2 finger as the most common in the family.[28] Based on a database of 131 sequences from 18 different proteins, a 26-mer peptide was designed with the consensus sequence (see Figure 1d).[36] Remarkably, the Zn^{II}-binding affinity of this designed peptide ($K_d \sim 2$ pM) is higher than those of any natural zinc fingers known, demonstrating that protein design can result in new proteins with unprecedented properties. This peptide was further modified to include a minimal number of amino acids.[37] This 'minimalist' zinc finger, containing mostly Ala in noncritical positions, has comparable Zn^{II}-binding affinity to those of native zinc fingers. This result showed that protein design can reveal, in the most unequivocal way, the key structural features of metalloproteins.

2.1.4 *Metalloporphyrin-peptides as Models for Heme Proteins*

Heme proteins are one of the largest classes of metalloproteins studied to date (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***; ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***).[38] More than 5% of protein structures in the Protein Data Bank contain at least one heme moiety.[27] It is no wonder that designing heme proteins has been one of the most active areas of research. Since the dominant secondary structure in heme proteins is α-helices (accounting for $\sim$77% of all secondary structures in known heme proteins),[27] a number of α-helix-containing metalloporphyrin-peptides have been synthesized using either covalent or noncovalent approaches.[17,18,22,27]

A classic metalloporphyrin-peptide was made by proteolytic digestion of the natural protein cytochrome *c*. The resulting metallopeptides, called microperoxidases, contain the **Cys**-Xaa-Xaa-**Cys-His** motif that binds to the heme covalently through the two Cys residues.[39] They are one of the few metalloporphyrin-peptides that are five-coordinate with an open binding site. Therefore they exhibit oxidation and oxygenation activities, such as peroxidase and cytochrome P450 activities. They have also been used as biosensors for H_2O_2.

To expand the sequence and structure diversity of the microperoxidases, other peptides have been covalently linked to different metalloporphyrins (Figure 3). For example, an undecapepetide whose sequence was derived from a natural protein was covalently attached to the deuteroporphyrin through its propionate group (Figure 4a).[40,41] Ligands to the heme center were provided either through addition of free ligands such as imidazole, or through covalent attachment of the histidine to the second heme propionate. In addition, by covalently attaching a chelating ligand for copper to the

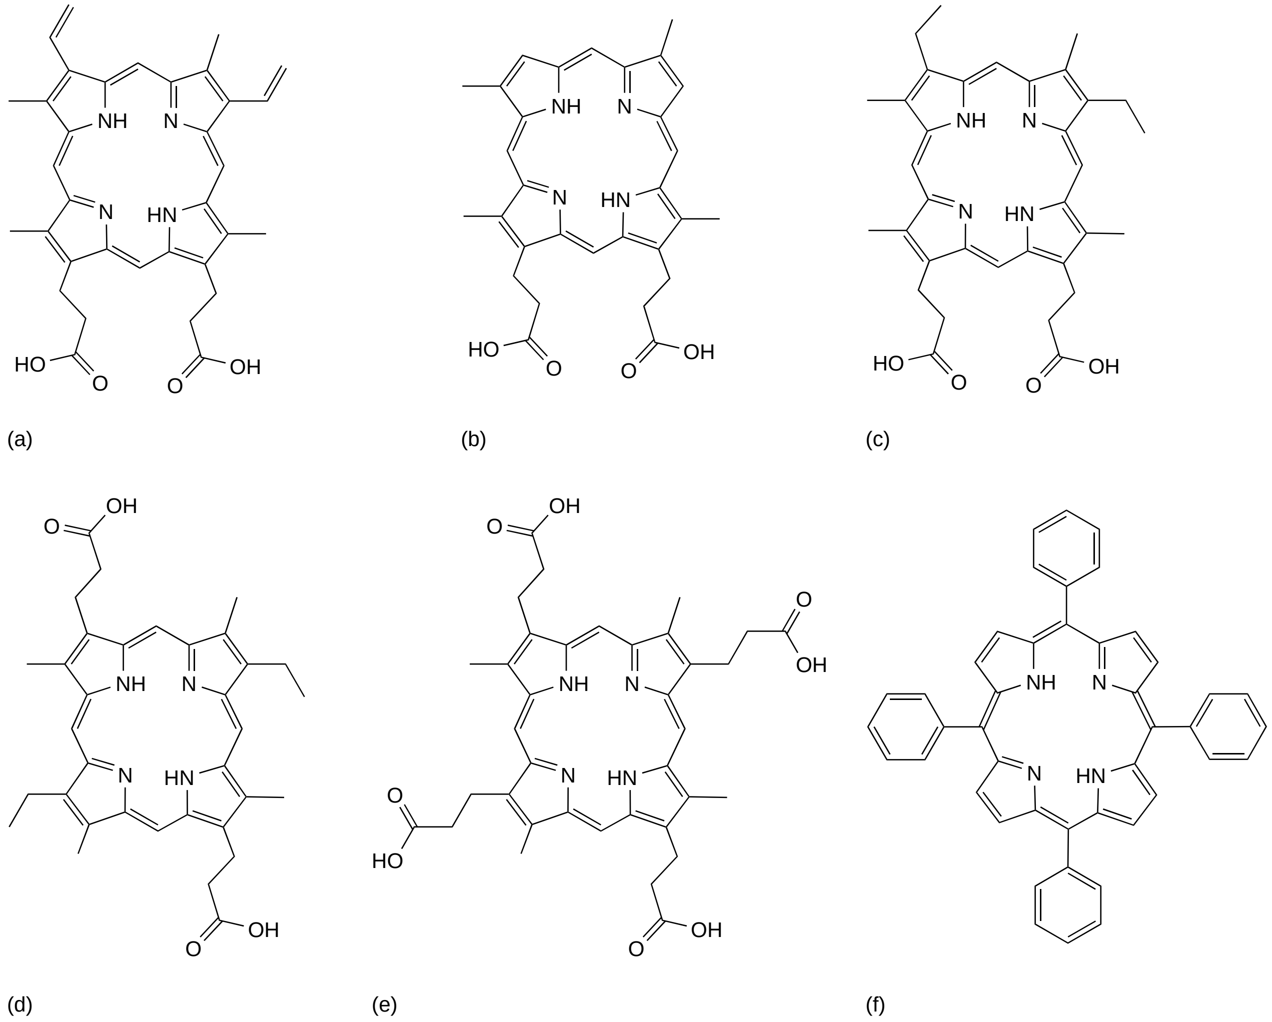

Figure 3 Chemical structures of porphyrins used in metallopeptide design. (a) protoporphyrin IX; (b) deuteroporphyrin IX; (c) mesoporphyrin IX; (d) mesoporphyrin II; (e) coproporphyrin; (f) *meso*-tetraphenylporphyrin[22]

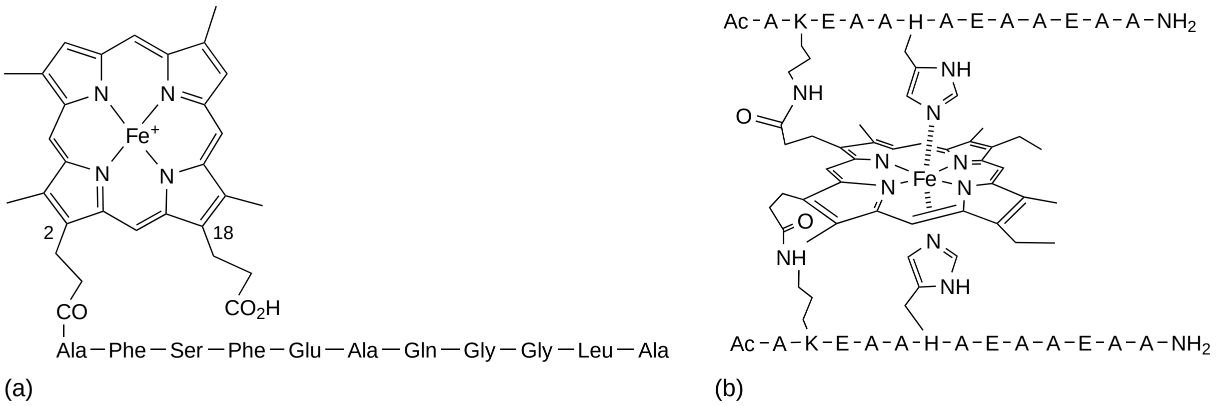

Figure 4 Metalloporphyrin-peptides models with covalent linkage through porphyrin propionate. (a) peptide deuteroporphyrin system (b) peptide sandwiched mesoporphyrin system

second heme propionate, this system also provided interesting models for cytochrome *c* oxidase (*see* ***Cytochrome Oxidase***).

One or two peptides have been attached to mesoheme through an amide linkage between the heme propionate and the Lys N-ε nitrogen (Figure 4b).[42] Investigation of this peptide sandwiched mesoporphyrin system showed that His to heme ligation is mainly responsible for the peptide transformation from random coil to helix. Independently, the same propionate-Lys linkage strategy has been exploited to attach deuteroporphyrin to peptides whose sequence is derived from the F helix of hemoglobin β-chain.[22,43,44] Detailed structural analysis of the resulting metallopeptides, called mimochromes, showed that diastereomerism may occur when polypeptides coordinate to metal ions (Figure 5). Finally, five-coordinate hemes have been obtained in both peptide sandwiched mesoporphyrin and mimochrome systems, paving the way for studies of their enzymatic activities.

In addition to the propionate group, other positions on metalloporphyrins have also been used as sites for attaching

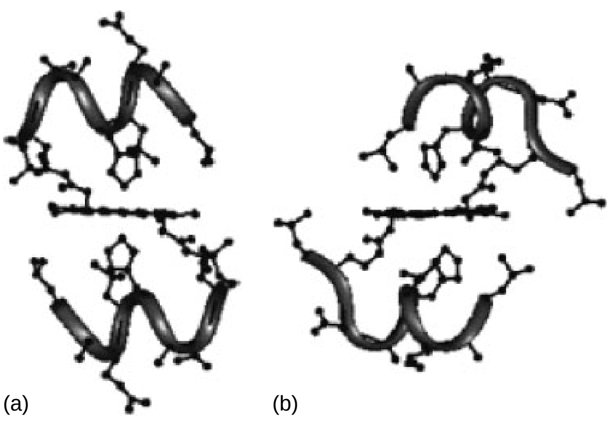

Figure 5 NMR structures of two diastereomers of Co^{III}-mimochrome I. (a) Δ isomer; (b) Λ isomer. (Reprinted with permission from Ref. 22. © 2001 the American Chemical Society)

peptides, including modified tetraphenylporphyrins coupled to peptides through a thioether linkage (Figure 6a)[45] or through copper coordination (Figure 6b).[46] In both cases, proper positioning of key amino acids on the peptide for the covalent linkage to the porphyrins is critical for the porphyrin-peptide assembly and induction of α-helical content. To create the thioether linkage, two Cys residues at position 2 and 13 of the 14-mer peptide are necessary to react with iodoacetamide-modified free base tetraphenylporphrin. To form the copper coordination, two pairs of His residues at positions at 4, 8, 15, and 19 (forming the His-X_3-His motif) of the 22-mer peptide are required, together with modified tridentate *meso*-phenyl groups.

The above described covalent approach to the design of metalloporphyrin-peptide models has the advantages of ensuring proper peptide/porphyrin stoichiometry and positioning, and reducing axial ligand dissociation. However, it requires multistep syntheses, making it difficult to introduce a number of variants of the peptide sequences. In addition, it may not be able to offer insight into folding and noncovalent interactions of a large number of heme proteins, such as globins, peroxidases, and oxidases, without covalent linkage between heme and peptide. Therefore metalloporphyrin-peptide models through spontaneous assembly of peptides around metalloporphyrins have been made. Without the covalent linkage, the challenges are to construct peptides that can fold into a unique conformation and can maximize both the interactions between the peptide and metalloporphyrin and the binding of ligand to the heme center. Toward these goals, several systems have been designed. With few exceptions, most systems utilize two α-helical peptides dimerized by a disulfide linkage through the N-terminal Cys residues, with His residues placed in the center of the two peptides for ligation to the metalloporphyrin center. These peptides spontaneously assemble around metalloporphyrins (such as Co^{III}coproporphyrin/Co^{III}octaethylporphyrin,[47] Fe^{III}mesoporphyrin,[48] or Fe^{III}coproporphyrin (Figure 7)[49–51]).

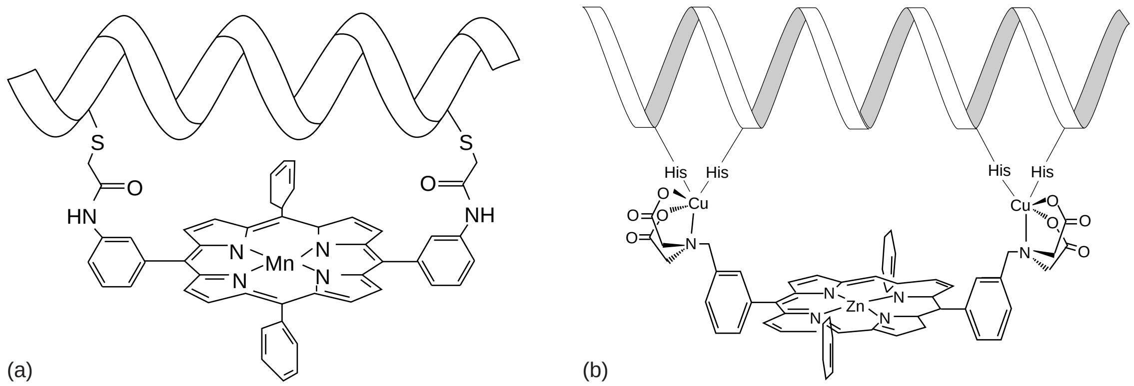

Figure 6 Metalloporphyrin-peptides models with covalent linkage through a thioether linkage (a);[45] or copper coordination (b)[46]

Strong evidence has been obtained about the roles of metal-ligand ligation and the disulfide linkage in promoting α-helix formation. Other effects have also been noted. For example, neutral and positively charged peptides bind to the negatively charged metalloporphyrins more strongly than anionic peptides.[51] Different degrees of hydrophobic interactions between the peptides and the metalloporphyrin can result in binding constants that span a range of ~6000 fold.[49]

2.2 Design of Metal-binding Sites into De Novo Designed Proteins

The metallopeptide systems described in the last section represent metalloprotein design at the most 'minimalistic' level. Successful designs of metallopeptides that mimic natural metalloproteins can not only reveal dominant factors determining the structural and functional properties, but also provide much simpler alternatives for practical applications. However, many of the peptides lack built-in secondary structure and, as demonstrated experimentally, require binding of metal cofactors to form stable structures.

This approach works fine for design of metalloproteins such as heme proteins and zinc finger proteins where metal cofactor binding plays an important role in protein folding and structure formation. However, a number of other metalloproteins fold independently of metal cofactor binding. In a few cases, such as type 1 blue copper proteins (*see* ***Copper Proteins with Type 1 Sites***), the protein scaffolds are believed to enforce metal-site geometry. Mimicking of those proteins is more likely to be successful using more rigid proteins as scaffolds. Toward this goal, de novo designed proteins with rigid scaffolds, such as four α-helical bundle proteins, have been used for metal-binding site design.

2.2.1 Introducing Heme into De Novo Designed Proteins

In an extension to the covalent approach in the metalloporphyrin models described above, metalloporphyrins have been used as a template to induce α-helical folding and formation of four α-helical bundles, a common heme protein scaffold. In these systems, metalloporphyrins play both a catalytic role in terms of performing electron transfer or oxidative function, and a structural role in terms of helping to position the four peptides to form a bundle without collapsing. The first example, called helichrome, was made by linking the N-termini of four identical 15-mer peptides to the four propionate groups of coproporphyrin I (Figure 8a).[52] The peptides are amphiphilic, resulting in a hydrophobic substrate-binding pocket in the folded four α-helical bundle. Therefore it displays interesting cytochrome P450-like activity (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***) by oxidation of aniline to *p*-aminophenol. The second example employed a structurally more rigid and chemically more stable tetraphenylporphyrin, and attached the N-termini of four hydrophobic 21-residue peptides to *meso*-tetrakis(*m*-carboxyphenyl)porphyrin through *m*-carboxyamido linkages (Figure 8b).[53] The resulting metalloporphyrin-peptides, called tetraphilins, mimic the ion-channel proteins. The presence

DeJonge, and W. Haehnel, *Proc. Natl. Acad. Sci. U.S.A.*, 1998, **95**, 11526. © 1998 National Academy of Sciences, USA)

of the porphyrin increased the conductance lifetime and eliminated the voltage dependence of the peptide ion channel. Finally, a similar strategy has also been used to design *meso*-tetrakis(m-carboxyphenyl)porphyrin-linked four α-helical bundles that can penetrate into membranes (Figure 8c).[54] This was made possible by using peptides whose sequences were derived from the C- and G-helices of the transmembrane regions of bacteriorhodopsin. An artificial electron transfer system was designed into the system by insertion of Mn^{III} into the porphyrin and covalent attachment of a flavin in the middle of the four α-helical bundles.

In addition to metalloporphyrins, other molecules have been used as templates for building artificial metalloproteins. Among those, cyclic peptides containing four cysteines with different protection groups offer considerable opportunities, as this system allows coupling of unprotected peptides either at the N-terminus or the ε-amino group of a C-terminal Lys.[55] In this way, both parallel or antiparallel four α-helical bundles can be made. For example, an antiparallel four α-helical bundle protein that mimics the heme-binding core of the b-subunit of the cytochrome bc_1 complex has been made this way through incorporation of two His residues in the middle of the peptides.[55,56] To demonstrate the versatility

and modularity of this approach, a ruthenium-tris(bipyridine) complex was also covalently attached to the surface of the model protein (Figure 8d), allowing a detailed investigation of distance-dependent electron transfer in this system.[56]

While the above template based approach has several advantages over the nontemplate approach in overcoming topology and folding issues in protein design, there are not many such examples of metalloproteins in nature. A more challenging design is through spontaneous assembly of linear peptides. A remarkable achievement in protein design was the design of four α-helical bundle proteins based on first principles.[16,57] Since then several heme-containing four α-helical bundle proteins have been made based on the design.[16–18,22,27,57] For example, a series of helix-loop-helix peptides containing one His residue was designed to dimerize via N-terminal Cys residues and form four α-helical bundles with bis-His ligated heme parallel to the helices in the bundle core (Figure 9a).[58] They also showed that the mere presence of two His residues is insufficient to achieve specific binding of heme; introducing a hydrophobic cavity is also required. In addition, multi-heme proteins have been designed using helix-disulfide-helix peptides (Figure 9b).[59] In this way, a di-α-helical peptide containing two bis-His heme groups has been synthesized and assembled into a four α-helical bundle with four parallel heme groups in the middle. The sequence design was based on the heme-binding site of cytochrome bc_1 complex, including the spacing of the two His ligands and the presence of other amino acid residues, such as Phe and Arg in the heme-binding site. The resulting proteins resemble native heme proteins in their spectral and electrochemical properties, including heme–heme redox interaction.

In the above multi-heme proteins, all heme planes are parallel to each other. In other multi-heme proteins in nature, such as heme a and heme a_3 center in cytochrome c oxidases (*see* ***Cytochrome Oxidase***), the heme planes are perpendicular to each other. Four heme groups with heme perpendicular to one another have been designed into four α-helical bundles through the use of a side-chain packing algorithm, called CORE (Figure 9c).[60] The same program also helps to design artificial electron transfer centers where a bis-His ligated heme is situated in the middle of the four α-helical bundle and a $Ru(bpy)_2$ attached to the end of the bundle.[61]

2.2.2 *Introducing Nonheme Di-iron Centers into De Novo Designed Proteins*

Dinuclear iron centers are found in a large number of metalloproteins with diverse functions (*see* ***Iron Proteins with Dinuclear Active Sites***). Despite very different overall folds, most of the proteins position the di-iron centers within a four-helix bundle, with conserved Glu-X-X-His motifs on two of the four helices.[62] Each of the remaining two helices also contributes a Glu residue. Introducing six polar ionizable groups in the hydrophobic core of the helix bundle represent a grand challenge. This task was accomplished by using a retrostructural analysis and computational design approach.[62,63] In addition to placing the above six residues (Glu_4His_2) in positions analogous to the native di-iron proteins, residues around the metal-binding site that play structural and functional roles have also been introduced. They include residues in the secondary coordination sphere that form hydrogen bonds to ligands of the metal ions,

such as a Tyr residue hydrogen-bonded to one of the Glu ligands, which is found in the di-iron center of R2 subunit of ribonucleotide reductase from Escherichia coli (*E. coli*). A crystal structure of the di-Zn^{II} derivative of the designed protein showed that the experimentally determined structure and the designed models are very similar (Figure 10a).[63] Since then significant progress has also been made in designing substrate accessible dinuclear metal centers by reducing the bulk of two hydrophobic Leu residues that blocked access to the metal sites.[64] This work paved the way for designing catalytically active metalloenzymes.

2.2.3 *Introducing Other Metal-binding Sites into De Novo Designed Proteins*

In addition to heme and nonheme di-iron, Zn^{II} has been introduced into the de novo designed four-helical bundle proteins. In one case, a $Zn^{II}(His)_3$ site has been introduced into two antiparallel helical pairs, with two His separated on a single turn of helix and the third one from the neighboring helix.[68,69] In another case, a $Zn^{II}(His)_2(Cys)_2$ site was created by two adjacent helices, each of which contributes a Cys and a His residue (Figure 10b).[5,70] The Cys and His residues are separated by about one turn of the helix. Unlike metal ion-induced metallopeptide folding, Zn^{II}-binding in these designed proteins resulted in no significant change of secondary structure. However, the metal binding did result in substantial stabilization of the protein toward denaturation.

As discussed in Section 2.2.1, metalloporphyrins or cyclic peptides have been used as a template for synthesis of topologically predetermined metallopeptides and proteins. The same strategy has been used to introduce other metal-binding sites into de novo designed proteins. A good example is the use of exchange-inert Ru^{II} or Co^{III} complexes to direct synthesis of three- and four-helix bundle proteins (Figure 10c).[66,71] Amphiphilic peptides functionalized with 2, 2′-bipyridine at the N-terminus were designed and shown to undergo spontaneous self assembly in the presence of metal ions. The oligomeric state and orientation of the helix bundle can be controlled through the intrinsic binding energy and stringent geometric requirements of the metal coordination. This approach has been extended to design a heterodinuclear three helix bundle protein where the Ru^{II} is located at one end and a $Cu^{II}(His)_3$ site at the opposite end.[72] Since Ru^{II} and Co^{III} complexes at the end of the designed helix proteins are redox active, placing another redox partner at defined location of the peptide allowed a systematic study of electron transfer influenced by such factors as distance, formation, and presence of hydrogen bonds.

Metal ion-induced assembly of designed helical bundle proteins has also been shown by introducing His or Cys residues in the middle of the peptides instead of the end of the peptide.[67] In addition, rather than using metal complexes to direct the assembly of designed proteins, one can use designed helical proteins to enforce unusual geometry and coordination numbers of metal ions.[73] A nice example is the use of three-stranded helical peptides to impose a three-coordinate trigonal Hg^{II}-binding site, even though Hg^{II} normally prefers two-coordinate linear geometry.[74] This was accomplished by introducing one Cys in the middle of each of the three helical peptides that has been designed to form three helical bundles. This driving force to form three helical bundles makes Hg^{II} adopt its unusual geometry.

While de novo designed helical proteins are the predominant scaffolds for incorporation of metal-binding sites, use of other de novo designed scaffolds for metalloprotein design is emerging. A good example is introducing a transition metal-binding site (with binding selectivity of $Cu^{II} > Zn^{II} \gg Cd^{II} > Co^{II}$) in a de novo designed all β-proteins.[75] The protein was designed based on a portion of heavy chain variable domain of an immunoglobin. Three His residues were then incorporated into two loops between the β-strands, with two on one loop and the third one on another loop.

2.3 Design of Metal-binding Sites into Native Protein Scaffolds

The design of metal-binding sites in de novo designed scaffolds described in the above section represents the ultimate goal of protein design and is considered de novo design in its most fundamental and challenging form. However, the number of de novo designed scaffolds is limited to a few well-characterized ones, such as helix bundles. In contrast, close to 600 different natural scaffolds are available in the Protein Data Bank.[76] It has been shown that the same protein scaffold is used many times in different proteins, with different metal-binding sites crafted into its scaffold. Therefore, the design of metal-binding sites into native scaffolds offers more scaffold choices at the present time and thus presents more opportunity to test our knowledge and to build proteins with novel properties.[23] In addition, most native scaffolds have high thermodynamic stability and extraordinary tolerance for residue substitution, deletion, and insertion, making drastic changes of the scaffold's metal-binding site more likely to succeed. Finally, years of research in native proteins make the construction, purification, and characterization (including X-ray crystallography) of the protein scaffolds a common laboratory practice. As the understanding of protein structure improves, de novo designed proteins will become more attractive as scaffolds. But until then, working with existing native scaffolds affords equal advantages.

2.3.1 Redesign of an Existing Metal-binding Site to a New Site with Dramatically Different Structure and Function

Redesign bypasses not only the design of the overall scaffold, but also the initial creation of the metal-binding site. In addition to being more technically feasible with a better chance of success than other methods, this approach best reveals the role of specific residues responsible for a particular structural or functional feature of the metal-binding site of interest.

A. Redesign of Heme Proteins. Heme proteins are one of the most diverse groups of metalloenzymes with functions ranging from electron transfer, small molecule transport and sensing, to oxygen activation (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***; ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). Key factors that determine functional specificity include the types of hemes, nature of the proximal ligands, and the architecture of the distal site. Therefore redesign has focused on these three areas.

Redesign of One Type of Heme Protein into Another Type. Different types of hemes, such as heme a, b, c, d, d_1, o, chloroheme, heme P460, and siroheme (*see* ***Iron Porphyrin Chemistry***), share a common skeleton and differ in structural details owing to substitutions at the various positions.[38,77] Most of those hemes bind to the protein noncovalently. Redesigning those types of heme proteins into another often involves making the apo-protein, through either heme extraction or protein expression under controlled conditions, and then incorporating different types of hemes. However, c-type heme proteins contain covalent linkage to the protein through the Cys residues and the thioether bond formation is believed to be assisted by proteins such as heme lyase. Therefore redesign involving c-type hemes entails additional challenges. Interestingly, both cytochrome b_5 and cytochrome b_{562} have been redesigned into c-type heme proteins without the requirement of heme lyase. The redesign of cytochrome b_5 was accomplished through mutation of a surface Asn residue to Cys that placed the thiol group 3–3.5 Å from the heme 4-vinyl group,[78] while the redesign of cytochrome b_{562} was aided by a structural homology between the cytochrome b_{562} and a major class of c-type cytochromes.[79] Cysteine residues were then introduced in positions of cytochrome b_{562} homologous to those in the c-type cytochromes. In addition, a c-type cytochrome, cytochrome c_{552}, was converted into a b-type cytochrome after both heme-binding cysteines were replaced with alanine, either individually[80] or together.[81] These studies suggest that assembly of certain c-type cytochromes may be a consequence of spontaneous thioether bond formation after binding of heme to a prefolded polypeptide.[81,82] The redesigned proteins with a c-type thioether attachment have a significantly increased stability, while conversion of the c-type to the b-type heme proteins resulted in decreased stability.

Redesign of Heme Protein Through Change of Axial Ligands. The axial ligands often play dominant roles in modulation of structure and function of heme proteins. Among the ligands, histidine is by far the most common and found in many types of heme proteins such as cytochromes, globins, and peroxidases. Cysteine and tyrosine are found in a few classes of heme enzymes such as cytochrome P450, chloroperoxidase (CPO), and catalase. Therefore changing the axial ligands is an effective way to redesign heme proteins. For example, the bis-His cytochrome b_5 (Figure 11a)[83] and cytochrome c_3[84,85] have been converted to His-Met cytochromes, commonly found in cytochrome c, by mutation of one of the His

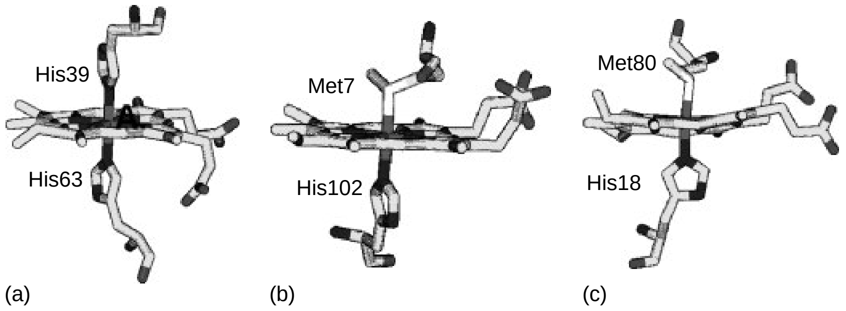

Figure 11 Cytochromes with different axial ligand coordination. (a) cytochrome b_5; (b) cytochrome b_{562} and (c) cytochrome *c*. (Reprinted with permission from Ref. 23. © 2001 the American Chemical Society)

ligands to Met. In the latter case, the mutation resulted in a 160–180 mV increase in reduction potential.[84,85] A still further increase in reduction potential was observed when the His-Met coordinated cytochrome b_{562} (Figure 11b) was changed to bis-Met.[86,87]

Both the axial Met and His ligands of cytochrome *c* (Figure 11c) have been replaced by other amino acids.[88–90] These studies indicated that replacement of the axial Met80 could lead to a dramatic change in the heme reduction potential. The His-to-Cys change resulted in ∼650 mV decrease in reduction potential, by far the largest change of reduction potentials from axial ligand mutations. In addition, by changing the Met ligand to a noncoordinating amino acid such as Ala using either protein semi-synthesis[91,92] or site-directed mutagenesis,[93] cytochrome *c* has been converted into an oxygen-binding protein such as myoglobin (Mb); the variant possessing a similar binding site for dioxygen and other exogenous ligands as in Mb. Similarly, cytochrome b_{562} was redesigned to a heme protein that binds exogenous ligands like CO, by changing Met to Gly or Ala.[94] In a redesign in the reverse direction, myoglobin (Figure 12a) has also been converted into a cytochrome like the bis-His cytochrome b_5 when the distal valine was replaced with a histidine.[95–97] Interestingly, the mutation resulted in ∼170 mV decrease in the reduction potential of myoglobin.

Oxidative degradation of heme is an important catabolic step in biology. The reaction is catalyzed by heme oxygenase (HO) (Figure 12b), which degrades heme to hydroxyheme, then to verdoheme, and finally to biliverdin.[98] Both cytochrome b_5 (with bis-His ligation) and b_{562} (with His-Met ligation) have been redesigned to mimic HO, through mutation of one of the His axial ligands to Met.[99–101] Further mutation of the remaining His in cytochrome b_5 to Val resulted in degradation of heme beyond verdoheme and to biliverdin, the final product of HO activity.[102]

Axial thiolate ligation from Cys is important for the reactivity and spectral characteristics of many heme enzymes such as P450, NOS, CPO, and CooA. In order to gain insight into the role of this ligation, the axial ligand His has been changed to Cys in both the human[103–105] and horse heart[106] myoglobins. This mutation resulted in not only a ∼280 mV decrease in reduction potential (which is consistent with thiol ligation to the heme iron), but also ∼5-fold increase in P450-type monooxygenase activity. Similarly, mutation of the proximal His to Cys was also made in heme oxygenase (Figure 12b).[107]

Unlike human Mb, the His-to-Cys mutation alone in horse heart Mb did not result in heme-thiolate ligation. However, an additional mutation of the distal histidine to either a valine or isoleucine resulted in a P450-like protein in its

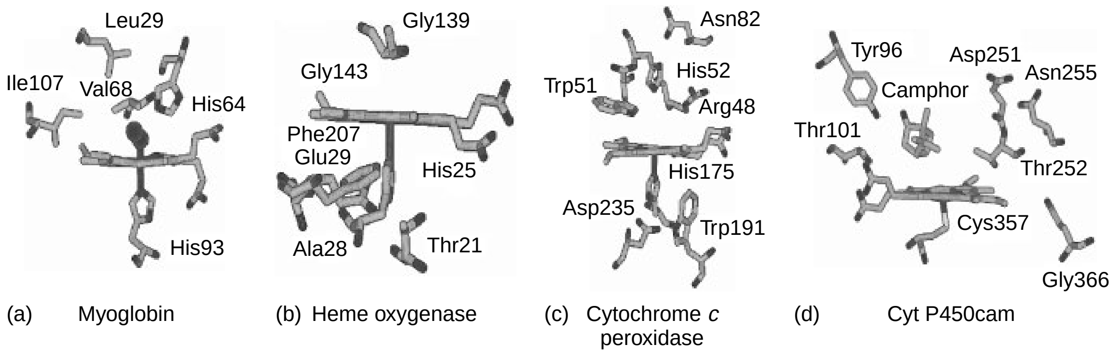

Figure 12 Heme proteins with one open coordination site. (a) myoglobin; (b) heme oxygenase; (c) cytochrome *c* peroxidase; (d) cytochrome P450. (Reprinted with permission from Ref. 23. © 2001 the American Chemical Society)

resting ferric state (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).[106] This effect, termed the trans effect by the authors, makes a significant contribution to the axial ligand binding and stability. Similarly, mutation of the axial His ligand to Cys in cytochrome *c* peroxidase (C*c*P) (Figure 12c) resulted in a very unstable ligand that was rapidly oxidized to cysteic acid.[108] It was then recognized that a nonpolar residue next to the Cys is conserved in P450 proteins, while the analogous amino acid in C*c*P is an aspartic acid (see Figure 3b). Therefore, a further mutation of this Asp to Leu resulted in a stable, penta-coordinate, high-spin heme with thiolate ligation.[109] The study also marked the first time a stable cyanoferric complex and ferrous state of a model P450 was made.[109,110] Stable cysteine thiolate coordination in the ferrous-CO derivative of an engineered protein was obtained by mutations of the His and Met axial ligands in cytochrome b_{562} to Cys and Gly, respectively.[111] The key to the success was to replace two glutamate residues, which make energetically unfavorable interactions with the heme propionate groups through electrostatic repulsion, to Ser. These works demonstrated the importance of the secondary coordination sphere around the primary coordination ligands in stabilizing metal-ligand ligation.

In a heme redesign in the opposite direction to the above work, the axial Cys ligand in CPO[112] and cytochrome P450 (Figure 12d)[113,114] was changed to a His. Replacing the axial Cys with His in cytochrome $P450_{cam}$ resulted in a greatly decreased camphor oxidation rate, elevated uncoupling rate, slower electron transfer rate from redox partner putidaredoxin, and much greater peroxidase activity. These results suggest that the proximal cysteine is essential for protein folding, substrate binding, and electron transfer and P450 monooxygenase activity.

Finally, the proximal histidines of myoglobin[103,104,115,116] and heme oxygenase[107] have also been mutated to tyrosine in order to convert these proteins to a catalase. As expected, replacement of His with Tyr in Mb resulted in a ∼250 mV decrease in reduction potential because of the negative charge of Tyr. Surprisingly, this mutation had little effect on myoglobin's ability to carry out heterolytic or homolytic O–O cleavage.

Redesign of Heme Protein Through Change of Distal Site. With the exception of cytochromes, the residues around the distal side of the heme do not coordinate to the iron directly, and they exert their influence by fine-tuning the properties of heme proteins. For example, a distal His is present in globins and many peroxidases (in addition to the common proximal His ligand). Despite this similarity, globins are oxygen carriers and only react with H_2O_2 at a much slower rate ($\sim 10^2\,M^{-1}\,s^{-1}$) than peroxidases (with a rate of $\sim 10^7\,M^{-1}\,s^{-1}$). Furthermore, unlike peroxidases, globins cleave the O–O bond of peroxide both heterolytically and homolytically. Watanabe and coworkers were the first to recognize the importance of the location of the two distal His residues in Mb and in CcP; the distances between the N_ε of the distal His and the ferric heme iron are normally 4.1–4.6 Å for globins and 5.5–6.0 Å for peroxidases (Figure 13).[24,117,118] Therefore, a series of variants were made that include His64Leu (to eliminate the distal His in Mb), His64Leu/Phe43His (to introduce a distal His at a similar position/distance as in peroxidases) and His64Leu/Leu29His (to introduce a distal His at a farther position/distance than in peroxidases). While His64Leu and His64Leu/Leu29His variants reacted with H_2O_2 ∼ 100 and ∼3–6 times slower than the native Mb, the His64Leu/Phe43His variant exhibited ∼11 fold higher activity. These changes in reactivity were rationalized in terms of the roles of the distal histidines as general acid-base catalysts.[24,118] The His64 in native Mb functioned only as a general base by enhancing the binding of H_2O_2 through hydrogen-bonding to both oxygen atoms of the peroxide, and it was too close to the heme center to support heterolysis of the peroxide bond. In contrast, the His43 in His64Leu/Phe43His variant was at a similar position and distance as in most peroxidases and thus can work both as a general base to enhance the binding of H_2O_2 through deprotonation of the peroxide, and as a general acid to facilitate the heterolytic cleavage of the peroxide O–O bond. The His29 in His64Leu/Leu29His was too far away to serve any of these purposes. This work was a beautiful demonstration that proper positioning of the distal histidine is essential for the activation of H_2O_2 by heme enzymes.

Another structure-based redesign has been demonstrated in the conversion of human heme oxygenase-1 (HO-1) into a peroxidase.[119] The crystal structure of HO-1 suggests that Gly139 interacts directly with iron bound ligands (Figure 12b). When this glycine was mutated to Ala, Leu, Phe, Trp, His, or Asp, the resulting protein gained peroxidase activity by reacting with H_2O_2 to form a ferryl species that catalyzed the peroxidation of guaiacol. Displacement of the distal helix, which shifted owing to steric interactions between the larger amino acid side chains introduced by the mutations and the heme group, appears to be responsible for the new reactivity. Therefore, the authors concluded that the ferryl species formation responsible for the peroxidase activity was a default reaction, and the principal role of the HO active site may be to suppress this unwanted reaction with respect to HO activity. The gain in peroxidase activity in HO-1 was also observed with mutations of Asp140, another distal side residue that may participate in a hydrogen-bonding network involving ligands coordinated to the heme iron.[120,121]

B. Redesign of Nonheme Iron Proteins. In heme protein redesign described above, the heme prosthetic group largely dictates the active site structure. Redesign focuses mainly on the proximal and distal sides of the heme, causing minimal effects on the overall protein scaffolds. This is not necessarily the case for nonheme metalloproteins in which metal sites are not as dominant and small changes may have more dramatic effects on the protein folds and stability.

From Rubrerythrin to Ribonucleotide Reductase. Dinuclear iron proteins (*see **Iron Proteins with Dinuclear Active Sites***) are an important class of nonheme iron proteins that share a similar di-iron oxo core and yet perform a variety of different functions ranging from dioxygen binding (hemerythrin, Hr), to ribonucleotide reduction (ribonucleotide reductase, RnR), and methane activation (methane monooxygenase, (MMO)). The majority of dinuclear iron proteins, including RnR and MMO, contain six ligands from 2 pairs of **Glu**X_{30-32}**Glu**XX**His** motifs. Only five of the six ligands are found at the corresponding positions in rubrerythrin (Rr) from *Desulfovibrio vulgaris*, a protein whose physiological role remains to be determined, (Figure 14). The putative sixth ligand, His56, is too far away to serve as a ligand to the nearest iron in Rr. Instead, Glu97 provides the sixth ligand at the other end, and it is believed to be a unique ligand for Rr proteins.[122] The di-iron oxo site of Rr was redesigned by mutation of Glu97 to Ala.[123] The X-ray crystal structure of the redesigned protein indicated that His56 was an iron ligand and this coordination was not a result of His56 moving closer to the iron. Instead the iron moved ~1.6 Å relative to the same iron in the native Rr. The di-iron oxo site of the new variant is very similar to that of RnR.

Since Tyr122 plays a critical role in RnR function, an effort was also made to introduce a Tyr at a similar position in Rr.[123] Even though a Tyr102 was present in Rr that seemed to correspond to Tyr122 in RnR, a sequence homology search indicated that a nonconserved residue (Leu60) in

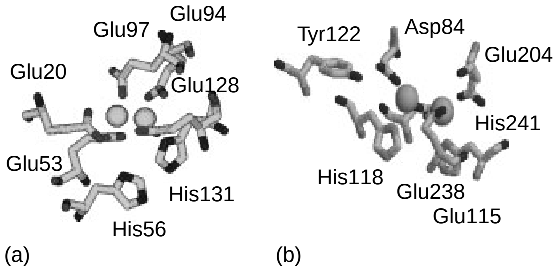

Figure 14 The di-iron oxo sites in rubrerythrin (a) and ribonucleotide reductase (b). (Reprinted with permission from Ref. 23. © 2001 the American Chemical Society)

Rr corresponded to Tyr122 in RnR. Therefore, a Leu60Tyr mutation was made and the crystal structure of the variant was obtained. According to the structure, the side chain of the introduced Tyr60 was now in a similar position as the Tyr122 in RnR. While the introduction of the Tyr into Rr was successful, no Tyr radical was detected in the redesigned protein. This result was explained based on the difference that Tyr122 in RnR made direct hydrogen bonds to an iron-coordinating terminal carboxylate while the Tyr60 in the redesigned protein did not. Both the Glu97Ala and Leu60Tyr mutation studies suggested that significant local structural changes might occur. These changes may not be readily predicted without homology information.

From Ribonucleotide Reductase to Methane Monooxygenase. Redesign of the di-iron site of ribonucleotide reductase (RnR) introduced a methane monooxygenase (MMO) type function.[124] The metal site of RnR is surrounded by hydrophobic residues. A tyrosine (Tyr122) close to the dinuclear iron center is proposed to form a radical, initiating the catalytic cycle of RnR (Figure 14b). To examine the importance of the hydrophobic environment around the iron oxo site of RnR, Phe208 was mutated to a Tyr, placing another phenolic group near the site. UV-vis and RR spectral studies of the variant showed that it contains a ferric catecholate instead of a Tyr radical. The mechanism for generation of this protein derived dihydroxyphenylalanine was proposed to be similar to that of MMO.

From One Type to Another Type of Fe–S Cluster. Iron−sulfur clusters, such as [2Fe–2S], [3Fe–4S], and [4Fe–4S], are found in proteins (*see* ***Iron–Sulfur Proteins***). One of the most interesting aspects of the iron−sulfur proteins is their ready conversion from one type to another through chemical oxidation and reduction, pH changes, or site-directed mutagenesis.[125–128] More importantly, several studies have indicated that some of the cluster conversions are physiologically relevant in that they play important roles in regulation of enzyme activity.

C. Redesign of Copper Proteins. Copper proteins are classified into three types according to their spectroscopic properties (*see* ***Copper Proteins with Dinuclear Active Sites***; ***Copper Proteins with Type 1 Sites***; ***Copper Proteins with Type 2 Sites***). Type 1 copper proteins, commonly called ‘blue copper’ proteins, usually have an intense blue color owing to a strong absorption around 600 nm. They also have a very small $A_{\|}$, which is the hyperfine splitting with the molecular z axis (d_z2 in the case of Cu(II) proteins) oriented parallel to the external magnetic field, in electronic paramagnetic resonance spectroscopy (EPR). Type 2 copper proteins have spectroscopic properties just like simple copper complexes. Type 3 copper proteins are a group of binuclear copper proteins that have no EPR signal in the oxidized state owing to antiferromagnetic coupling of the two neighboring Cu(II) ions. Recently, new classes of copper centers, such as the purple Cu_A (*see* ***Cytochrome Oxidase***) and the Cu_z (*see* ***Copper Enzymes in Denitrification***) sites, have been identified.

From One Type 2 Copper Protein to Another Type 2 Copper Protein. It has been shown that a type 2 copper protein called copper−zinc superoxide dismutase (CuZnSOD) (Figure 15b) shares the same overall scaffold as its copper chaperone protein called copper chaperone for SOD (CCS).[129–131] All of the zinc site ligands and three of four copper site histidine ligands in CuZnSOD are conserved in human CCS (hCCS). The zinc site in hCCS displayed the same structure as in CuZnSOD.[132] The fourth ligand in the copper site of CuZnSOD is replaced by an aspartate residue in hCCS. Although aspartate could be a ligand to copper, no copper binding is evident from the X-ray structure of hCCS,[132] and hCCS exhibits no SOD activity.[133] Based on this analysis, the Asp residue in hCCS was converted to His as in CuZnSOD.[133] The resulting protein gained significant SOD activity, indicating that this mutation allows the formation of a new catalytically active copper site as in CuZnSOD and is critical in conferring the SOD activity. Furthermore, they demonstrated that this mutation did not inhibit the protein from functioning as a copper chaperone. This work strongly suggests that the aspartate residue is present in hCCS to preclude the deleterious SOD reaction as a result of copper binding, so that hCCS can function as a pure copper chaperone. Furthermore, it indicates that both the location and the exact nature of the amino acid residues are important for the formation of the metal-binding sites in proteins.

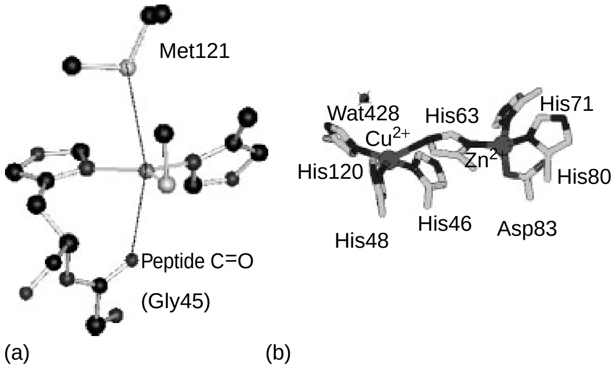

Figure 15 Structures of type 1 copper protein, Azurin (a) and Type 2 copper protein, Copper, zinc superoxidase dismutase (b). (Reprinted with permission from Ref. 23. © 2001 the American Chemical Society)

From A Type 2 Copper Protein to A Type 1 Blue Copper Protein. The essential features of type 1 copper proteins appear to be two histidine imidazoles and a cysteine thiolate coordinated to Cu(II) in a trigonal planar (or distorted tetrahedral) geometry with one or two additional weak axial ligands such as methionine (Figure 15a) (*see* ***Copper Proteins with Type 1 Sites***).[134] To elucidate the relationship between the type 1 and type 2 copper proteins and to take advantage of predefined scaffolds and metal-binding sites in the design of the unusual type 1 copper center, Lu *et al.* introduced cysteines into the metal-binding sites of yeast CuZnSOD (Figure 15b), a type 2 copper protein.[135–139] When a cysteine was substituted for a histidine in the copper site, a site having a distorted square-planar geometry (Figure 15b), a strong new absorption around 400 nm and a typical type 2 or ‘normal’ EPR were observed, suggesting that the presence of cysteine was not sufficient in itself to produce the unusual type 1 or ‘blue’ copper spectra.[135,139] On the other hand, substitution of a cysteine for a histidine in the zinc site, a site possessing a distorted tetrahedral geometry, resulted in a type 1 copper protein.[135–138] All three His-to-Cys mutant proteins

reacted with ascorbate much faster than the wild type protein, indicating that the presence of a thiolate greatly increased the redox reactivity of the metal-binding site, consistent with the thiolate providing an efficient superexchange pathway for electron transfer.[138] The bridging histidine in CuZnSOD was also replaced with a cysteine by Banci *et al.*, but the resulting protein did not display any S-to-Cu(II) charge transfer absorption, indicating the lack of a Cu-cysteine bond.[140] These studies demonstrated that both the cysteine ligand and the geometry define the structural and functional properties of type 1 blue copper proteins.

From A Type 1 Blue Copper Protein to A Type 2 Copper Protein. The type 1 blue copper protein azurin from *Pseudomonas aeruginosa* has been converted into a type 2 copper protein through mutation of the Cys ligand (Figure 15a) to Asp.[141] The mutation resulted in not only a type 2, five-coordinate copper site, with both oxygens of the aspartate residue serving as potential ligands to copper,[142,143] but also in a dramatically reduced electron self exchange rate and intramolecular electron transfer rate compared to the native azurin.[144] The type 1 to type 2 copper conversion has also been accomplished by replacing one of the histidines in the type 1 blue copper azurin with glycine.[145–147] Interestingly the blue copper site can be restored by addition of external ligands such as N-methyl imidazole. Despite this restoration, the protein was not able to rapidly interconvert between the Cu(II) and Cu(I) forms, indicating that the covalent attachment of the ligand at the histidine position to the protein backbone is essential for the electron transfer function of the protein.

D. Redesign of Other Metalloproteins.

Redesign of Ca^{II}/Mg^{II} Specificity. Proteins in the calmodulin superfamily (including troponin C, parvalbumin (PV) and oncomodulin (OM)) share similar overall structure and yet have different selectivity for Ca^{II} and Mg^{II} (*see* ***Calcium-binding Proteins***; ***Cation-activated Enzymes***). For example, PV and OM have four helix-turn-helix domains, two of which contain mixed Ca^{II}/Mg^{II} sites and two Ca^{II}-specific sites. The mixed Ca^{II}/Mg^{II} sites have been converted to Ca^{II}-specific sites by replacing amino acids with the corresponding residues in the Ca^{II}-specific site.[148–150]

Redesign of Mg^{II}/Mn^{II} Specificity. Many endonucleases require divalent metal cofactors for DNA cleavage.[151] Like most endonucleases, EcoRV prefers Mg^{II} over Mn^{II}. However, mutation of Ile91 to Leu reversed the preference to Mn^{II} over Mg^{II}.[152] Surprisingly, Ile91 does not interact with the metal or recognition site, but points away from it into a hydrophobic core. The Ile91Leu mutation thus indirectly alters the coordination sphere providing better coordination of Mn^{II}. This result shows again that selectivity can be altered without directly replacing any of the metal ligands.

Redesign of Mg^{II}/Zn^{II} specificity. Mammalian alkaline phosphatase (AP) contains a tetrahedral Zn^{II} site (*see* ***Zinc Enzymes***), whereas *E. coli* AP has an octahedral Mg^{II} at the corresponding location. Mutation of a single amino acid (D153H) in *E. coli* AP, converted the specificity and geometry of the site to that of mammalian AP.[153]

Redesign of Fe^{II}/Mn^{II} Specificity. Among the many interesting cases of metal-ion specificity in proteins, the difference in specificity of Fe- and Mn-containing superoxide dismutase (SOD) is perhaps the most intriguing.[154,155] Both FeSOD and MnSOD share the same sequence and structural homologies. The overall structures and metal-binding sites of both proteins are virtually identical. However, even though FeSOD binds nonnative Mn ions, it is active only with Fe ions. The reverse is true for MnSOD. Since the primary coordination spheres of FeSOD and MnSOD are quite similar, efforts in redesigning their metal-ion specificity have been focused on the secondary coordination sphere, including a conserved glutamate residue (Glu170) in the dimer interface of MnSOD, and conserved glutamine residues believed to be central to the hydrogen-bonding network of FeSOD and MnSOD. For example, mutation of Glu170 to Ala in MnSOD resulted in purified protein that binds exclusively Fe, with similar spectroscopy to that of FeSOD, but no SOD activity.[156] When the histidine in FeSOD from *Mycobacterium tuberculosis* is mutated to Gln to mimic that in MnSOD, the variant protein was still found to bind Fe preferentially.[157] On the other hand, similar mutations in *Porphyromonas gingivalis* Cambialistic SOD made to mimic MnSOD resulted in a variant whose electronic absorption spectrum resembled more closely that of MnSOD.[158] More importantly, the variant displayed increased SOD activity over the wild type enzyme when Mn was in the metal-binding site. Finally, a mutation in MnSOD, to incorporate a Gln corresponding to that in FeSOD, did not result in a new, FeSOD-like active site. However, the MnSOD variant gained new SOD activity (~7% that of FeSOD) when Fe was in the metal-binding site.[159] These studies suggest that the presence and the position of the glutamine residue is important but not the sole determinant of the metal-ion specificity of FeSOD and MnSOD. Major differences in other conserved residues need to be elucidated before a successful redesign of metal-ion specificity can be accomplished.

2.3.2 Design and Engineering of New Metal-binding Sites

While redesign of existing metal-binding sites provides insight into the critical differences between the template and target proteins, it cannot address the roles of important residues that are common to both proteins. Designing new metal-binding sites provides such opportunities.

A. Design Through Homology. New metal-binding sites can be created based on either sequence or structural homology

between a starting protein lacking the metal-binding site and the target protein with the metal-binding site. This approach relies on guidance from homology and offers a better chance of success than design by inspection. It is an important exercise for protein designers, especially in the early stages of protein design when our knowledge of creating metal-binding sites is limited.

Creation of a New Zn^{II}-binding site. New Zn^{II}-binding sites have been created in several proteins based on structural homology. For example, the X-ray structure of the 37 amino acid protein, charybdotoxin, was examined for a Zn(II) binding site analogous to that in carbonic anhydrase.[160–162] A region containing two antiparallel strands of β-sheet was identified in charybdotoxin and the appropriate residues were mutated to His, as in carbonic anhydrase. A few other sterically conflicting residues were also mutated. The same metal-ion specificity as carbonic anhydrase, with Cu(II) preferred over Zn(II), was obtained with the new metal-binding site. This study demonstrated the success obtained from careful modeling and structural homology searches.

The stabilization of an adenylate kinase was achieved by placing the metal-binding site common to one protein family member into another member of the protein family. For the adenylate kinase family, those from gram-positive bacteria contain a Zn^{II} site while those from gram-negative bacteria do not. The Cys-X_2-CysX_{16}-Cys-X_2-Cys zinc binding motif of adenylate kinases from gram-positive organisms was engineered into a gram-negative protein.[163,164] The resulting protein displayed increased thermal stability. Similarly, a mammalian serum retinal binding protein (RBP) variant was also stabilized with the introduction of a Zn^{II} site.[165] The Zn^{II} site was modeled after the carbonic anhydrase (CA) site. As in CA, three residues on adjacent antiparallel β-strands of the RBP were mutated to His.

Creation of a New Mn(II)-binding Site in Peroxidases: Toward A New Manganese Peroxidase. Cytochrome *c* peroxidase (C*c*P) and manganese peroxidase (MnP) are members of the plant peroxidase superfamily (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). C*c*P catalyzes the oxidation of ferrocytochrome *c* while MnP plays a key role in the oxidative biodegradation of lignin and many aromatic pollutants. Despite the limited sequence homology (less than 20%) between the two peroxidases, the overall structural folds of the two enzymes are quite similar (Figure 16a).[166] One major difference is that C*c*P lacks the Mn^{II}-binding site found in MnP (Figure 16b). On the basis of a comparison of X-ray structures of the two peroxidases, the Lu group[167–169] and Goodin group[170] succeeded in engineering a Mn^{II}-binding site in C*c*P by introducing amino acids found in MnP into the corresponding positions in C*c*P.[171] More importantly, they showed that the introduction of the new Mn^{II}-binding site resulted in a significant increase in Mn^{II} oxidation activity. Similarly Tien group created a Mn^{II}-binding site in lignin peroxidase, another peroxidase that shares similar overall structural and heme-binding site, but lacks the Mn^{II}-binding site.[172] The resulting enzyme was able to oxidize Mn^{II} and still retain lignin peroxidase activity.

Creation of A New Cation-binding Site in Cytochrome c Peroxidase: Toward a Cation-controlled Molecular Switch. Heme peroxidases catalyze oxidation of a variety of substrates using H_2O_2 (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). Structural comparison showed that a cation-binding site is present in ascorbate peroxidase (APX) and many plant peroxidases (a K^+ site for APX and a Ca^{II} for most other peroxidases), while only a water molecule was present at the same location in cytochrome *c* peroxidase (C*c*P). To engineer a protein whose activity can be controlled by a designed cation site, Poulos' group introduced the APX K^+-binding site into C*c*P based on a strong structural homology between the two proteins, and showed that long-range electrostatic effects can control the reactivity of a redox active amino acid chain.[173,174] Furthermore, based on a structural homology between C*c*P and Ca^{II}-containing peroxidases such as lignin peroxidase and manganese peroxidase, the same group replaced amino acid

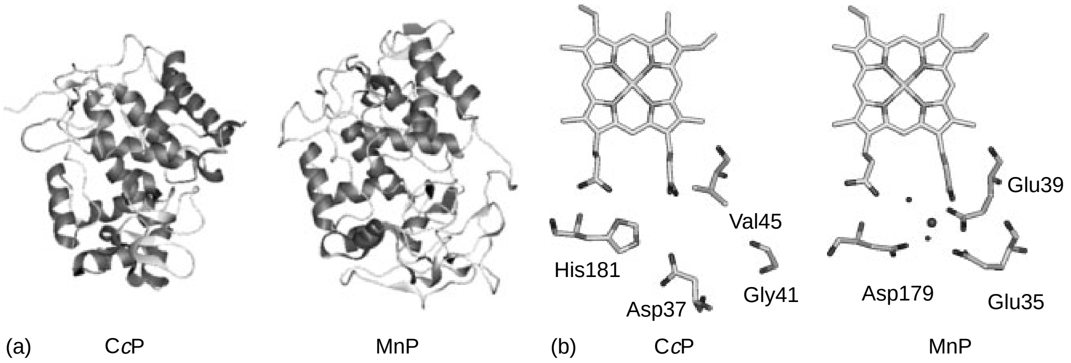

Figure 16 (a) Overall structure of C*c*P and MnP; (b) active site structure of C*c*P and MnP. (Reprinted with permission from Ref. 23. © 2001 the American Chemical Society)
